In the case of the carbonate the change was more minutely studied. A small platinum crucible, containing 4.219 grms. of carbonate of lithia (recently dehydrated in it at a gentle heat), was placed in the platinum crucible, provided with inlet and outlet tubes, and heated within it for many hours over a good Iserlohn burner,* while a current of dry hydrogen passed through the apparatus to keep out the air. From time to time the heating was stopped, and the residue examined and weighed. There always was a small sublimate on the inside of the lid of the outer crucible, which was weighed, to be allowed for in the calculation of the loss of volatile matter up to the respective time, and removed before the process was resumed. The corrected loss was very considerable in the earlier periods of heating, but became less and less as the process progressed. It was also noticed that the substance while losing carbonic acid became more and more difficultly fusible. Calculating from the weights of the successive residues and sublimates obtained, and on the assumption that the aggregate (duly corrected) loss was just carbonic acid (lost and not replaced by water), the ultimate residue was very nearly of the composition $\text{Li}_2\text{O} + \frac{1}{3}\text{CO}_2$. A determination of the carbonic acid, by the direct method, and of the lithia (as Li_2SO_4) gave the following results:—

Lithia (Li_2O)	88.27 + 30 = 2.942
Carbonic acid (CO_2)	7.50 + 44 = 0.171
Water (?) by difference)	4.23 + 18 = 0.235

100.00

These numbers agree with the formula—

Part of this product was utilised for studying its action on platinum in the presence of air. But as a number of days had elapsed before this could be done, and the substance meanwhile had been standing in the crucible (within an exsiccator), we first re-heated it in hydrogen gas within the same platinum apparatus as had been used before, with this difference, however, that after thirty minutes' application of an Iserlohn burner the heating was continued for twenty minutes over a gas blowpipe. Weight of substance operated upon equal 0.4692 gm.; total loss equal 79 milligrams, which is (by 24 m. grms.) more than the weight of ($\text{CO}_2 + \text{H}_2\text{O}$) calculated for 0.4692 gm. of $\text{Li}_2\text{O} + 0.13(\text{H}_2\text{O} \text{ or } \text{CO}_2)$, showing that the substance while in the exsiccator had absorbed water or carbonic acid. But obviously the substance, by being re-heated, had come still closer in its composition to plain Li_2O . It had assumed a gray colour, and showed only signs of incipient fusion. This gray substance was now heated within the same apparatus, in a current of dry air, a gas blowpipe supplying the heat. As part of the substance was lost accidentally, the residue was not weighed. It was now of a perfectly white colour, although the empty

part of the crucible, through the conjoint action of the air and the vapour of lithia produced, had got badly attacked. This residue again stood in an exsiccator for some days before we had time to analyse it. To remove any absorbed water or carbonic acid we began by re-heating it in hydrogen. 0.347 gm. of the re-heated substance, when subjected to the action of water, dissolved only very slowly, with evolution of very little heat. Without waiting for a complete solution we added excess of sulphuric acid, evaporated to dryness, and weighed the sulphate. It amounted to 1.2459 gm. corresponding to 97.9 per cent of Li_2O in the substance analysed. To sum up: Carbonate of lithia, when ignited in a platinum crucible in air, attacks the metal, and is itself largely converted into peroxide. A considerable percentage, however, of Li_2CO_3 remains as such. When it is heated in hydrogen it does not attack the metal, but gradually loses more and more of its carbonic acid, so that at last almost pure Li_2O is left as an almost infusible solid, which acts only very slowly on water; and consequently is widely different from what the oxides K_2O and Na_2O are supposed to be. (I have no personal experience regarding these myself.) In order to see whether the hydrogen, in reducing the carbonate, acts chemically, perhaps by removing the CO_2 as CO and H_2O , or merely as a supporter of dissociation—i.e., by preventing accumulation of carbonic acid within the crucible's atmosphere—a known weight of carbonate of lithia was heated (within the same platinum apparatus as had served in the hydrogen experiments) in a current of dry nitrogen gas. But as our stock of specially purified carbonate of lithia was exhausted, we operated upon commercial *Lithia carb. puriss.*, as obtained from Trommsdorff. The following weighings were recorded:—

Original substance	Gm. 0.7227
After preliminary dehydration at a gentle heat in nitrogen gas	0.7180
Heated over blowpipe for fifteen minutes.	

The out-going nitrogen, when blown through a flame, coloured it strongly red. Neglecting this loss of Li_2O , and assuming the 0.239 gm., which the 0.7180 of Li_2CO_3 had lost, to be all carbonic acid, it represents 33.40 out of the 59.46 per cent of CO_2 present in the original carbonate. The platinum remained, unattacked. The heating in nitrogen was resumed, but the experiment miscarried, which is of no consequence, because the result already obtained clearly proved that we have to deal with dissociation pure and simple. I intend to inquire more fully into the behaviour of Li_2CO_3 and of LiOH when heated in hydrogen or other gases, and to extend my inquiry to the potassium, sodium, and barium compounds.

In conclusion, it is an agreeable duty to me to acknowledge the very able and zealous manner in which I was supported by Mr. Robert Anderson in the execution of the many experiments involved in this investigation.—*Journal of the Society of Chemical Industry.*

THE "DROP" METHOD OF CHEMICAL ANALYSIS.

By Dr. H. HAGER.

THE customary methods for testing medicinal agents, which are both tedious and require a larger quantity of material, can be superseded by a method which requires merely single drops of the reagent, as well as of the liquid to be examined. For this method the following reagents are needed:—

Red and blue litmus paper and turmeric paper.

Extract of indigo paper, which is turned yellow by hot nitric acid and caustic alkalis, but not by ammonia.

Rosaniline paper as a test for alcohol.

Potassium ferrocyanide paper as a reagent for ferric

* A powerful Bunsen, constructed on the Argand principle.

salts (blue), copper and uranium (deep brown), gold (greenish brown), platinum (brownish green to reddish), thallium and vanadic acid (yellow).

Potassium sulphocyanide paper is turned decidedly yellow by bismuth nitrate, bluish black by salts of copper, red by solution of gold, white by mercuric nitrate, black by mercurous nitrate, and blood-red by ferric salts.

Potassium iodide paper is turned red by mercuric salts, green by mercurous salts, yellow by solution of lead. For detecting chlorates 2 to 3 c.c. of the liquid are placed in a small test-tube along with a slip of the paper; 1 c.c. of dilute sulphuric acid is then added, and heat is applied. If chlorate is present the liquid turns yellow.

Mercurous nitrate paper serves when moistened to detect ammoniacal gas, which turns it black; caustic alkalies and alkaline mono-carbonates stain it greenish-brown to black, whilst the alkaline bicarbonates leave it colourless.

Silver bichromate paper turns yellow with free hydrochloric acid.

Besides these the author mentions a number of other papers less frequently needed. The use of all consists in letting a drop of the liquid in question fall upon a slip of the paper.

The author tests for arsenic (arsenious and arsenic acids) by means of slips of sheet brass, 2.5 to 3 centimetres in length and 15 to 17 centimetres in length. The hydrochloric solution is mixed with a little oxalic acid, or the ammoniacal solution is supersaturated with hydrochloric acid and mixed with oxalic acid in order to reduce arsenic to arsenious acid. A drop of the solution is put upon a brass plate and sharply dried; the place of the drop is then washed with water, when a dark spot of a permanganate colour reveals the presence of arsenic. Dark thin outlines still appear in case of dilution with 150,000 parts.

In cases where the papers and the brass plate are not used the author places the two drops (of the reagent and the liquid in question) near each other upon a slip of glass and mixes them. The transparency of the glass renders the slightest turbidity visible.—*Pharmaceut. Central-Halle and Chemiker Zeitung.*

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING MAY 31ST, 1884.

By WILLIAM CROOKES, F.R.S.

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford.

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To the Water Examiner, Metropolis Water Act, 1871.

London, June 6th, 1884.

SIR,—We submit herewith the results of our analyses of the 189 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily from May 1st to May 31st inclusive. The purity of the water, in respect of organic matter, has been determined by the Oxygen and the Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter, and the quantities of free oxygen present in the whole of the samples submitted to analysis.

Of these 189 samples of water, the whole were, without exception, clear, bright, and well filtered.

The quality of the water supplied to the Metropolis during the past month, as indicated by its state of aëration, and high degree of freedom from colour and excess of organic matter, was excellent. Its perfect filtration was shown by the absence of even a trace of suspended matter in any one of the numerous samples submitted to examination.

We are, Sir,
Your obedient Servants,
WILLIAM CROOKES,
WILLIAM ODLING,
C. MEYMOTT TIDY.

A RECALCULATION OF

THE ATOMIC WEIGHTS.*

By FRANK WIGGLESWORTH CLARKE, S.B.,
Chief Chemist to the U.S. Geological Survey, Washington.

LANTHANUM.

LEAVING out of account the work of Mosander, and the valueless experiments of Choubine, we may consider the estimates of the atomic weight of lanthanum which are due to Hermann, Rammelsberg, Marignac, Czudnowicz, Holzmann, Zschiesche, Erk and Cleve.

From Rammelsberg† we have but one analysis. 0.700 grm. of lanthanum sulphate gave 0.883 grm. of barium sulphate. Hence 100 parts of BaSO₄ are equivalent to 79.276 of La₂(SO₄)₃.

Marignac,‡ working also with the sulphate of lanthanum, employed two methods. First, the salt in solution was mixed with a slight excess of barium chloride. The resulting barium sulphate was filtered off and weighed; but, as it contained some occluded lanthanum compounds, its weight was too high. In the filtrate the excess of barium was estimated, also as sulphate. This last weight of sulphate, deducted from the total sulphate which the whole amount of barium chloride could form, gave the sulphate actually proportional to the lanthanum compound. The following weights are given:—

La ₂ (SO ₄) ₃ .	BaCl ₂ .	1st BaSO ₄ .	2nd BaSO ₄ .
4.346 grms.	4.758 grms.	5.364 grms.	0.115 grm.
4.733 „	5.178 „	5.848 „	0.147 „

Hence we have the following quantities of La₂(SO₄)₃ proportional to 100 parts of BaSO₄. Column A is deduced from the first BaSO₄ and column B from the second, after the manner above described:—

A.	B.
81.022	83.281
80.934	83.662

Mean 80.978 ± 0.030 Mean 83.471 ± 0.128

From A La = 138.776
„ B „ 147.474

A agrees best with other determinations, although, theoretically, it is not so good as B.

Marignac's second method, described in the same paper with the foregoing experiments, consisted in mixing solutions of La₂(SO₄)₃ with solutions of BaCl₂, titrating one with the other until equilibrium was established. The method has already been described under cerium. The weighings give maxima and minima for BaCl₂. In another

* Smithsonian Miscellaneous Collections. The Constants of Nature.

† Poggend. Annal., 55, 65.

‡ Arch. des Sci. Phys. et Nat.. (1), 11, 29. 1849.

column I give $\text{La}_2(\text{SO}_4)_3$ proportional to 100 parts of BaCl_2 , mean weights being taken for the latter:—

$\text{La}_2(\text{SO}_4)_3$.	BaCl_2 .	Ratio.
11'644 grms.	12'765—12'825 grms.	91'004
12'035 "	13'195—13'265 "	90'968
10'690 "	11'669—11'749 "	91'297
12'750 "	13'920—14'000 "	91'332
10'757 "	11'734—11'814 "	91'362
12'672 "	13'813—13'893 "	91'475
9'246 "	10'080—10'160 "	91'364
10'292 "	11'204—11'264 "	91'615
10'192 "	11'111—11'171 "	91'482

Mean 91'322 $\pm$ 0'048

Hence $\text{La} = 140'484$.

Although not next in chronological order, some still more recent work of Marignac's* may properly be considered here. The salt studied was the sulphate of lanthanum, purified by repeated crystallisations. In two experiments the salt was calcined, and the residual oxide weighed; in two others the lanthanum was precipitated as oxalate, and converted into oxide by ignition. The following percentages are given for La_2O_3 :—

57'56	} By calcination.
57'58	
57'50	} Ppt. as oxalate.
57'55	

Mean 57'5475 $\pm$ 0'0115

The atomic weight determinations of Holzmänn† were made by analyses of the sulphate and iodate of lanthanum, and the double nitrate of magnesium and lanthanum. In the sulphate experiments the lanthanum was first thrown down as oxalate, which, on ignition, yielded oxide. The sulphuric acid was precipitated as BaSO_4 in the filtrate.

$\text{La}_2(\text{SO}_4)_3$.	La_2O_3 .	BaSO_4 .
0'9663 grm.	0'5157 grm.	1'1093 grm.
0'6226 "	0'3323 "	0'7123 "
0'8669 "	0'4626 "	0'9869 "

These results are best used by taking the ratio between the BaSO_4 , put at 100, and the La_2O_3 . The figures are then as follows:—

46'489
46'652
46'873

Mean 46'671 $\pm$ 0'075

In the analyses of the iodate the lanthanum was thrown down as oxalate, as before. The iodic acid was also estimated volumetrically, but the figures are hardly available for present discussion. The following percentages of La_2O_3 were found:—

23'454
23'419
23'468

Mean 23'447 $\pm$ 0'0216

The formula of this salt is $\text{La}_2(\text{IO}_3)_6 \cdot 3\text{H}_2\text{O}$.

The double nitrate, $\text{La}_2(\text{NO}_3)_6 \cdot 3\text{Mg}(\text{NO}_3)_2 \cdot 24\text{H}_2\text{O}$, gave the following analytical data:—

Salt.	H_2O .	MgO .	La_2O_3 .
0'5327 grm.	0'1569 grm.	0'0417 grm.	0'1131 grm.
0'5931 "	0'1734 "	0'0467 "	0'1262 "
0'5662 "	0'1647 "	0'0442 "	0'1197 "
0'3757 "	—	0'0297 "	0'0813 "
0'3263 "	—	0'0256 "	0'0693 "

These weighings give the subjoined percentages of La_2O_3 :—

21'231
21'278
21'141
21'640
21'238

Mean 21'3056 $\pm$ 0'058

These data of Holzmänn give values for the molecular weight of La_2O_3 as follows:—

From sulphate	$\text{La}_2\text{O}_3 = 325'674 \pm 0'522$
" iodate	322'419 0'113
" magnesian nitrate	324'355 0'923

Czudnowicz* based his determination of the atomic weight of lanthanum upon one analysis of the air-dried sulphate. The salt contained 22'741 per cent of water.

0'598 grm. gave 0'272 grm. La_2O_3 and 0'586 grm. BaSO_4 .

The La_2O_3 was found by precipitation as oxalate and ignition. The BaSO_4 was thrown down from the filtrate. Reduced to the standards already adopted these data give for the percentage of La_2O_3 in the anhydrous sulphate the figure 58'668. 79'117 parts of the salt are proportional to 100 parts of BaSO_4 .

Hermann† studied both the sulphate and the carbonate of lanthanum. From the anhydrous sulphate, by precipitation as oxalate and ignition, the following percentages of La_2O_3 were obtained:—

57'690
57'663
57'610

Mean 57'654 $\pm$ 0'016

The carbonate, dried at 100°, gave the following percentages:—

68'47 La_2O_3 .
27'67 CO_2 .
3'86 H_2O .

Reckoning from the ratio between CO_2 and La_2O_3 the molecular weight of the latter becomes 325'896.

Zschiesche's‡ experiments consist of six analyses of lanthanum sulphate, which salt was dehydrated at 230°, and afterwards calcined. I subjoin his percentages, and in a fourth column deduce from them the percentage of La_2O_3 in the anhydrous salt:—

H_2O .	SO_3 .	La_2O_3 .	La_2O_3 in anhydrous salt.
22'629	33'470	43'909	56'745
22'562	33'306	44'132	56'964
22'730	33'200	44'070	57'034
22'570	33'333	44'090	56'947
22'610	33'160	44'240	57'150
22'630	33'051	44'310	57'277

Mean 57'021 $\pm$ 0'051

Erk|| found that 0'474 grm. of $\text{La}_2(\text{SO}_4)_3$, by precipitation as oxalate and ignition, gave 0'2705 grm. of La_2O_3 , or 57'068 per cent. 0'7045 grm. of the sulphate also gave 0'8815 grm. of BaSO_4 . Hence 100 parts of BaSO_4 are equivalent to 79'921 of $\text{La}_2(\text{SO}_4)_3$.

Last of all, and probably best of all, we come to the determinations of Cleve.§ Strongly calcined La_2O_3 , spectroscopically pure, was dissolved in nitric acid, and then, by evaporation with sulphuric acid, converted into sulphate:—

* Journ. f. Prakt. Chem., 80, 33. 1860.

† Ibid., 82, 396. 1861.

‡ Ibid., 104, 174.

§ Zschiesche's Zeitschrift, 6, 306. 1871.

|| K. Svenska. Vet. Akad. Handlingar, Bd. 2, No. 7. 1874.

* Ann. d. Chim. et de Phys., (4), 30, 68. 1873.

† Journ. f. Prakt. Chem., 75, 321. 1858.

19215 grms. La_2O_3 gave 3'3365 sulphate. 57'590 per cent.		
2'0570 "	3'5705 "	57'611 "
1'6980 "	2'9445 "	57'667 "
2'0840 "	3'6170 "	57'617 "
1'9565 "	3'3960 "	57'612 "

Mean 57'619 $\pm$ 0'0085

From the last column, which indicates the percentage of La_2O_3 in $\text{La}(\text{SO}_4)_3$, we get, if $\text{SO}_3=80$, $\text{La}=139'15$.

We may now combine the similar means into general means, and deduce a value for the atomic weight of lanthanum. For the percentage of oxide in sulphate we have six estimates, as follows. The single experiments of Czudnowicz and of Erk are assigned the probable error and weight of a single experiment in Hermann's series:—

Czudnowicz	58'668 $\pm$ 0'027
Erk	57'068 0'027
Hermann	57'654 0'016
Zschiesche	57'021 0'051
Marignac	57'5475 0'0115
Cleve	57'619 0'0085

General mean .. 57'620 0'0059

For the quantity of $\text{La}_2(\text{SO}_4)_3$ proportional to 100 parts of BaSO_4 , we have five experiments, which may be given equal weight and averaged together:—

Marignac	81'022
"	80'934
Rammelsberg	79'276
Czudnowicz	79'117
Erk	79'921

Mean 80'054 $\pm$ 0'270

In all, there are seven ratios from which to calculate:—

- (1). Percentage of La_2O_3 in $\text{La}_2(\text{SO}_4)_3$, 57'620 $\pm$ 0'0059
- (2). $\text{BaCl}_2 : \text{La}_2(\text{SO}_4)_3 :: 100 : 91'322 \pm 0'048$ —Marignac.
- (3). $\text{BaSO}_4 : \text{La}_2(\text{SO}_4)_3 :: 100 : 80'054 \pm 0'270$
- (4). $\text{BaSO}_4 : \text{La}_2\text{O}_3 :: 100 : 46'671 \pm 0'075$ —Holzmann.
- (5). P.c. of La_2O_3 in iodate, 23'447 $\pm$ 0'0216—Holzmann.
- (6). " " magnesian nitrate, 21'3056 $\pm$ 0'058—Holzmann.
- (7). " " carbonate, 68'47—Hermann.

These ratios give five values for the molecular weight of lanthanum oxide, and two for that of the sulphate:—

From (2)	$\text{La}_2(\text{SO}_4)_3=568'488 \pm 0'320$
" (3)	558'624 1'888

General mean .. " 568'212 0'316

Hence $\text{La}=140'346 \pm 0'160$.

From (1)	$\text{La}_2\text{O}_3=325'791 \pm 0'074$
" (4)	325'674 0'522
" (5)	322'419 0'113
" (6)	324'355 0'923
" (7)	325'896 0'488

General mean .. " 324'810 0'061

Here the value derived from ratio (7) is given the weight of a single experiment in ratio (1). Hence $\text{La}=138'460 \pm 0'031$.

Combining the two values for La , we get this final result:—

From La_2O_3	$\text{La}=138'460 \pm 0'031$
" $\text{La}_2(\text{SO}_4)_3$	140'346 0'160

General mean .. " 138'526 0'030

Or, if $\text{O}=16$, $\text{La}=138'844$.

Since this value is a little under and Cleve's a little over 139, the latter figure may fairly be used in all calculations involving a knowledge of the atomic weight of lanthanum.

The following additional note has been communicated by the author:—

Later determinations of the atomic weight of lanthanum, by Brauner and Cleve, essentially modify the conclusions stated in this chapter. In a first paper,* Brauner gives two experiments upon the synthesis of the sulphate from the oxide: which, expressed in percentages, give 57'5775 of La_2O_3 in 100 of $\text{La}_2(\text{SO}_4)_3$. In a second paper,† with purer material, the mean percentage in five experiments is 57'480.

Cleve,‡ with the same method, and very pure material, also gives a mean percentage of 57'480, from twelve experiments. Hence $\text{La}=138'019$. If $\text{SO}_3=80$, $\text{La}=138'22$. These results supplant all previous determinations of this constant.

NOTICES OF BOOKS.

A Treatise on Earthy and other Minerals and Mining. By D. C. DAVIES, F.G.S. London: Crosby Lockwood and Co.

THIS book is devoted to an account of the more important minerals, their properties, localities, and mining. The so-called useful and the precious or noble metals—in short, all those which are commonly used in the metallic state—have been discussed by the author in a previous treatise on "Metalliferous Minerals and Mining."

The notice of common salt as a mineral is very elaborate. We find, among other unusual information, a history of the salt works of Cheshire and Worcestershire from the earliest times on record. The account of the salt deposits near Middlesbrough does not seem to be brought down to the present date, so that the reader remains in doubt whether the operations of Messrs. Bolckow and Vaughan, and of Bell Brothers, have proved commercially successful. It has always been understood that the want of a supply of salt on the spot has been one main reason why the alkali trade on the Tyne has been less flourishing than that in South-west Lancashire. The account given of the great Wieliczka mine is very correct, as we know from personal examination.

The most enormous deposit of salt in the world is probably that on the Indus, of which the author gives an account taken from the "Memoirs of the Geological Survey of India."

The potash deposits of Staassfurt do not seem to be mentioned, though sylvine is noticed as occurring along with the rock-salt of Salzburg.

Under borax we find a very good account of the sources of this useful mineral, the recently discovered deposits in Nepal and Iceland being mentioned. The Chilian sources of borax seem to have been overlooked.

The total annual output of witherite (native barium carbonate) in Great Britain and Ireland is given as 21,313 tons. Considering the poisonous nature of this mineral it is surprising that those authorities who are constantly clamouring for additional restrictions on the sale of poisons,—at whatever inconvenience to the industrial arts,—have not proposed to have a constant guard stationed at all mines and accessible deposits of witherite.

The value of fluor-spar is stated at about 14s. per ton. This is doubtless correct as regards fragments, but large blocks of "blue john," without a flaw, as sometimes met

* Journ. Chem. Soc. Feb., 1882.

† Sitzungsber. Akad. Wein., June, 1882.

‡ Bulletin de la Soc. Chimique, 39, 131. 1883.

with at Castleton, are worth more than twenty times that sum.

The sources of alum are scarcely treated in a satisfactory manner. There is no mention of the alunite of La Tolfa which serves for the manufacture of the famous Roman alum. The alum manufacture at Whitby is now abandoned. At least, having occasion to visit the locality a few years ago, we found the works gone to decay, and were told that alum-making had ceased for some time. The quarries were occupied merely by a few men who were picking out stones used in the manufacture of cement. In fact the chief raw materials used in alum-making are now China clay and bauxite.

The account of phosphate of lime occupies four chapters and almost rises to the rank of a monograph. Coprolite mining, which at one time was a very important industry in Suffolk, Cambridgeshire, and Bedfordshire, and which even extended into Buckinghamshire, has seriously fallen. The annual value raised, which in 1875 was £627,000, had in 1882 dwindled to £86,628. This decline is partly due to the exorbitant royalty demanded by the landowners, which ranges from £100 to £140 per acre, whilst the average field of coprolites is about 300 tons per acre, worth perhaps fifty shillings per ton. "When it is considered that the digger has to turn over from 3 to 15, sometimes 20 feet of soil and sand, and to restore the land afterwards to its original condition; that he has also to wash, sort, and convey the nodules to a railway, it will be plain that the price paid to the landowner is too much, and that in the face of phosphates more cheaply won abroad, English phosphate digging can hardly be profitably carried on."

In the chapter on the diamond we find a quotation from the *Geographical Magazine* for 1868 which, in the light of subsequent experience, reads strangely. Says the writer—whose name is charitably withheld—"I can only now conclude by expressing my conviction that the whole diamond discovery in South Africa is an imposture, a bubble scheme!"

In the chapter on bitumen, petroleum, &c., we notice the following passage:—"About one hundred and thirty years ago the *Philosophical Transactions*, the *Transactions of the Royal Society of Great Britain*, and the scientific papers of other countries of Europe, &c." The above sentence is misleading. The *Philosophical Transactions* are the *Transactions of the Royal Society*. Probably the author meant to say in the second place, the "*Proceedings of the Royal Society*."

In speaking of sulphur and sulphur ores Mr. Davies gives a discouraging view of the sulphur deposits of Iceland.

Taken as a whole this work will prove exceedingly useful as a manual of reference to all persons interested in the industries discussed.

he was engaged by the Cavendish Society to prepare a translation, with additions, of the great "*Handbuch der Chemie*," of Leopold Gmelin, a work which extended to 18 volumes, and occupied a large portion of his time for more than twenty years, the last volume and index having been published in 1872. In 1858 he was engaged by the eminent publishers, Messrs. Longmans and Co., to prepare a new edition of "*Ure's Dictionary of Chemistry and Mineralogy*," but finding that this book, the last edition of which appeared in 1831, had fallen too much behind the existing state of chemistry to be made the groundwork of a dictionary adapted to the requirements of the time, he undertook, with the consent of the publishers, and the assistance of a staff of contributors distinguished for their attainments in different branches of physics and chemistry, the compilation of a new "*Dictionary of Chemistry and the Allied Branches of other Sciences*." This work, in five large octavo volumes, was completed in 1868, but as additions were required to keep it abreast of the continual advances of science, a supplementary volume was published in 1872, a second supplement in 1875, and a third (in two parts) in 1879 and 1881.

Mr. Watts also brought out three editions of "*Fownes's Manual of Chemistry*," viz., the 10th, published in 1868, the 11th in 1872, and the 12th in 1877.

He held for many years the appointments of editor of the *Journal*, and Librarian, to the Chemical Society, having been appointed to the former in 1850, and to the latter in 1861. He was elected a Fellow of the Chemical Society in 1847, a Fellow of the Royal Society in 1866, and a Member of the Physical Society in 1879. He was also an Honorary Member of the Pharmaceutical Society, and a Life Governor of University College.

He was engaged at the time of his death in writing a new and abridged edition of the "*Dictionary of Chemistry*." He was also editing a re-edition of "*Richardson and Watts's Technology*," and the 13th edition of "*Fownes's Manual of Chemistry*," of which the 2nd volume is left in manuscript.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Bulletin de la Société Chimique de Paris.
No. 8, April 20, 1884.

Formation-Heat of Antimony Fluoride, Chloride, and Oxy-Chlorides.—M. Guntz.—The author gives his results in the form of tables.

Decomposition of Cements by Water.—H. Le Chatelier.—The author has observed that the lime removed from cements by the action of water is not free, as generally supposed, but in a state of combination.

Preparation of a Propyl and an Amyl-Naphthalin.—Léon Roux.—To obtain the former of these compounds the author heats in a flask fitted with a reflux-condenser a mixture of 200 grms. naphthalin and 120 grms. propyl bromide. When the latter begins to distil over about 10 grms. aluminium chloride are added in small proportions, shaking up the flask each time. When about the theoretical quantity of hydrobromic acid has come over, the flask is let cool, and from 300 to 400 grms. of carbon disulphide are added. The resulting matter is treated with water to decompose the aluminium chloride. The carbon disulphide is decanted off, dried, and distilled in the water-bath. There remains finally a brown, pasty mass, which is submitted to fractionated distillation. The compound in question passes over between 145° to 150° under a pres-

OBITUARY.

HENRY WATTS, F.R.S.

WITH great regret we have to announce the sudden death of Mr. Henry Watts, on the 30th ultimo, of syncope of the heart. Mr. Watts was born in London on the 20th January, 1815. He was educated first at a private school in London, and subsequently attended lectures at the University College, London. In 1841 he graduated as Bachelor of Arts in the University of London. In 1846 he entered the Birkbeck Laboratory of Chemistry, then recently established at University College, as Assistant to his highly-valued friend, the late Professor Fownes, and in that capacity was engaged in directing the work of the students till the death of Professor Fownes in 1849, and afterwards till 1857 under Professor Williamson. In 1848

sure of 2 centimetres to mercury. Amyl-naphthalin is obtained in a similar manner, using amyl-chloride.

Action of the Chlorised Aldehyds upon Benzol.—A. Comtes.—The author has obtained an aldehyd, $C_8H_6Cl_2O$, which is very stable and may be distilled in a vacuum without decomposition. It reduces Fehling's liquid and silver nitrate energetically, and combines with sodium bisulphite, although with difficulty.

Influence of the Ammonia-Soda Process upon the Value of Hydrochloric Acid and of Chlorine.—W. Weldon.—From the *Journal of the Society of Chemical Industry*.

Analysis of Soils.—Antony Guyard.—The mineral products useful as plant-food and which require to be determined in the analysis of soils exist mainly in two forms:—In a state readily assimilable in the mineral portion and in an assimilated state in the organic portion. In order to obtain the former in a separate state the author treats in the cold 100 grms. of soil with a refrigerated mixture of 150 c.c. hydrochloric acid with an equal volume of water. He filters and washes at first with cold water, and then with boiling water until it is exhausted, and in the solution he determines lime, magnesia, alkalies, and phosphoric acid. He thinks it advisable not to reduce samples of soil to an impalpable powder, and, on the other hand, that stones, &c., should be broken up, ground, passed through the same sieve, and mixed with the rest of the sample. To obtain the assimilated elements he ignites 100 grms. of soil at as low a heat as possible, stirring until all the carbon is burnt off. This portion, when cold, is treated with 300 c.c. of dilute hydrochloric acid, and exhausted as above.

Russian Chemical Society.—November 3/15, 1883.—M. Tchijevsky sent in an account of his preliminary experiments on the volatilisation of different salts on the evaporation of their aqueous solutions. From his researches it results that the quantities of the salt carried away with watery vapour in the evaporation of solutions are sometimes very considerable. The volatilisation of the salt increases with the concentration of the solutions up to a certain maximum, and then decreases. It increases also directly as the molecular weight of the salt.

M. Kajander sent a communication on certain corrections which must be introduced into thermo-chemical data.

M. Kutcheroff explained the result of his studies on the action of allylene upon mercuric oxide and its salts.

M. Prokofieff discussed the analogy existing between the compounds of boron and those of the residue C_2H_3 contained in acetic acid.

M. Louguinine communicated the results of his researches on the combustion-heat of several acetones and of ethyl-carbonate.

M. Wroblevsky called attention to the contradictions which result if we express the structure of benzol by the prismatic formula.

M. Bakmetieff exhibited an automatic apparatus for washing precipitates with hot water.

M. L. Wagner gave an analysis of the epidermis in a case of red tetters.

M. Sokoloff gave the results of an analysis of the water of the Neva during October last.

MM. Sabanieff and Kislakowsky have studied the product obtained from the action of ethylene bibromide upon naphthalin in presence of aluminium chloride. The authors suppose that the hydrocarbon obtained is picene.

M. Konovaloff gave a communication on the decomposition of solutions.

The 8th part of vol. xv. of the *Journal of the Russian Chemical Society* contains the following memoirs:—

Analysis of a Phosphorite from Nijni-Novgorod, by M. Lutavine. It contains 25 per cent of phosphoric acid and appears to be apatite mixed with calcium carbonate, quartz, and some zeolite.

On the β -dipropyl-acrylic acid obtained from β -dipropyl-ethylene-lactic acid, by M. Albitzky.

On the action of allyl iodide and zinc upon epi-chlorhydrin, by M. Lopatkine.

On the composition of the accessory product obtained on the preparation of diallylcarbinol, by M. Chestakoff.

Action of a mixture of allyl iodide and primary isobutyl iodide upon acetone in presence of zinc, by M. Chatzky.

On the hydrocarbon, C_8H_{14} , derived from allyl-diethylcarbinol, by M. Reformatzky.

The specific refractive energy of the hydrocarbon, $C_{12}H_{20}$, by M. Albitzky.

Theory of solutions, by M. Alexeef.

On diphenyl-xylyl-methane and its oxidation products, by M. Hemilian.

Meeting of December 1/13, 1883.—The President announced that the committee chosen to award the Sokaloff prize proposed to allot it to M. Gustavson, for the discovery and study of the reactions of organic substances in presence of aluminium chloride, bromide, and iodide.

M. Parloff and M. Poehl gave the results of analyses of the water of the Neva.

P. Alexeef gave an account of new researches on azo-cuminic acid.

Researches from the Chemical Laboratory of the University of Kiev were handed in.

On the structure of the nitro-compounds of the fatty series, by M. Kissel.

Analyses of the mineral waters of the Caucasus, by M. Barsilovsky.

On the structure of indigo blue, by M. Alexeef.

M. Smolensky communicated analyses of the waters of the lakes and wells of Schouvaloff, and of the rivers Oxta and Loupa.

M. Lukianoff sent in a memoir on the composition of the aniline oils.

MM. Gorboff and Kessler announce that dimethacrylic acid (obtained by the action of CHI_3 upon sodium isobutylate) is split up into isobutylene and CO_2 if heated to 210° to 220° for 25 to 30 hours.

M. Wilm has obtained a rhodium salt of the composition $R_4Cl_4 \cdot 8NH_4Cl + 7H_2O$.

M. Prijbytek gave a preliminary communication on the product of the action of caustic potassa upon the dichlorhydrine of erythrite.

M. Alexeef has studied the change which the dissolving heat of isobutylic alcohol in water undergoes according to the temperature of the experiment.

The 9th part of vol. xv. of the *Journal of the Russian Chemical Society* contains the following memoirs:—

Thermic data relating to pyro-sulphuryl chloride, by M. Konovaloff.

On the hydrate of silica obtained from the decomposition of cast-iron, by M. Zaboudsky.

The action of allylene upon mercuric oxide and its salts, by M. Kutcheroff.

On the corrections of thermo-chemical data, by M. Kajander.

Moniteur Scientifique, Quaesneville.

Vol. xiv., May, 1884.

Colours employed in Calico-Printing and the General Means of fixing them upon the Cloth.—R. Bourcart (of Manchester).—A continuation from the April number, extending to nearly 50 pages, and being from its nature quite incapable of useful abstraction.

Industrial Society of Mulhouse.—Meeting of March 12th, 1884.—M. Goppelsroeder sent a letter on the possibility of utilising in chemical telegraphy the electrolytic reactions which he has described in his different publications,—the simultaneous formation and fixation of colouring-matters upon cloth, paper, &c., as well as the discharge of colours fixed upon the same materials.

M. Dominique Sifferlen, of Moscow, sent a note on a means of utilising worn caoutchouc cloths for covering

the wooden rollers of washing machines. Certain sealed notes were opened, including one by M. Rosenstiehl (No. 188, Dec. 16th, 1872), on an improvement in printing by relief engraving, by means of caoutchouc rollers; another by the same author (No. 187, of the same date) on "toluidine brown"; a third by MM. Poirrier and Lauth (No. 185, Oct. 31st, 1872), on "a secondary product of the manufacture of dimethyl-aniline, and the colouring matters derived from it. These three papers were ordered to be printed. A note by M. Mulhauser (No. 198, Oct. 4th, 1873) on "the synthesis of certain derivatives of indigo," contained merely theoretical speculations, and was deposited in the archives.

M. Horace Kœchlin submitted swatches dyed and printed with canarine, by MM. Prochoroff and O. Müller. The procedure followed was:—x part of canarine is heated to a boil with 20 parts of distilled water; x part of potassa is added, and the mixture is heated until the solution is complete and the liquid takes a brown colour; from 7 to 20 parts per cent of soap are added and the mixture is let cool for working. Calcium and magnesium salts precipitate the colouring-matter. Caustic soda cannot be used in place of potassa, as the sodium compound is insoluble in the cold. The canarine should not be heated too long with the potassa, or decomposition may set in. Cold solutions should be used for padding, to prevent unevenness. The pieces opened out are passed into a cistern with rollers, containing 80 litres of water and 60 litres of solution of canarine. They are wrung out, left in heaps for 4 to 6 hours, washed and soaped at a boil. M. Kœchlin modifies the process, boiling 100 grms. canarine, 100 borax, and 1 litre of water. In dyeing, he raises the temperature gradually, as is done with alizarin.

Chemical Patents and Certificates of Addition taken in France during the year 1884.—An enumeration of patents, drawn up so briefly as to throw little light on their character.

Fermentation of Indigo Vats.—L. Benoist.—The author argues that the reduction of the indigo in the warm vats is effected by anaerobic microbia. Under their influence the sugar is converted into butyric and succinic acids with a plentiful liberation of carbonic acid and hydrogen. The nascent hydrogen fixes itself upon the indigo and in presence of alkali converts it into soluble indigo-white. Under certain circumstances the bacillus may, if other matters are wanting, destroy the indigo. He therefore breeds one particular *desmobacterium* which he finds most suitable, and sets his vat in such a manner that the bacillus may be nourished at the expense of the starch, which is gradually converted into glucose and protects the colouring-matter.

Use of the Oil of Winter Green in the Treatment of Acute Rheumatism.—Dr. F. P. Kinnicutt.—A purely medical paper.

Influence of the Temperature of Distillation upon the Composition of Coal Gas.—L. T. Wright.—From the *Journal of the Chemical Society*.

The Deposits of Borocalcite of Maricunga and Pedernal (Chili).—F. Witting.—This mineral contains from 21 to 26 per cent of boric acid. The daily production is 5 to 6 tons of an acid at 90 to 92 per cent.

Vol. xiv., June, 1884.

This number, in addition to the usual abstract of the proceedings of the Academy of Sciences, contains a treatise on the analysis of milk, occupying more than 100 pages.

Justus Liebig's Annalen der Chemie,
Vol. 222, Part 3.

Synthesis by Means of Malonic Ester.—M. Conrad and M. Guthzeit.—(Fourth Treatise). In this memoir the authors discuss dicarboxyl-glutaconic ester and its derivatives.

The Derivatives of Naphthalin.—Icilius Guareschi.—In this very extensive treatise the author examines the dibrom-naphthalins; the action of nitric acid upon dibrom-naphthalin, fusible at 81° to 82°; the behaviour of chromic acid with dibrom-naphthalin; the action of bromine upon nitro-naphthaline; the nitro-brom-naphthalins, and the amid-brom-naphthalins.

Constitution of Thio-aldehyde and Carbo-valer-alidine.—Icilius Guareschi.—The author considers the latter compound as a divaleryliden ammonium dithiocarbamate.

Communications from the Laboratory of the University of Halle.—These comprise a paper on picrotoxine, by Ernst Schmidt, and a memoir on cocculine, by Emil Löwenhardt.

Silicium-Propyl Compounds.—Carl Pape.—The author following the guidance of Wöhler calls attention to the analogy between the carbon compounds and those of silicon. He investigates particularly the silicon-tri-propyl compounds.

Vol. 223, Part 1.

Proportion of Crystalline Water of Salts.—Theodor Salzer.—The author arrives at the following generalisations:—(1). When a monobasic acid forms with a metal acid salts, in addition to the neutral salt, the number of the molecules of crystalline water which can be taken up (referred to 1 mol. of acid), decreases with an increasing proportion of acid. (2). When by the union of an acid with a metallic oxide there are formed, in addition to the neutral salt, one or more basic salts, the latter take up less crystalline water than the neutral salt. (3). If a polybasic inorganic acid forms several normal salts with a metal the number of the mols. of crystalline water taken up increases in proportion as the hydroxylic hydrogen is replaced by metal. (4). If a polybasic organic acid forms several normal salts with a metal the number of the mols. of crystalline water taken by these salts increases as the carboxylic or sulphylic hydrogen is replaced by the metal. (5). The crystalline salts of the benzol derivatives in which two negative groups such as hydroxyl, carboxyl, sulphylic, or nitroyl, bear the ortho relation to each other do not combine with as much crystalline water as the isomeric salts of the para-acids.

On Hipparaffin.—K. Kraut and York Schwartz.—Hipparaffin is an oxidation product of hippuric acid, discovered by H. Schwartz in 1850. The authors regard it as a methylen-dibenzamide.

Capillarity—Constants of Liquids at their Boiling-points.—R. Schiff.—This paper does not admit of abstraction, as the results are given in the form of tables.

Chloride of Lime and Chloride of Lithia.—G. Lunge.—A reply to the criticisms of Kraut (*Annalen*, 221, p. 108 to 124) on the paper of the author, and of Naef (*Annalen*, 219, p. 129).

On Bismuthic Acid.—Dr. C. Hoffmann.—Bismuthic acid, the highest stage of oxidation of bismuth, has the composition Bi_2O_5 . Its potassium compounds are formed when bismuth hydroxide is suspended in potassa lye of sp. gr. 1.539, chlorine is introduced in the cold, and after the addition of more potassa-lye the liquid is boiled until it has an alkaline reaction. This process is repeated three times with the bismuth compound obtained, using fresh quantities of the lye. The potassium bismuthates thus obtained are of the general type $2\text{BiO}_3\cdot\text{K}+n\text{Bi}_2\text{O}_5$; they vary from a red-brown to a deep violet brown in colour, and they are richer in potassium the stronger the lye employed. If treated with boiling water they pass into salts poorer in potassium and of a lighter colour. All these compounds are anhydrous. If bismuth hydroxide is suspended in lye so strong that it solidifies on cooling, and treated with chlorine at a boil, yellow and red compounds are obtained in which the bismuth is partly pentavalent and partly trivalent.

Vol. 223, Part 2.

Condensations of Acetone with the Aromatic Aldehyds and with Furfural.—L. Caissen and A. C. Ponder.
—Not adapted for abstraction.

Communications from the Chemical Laboratory of the University of Graz.—These consist of a continuation of a memoir by K. Garzarolli-Thurnlackh, on the action of zinc-ethyl and zinc-methyl upon chlorinised aldehyds, and a paper by K. Garzarolli-Thurnlackh and A. Popper on the action of zinc-propyl and zinc-isobutyl upon butyl-chloral.

Tri-chloro-pheno-malic Acid and the Constitution of Benzol.—A. Kekulé and Otto Strecker.—This paper is essentially a defence of the "benzol-ring." The authors state in conclusion that they are "far removed from asserting that the formation of β -tri-chloro-acetyl-acrylic acid proves the truth of the view advanced by one of them concerning the constitution of benzol," but they think it agrees better with this supposition than with any other.

Changes of Volume during Fusion.—R. Schiff.—The author's researches do not confirm the view of Kraft, i.e., that a constant difference in composition corresponds to a constant difference in the molecular volumes referred to the melting-point. It appears that the melting-point is not a point of physical comparability, as is the case, in part at least, with the boiling-point.

Cosmos les Mondes.
No. 1, May 3, 1884.

Combination-Heats of the Soluble Compounds of Thallium.—Dr. D. Tommasi.—The author shows that the thermic constant of thallium is exactly equal to the mean of the thermic constants of potassium and lead, with both which metals thallium presents analogies. The thermic constant of manganese is equal to the mean of the thermic constants of iron (ferrosium) and aluminium; that of nickel is equal to the mean of the thermic constants of ferrosium and ferricum.

MISCELLANEOUS.

Powerful Blowpipes adapted for Engineering and Metallurgical Work.—Several new forms of blowpipes have recently been devised by Mr. Fletcher, forming the latest additions to his already long list of ingenious appliances for utilising coal-gas as fuel. One of the neatest forms of these large blowpipes is shown in the accompanying sketch, which explains itself. These blowpipes act as injectors; the one shown in the sketch requires Mr. Fletcher's No. 5 foot-blower, which supplies one-fifth of the necessary volume of air for complete combustion, the remainder being drawn in by the momentum of the air from the blower. At full power it will burn 300 cubic feet of gas per hour, requiring a $1\frac{1}{4}$ " main for supply. As an example of what one of these instruments is capable of doing, in one trial, in five minutes from starting, a T-

joint was brazed on a 3" wrought-iron pipe. These blowpipes are the largest yet made not worked by power, and as they can be conveniently held in the hand, they are of special value for effecting small repairs in machinery,

without the necessity of pulling down and re-erecting, as well as in metallurgical operations.

MEETINGS FOR THE WEEK

MONDAY, July, 7th.—Royal Institution, 5 p.m. General Monthly Meeting.
FRIDAY, 11th.—Quekett Microscopical Club, 8.

LIVERPOOL UNITED GAS LIGHT COMPANY.

AMMONIACAL LIQUOR.

The Directors of the Liverpool United Gas Light Company are prepared to receive TENDERS for the Ammoniacal Liquor produced at their several works for a term of three years from April 1st, 1885.

The quantities of Ammoniacal Liquor produced per annum are estimated to be as follows, but the same cannot be guaranteed, and may be more or less:—

At the Athol Street Works, about	1,400,000	gallons.
" Eccles Street	504,000	"
" Caryl Street	1,030,000	"
" Wavertree	1,313,000	"
" Linacre	3,010,000	"

The Tenders may be for the whole, or for one or more of the works separately.

Forms of Tender and full particulars may be obtained on application to the undersigned.

Tenders sealed and endorsed "Tender for Ammoniacal Liquor," are to be delivered here not later than the 5th day of August next.

The Directors reserve to themselves the right to accept any Tender in part or in whole, and do not bind themselves to accept the highest or any Tender.

WILLIAM KING, Engineer.

Gas Office,
Duke Street, Liverpool,
June 27th, 1884.

LIVERPOOL UNITED GAS LIGHT COMPANY.

TAR.

The Directors of the Liverpool United Gas Light Company are prepared to receive TENDERS for the Tar produced at their several Works for a term of three years from April 1st, 1885.

The quantities of Tar produced per annum are estimated to be as follows, but the same cannot be guaranteed, and may be more or less:—

At the Athol Street Works, about	757,000	gallons.
" Eccles Street	454,000	"
" Caryl Street	514,000	"
" Wavertree	636,000	"
" Linacre	1,672,000	"

The Tenders may be for the whole, or for one or more of the Works separately.

Forms of Tender and full particulars may be obtained on application to the undersigned.

Tenders sealed and endorsed "Tender for Tar" are to be delivered here not later than the 5th day of August next.

The Directors reserve to themselves the right to accept any Tender in part or in whole, and do not bind themselves to accept the highest or any Tender.

WILLIAM KING, Engineer.

Gas Office,
Duke Street, Liverpool,
June 27th, 1884.

DOULTON & WATTS

HIGH STREET, LAMBETH, LONDON, S.E.

MANUFACTURERS OF

STILLS, RETORTS; CONDENSING WORMS, WOLFF'S BOTTLES
ACID PUMPS, COCKS, PERCOLATORS, AIR-TIGHT JARS.

And every description of Stoneware for Chemical Purposes,
warranted to resist the strongest acids.

PLUMBAGO CRUCIBLES AND OTHER
FIRE STANDING GOODS.

DOULTON'S
MANGANOUS

CARBON
FILTER.

(Dr. BERNAYS'S PATENT.)

The combination prepared under this Patent gives to Charcoal its highest value as a FILTERING MEDIUM. The Filter is made in four movable parts—the body, the lining, the manganous carbon block, and the cover—by this means every portion of the Filter may be KEPT PERFECTLY CLEAN, and the manganous carbon block may be changed as often as necessary without parting with the Filter.

NEW SHOW ROOMS, ALBERT EMBANKMENT, LAMBETH, S.E.

THE CHEMICAL NEWS.

VOL. L. No. 1285.

ON THE HEATS OF FORMATION OF ORGANIC COMPOUNDS CALCULATED INDIRECTLY.

By WILLIAM RAMSAY, Ph.D.,
Professor of Chemistry at University College, Bristol.

This note is intended to direct the attention of chemists to a mistake which has, so far as I am aware, uniformly pervaded all calculations of the heats of formation of organic compounds by the indirect method. This mistake, which is, to include the heat of volatilisation of carbon in the heat of formation of organic compounds, pervades the work of Berthelot (see *Comptes Rendus*, 1880, 91, 786), and of J. Thomsen (see *Berichte der Deut. Chem. Ges.*, 1880, 1325 and 1806); and, so far as I know, it is to be found in all other calculations of such constants.

It is customary to ascertain the heats of formation of organic compounds as follows:—The heat absorbed by the decomposition of the compound is justly assumed to be equal to the heat which would be evolved were the elements to combine directly with each other. Now when a compound, say, of carbon and hydrogen is oxidised to carbon dioxide and water, the heat evolved is assumed to differ from that evolved when the same weight of carbon, as diamond or as charcoal, plus the same weight of hydrogen are burned, by the heat which would be evolved or absorbed during formation of the compound from its elements. Thus, to take examples from the classical researches of Berthelot and of Thomsen, the heat of formation of dipropargyl is calculated by the former as follows (*loc. cit.*):—

Dipropargyl, C_6H_6 ; molecular weight, 78.
72 grms. C (diamond) oxidised to CO_2 =
 $6 \times 93,866 = +563,196$ c.
6 grms. H, oxidised to $H_2O = 6 \times 34,600 = +207,600$

Sum of heats evolved by combstn. of elements +770,796
Heat evolved by combustion of C_6H_6 +853,600

Difference=heat of formation of C_6H_6 .. - 82,800

These numbers vary somewhat if amorphous carbon be substituted for diamond. The heat of formation is given as -64,800; thus:—

72 grms. C. (amorphous) oxidised to CO_2 =
 $6 \times 96,926 = +581,200$ c.
6 grms. H oxidised to $H_2O = 6 \times 34,600 = +207,600$

Sum of heats evolved by combstn. of elements +788,800
Heat evolved by combustion of C_6H_6 +853,600

Difference=heat of formation of C_6H_6 .. - 64,800

The heat of formation of benzene is similarly calculated by J. Thomsen. As the method of working is in every respect similar details need not be given.

A list of those who employ a similar method would comprise all those chemists who publish on the subject.

Now the following proof will show the incorrectness of this procedure, and will point to the true method of calculating the heats of formation of organic compounds from gaseous carbon.

The heat of formation of formic acid, CH_2O_2 , may be calculated in two separate ways. $CH_2O_2 = 46$.

The reaction is $CH_2O_2 + O = CO_2 + H_2O$.

(1) The hydrogen may be regarded as already oxidised.
26 grms. of CO, oxidised to CO_2 +68,370 c.
18 grms. H_2O (already formed) 0

Sum of heats evolved by combstn. of elements +68,370
Heat evolved by combustion of CH_2O_2 +96,190

Heat of formation of CH_2O_2 from its elements - 27,820

(2) The carbon may be regarded as already oxidised.

2 grms. of H, oxidised to H_2O +68,360 c.
44 grms. of CO_2 (already formed) 0

Sum of heats evolved by combstn. of elements +68,360
Heat of combustion of CH_2O_2 +96,190

Heat of formation of CH_2O_2 from its elements - 27,830

It is evident that both methods give an identical result. It is also to be noticed that $H_2, O = CO, O$.

Similarly, the heat of formation of acetic acid may be calculated in two ways, $C_2H_4O_2 \times 40 = 2CO_2 + 2H_2O$.

(1) Assuming the hydrogen to be already oxidised.

24 grms. of amorphous C oxidised to CO_2 =
 $2 \times 96,960 = +193,920$ c.
36 grms. of H_2O (already formed) 0

Sum of heats evolved by combstn. of elements +193,920
Heat of combustion of $C_2H_4O_2$ (by expt.).. +210,300

Heat of formation of $C_2H_4O_2$ from its elemnts. - 16,380

(2) Assuming the carbon to be oxidised to CO.

Twice 28 grms. of CO, oxidised to CO_2 =
 $2 \times 68,370 = +136,740$ c.
Twice 2 grms. of H, oxidised to H_2O =
 $2 \times 68,360 = +136,720$

Sum of heats evolved by combstn. of elements +273,460
Heat of combustion of $C_2H_4O_2$ (by expt.).. +210,300

Heat of formation of $C_2H_4O_2$ from its elements + 63,160

In the first case the heat of formation is calculated as - 16,380, while by the second method it is +63,160. Now it is evident that the result of the second method is alone correct; and the reason of the discrepancy is also evident, viz., that the heat of combustion of amorphous carbon, or of diamond, includes that required to volatilise the carbon. It would follow that the heat of combustion of carbon supposed to be gaseous to form CO is identical with that evolved when CO burns to CO_2 ; in fact that $(C, O) = (CO, O)$. For, on re-calculating the heat of formation of acetic acid on this supposition, a result is obtained identical with that of (2). Thus—

(3) Assuming the hydrogen to be already oxidised:—

Twice 12 grms. of carbon (gaseous) to CO_2 = +273,480 c.
Twice 18 grms. of water (already formed) = 0

Sum of heats evolved by combstn. of elements +273,480
Heat of combustion of $C_2H_4O_2$ +210,300

Heat of formation of $C_2H_4O_2$ from its elements + 63,180

From this it follows that the heat of volatilisation of 12 grms. of amorphous carbon at the ordinary temperature is 39,780 c.

It is clear that none but the most misleading results as to the heats of formation are to be obtained from the very numerous observations of the heats of combustion of carbon compounds until this correction has been adopted. The greater part of the numerical results of this branch of thermal chemistry must therefore be re-calculated.

In conclusion, it may be noted that similar instances to that of carbon are known. For just as—

	$(C, O) = (CO, O) = + 68,370$ c.,
so	$(Sn, O_2) = + 135,360$
	$(Sn, O) = + 69,580$
	$(Cu_2, O_2) = + 76,580$
	$(Cu_2O, O) = + 36,610$

In many instances, therefore, union of an element with one atom of oxygen evolves half as much heat as union with two atoms of oxygen.

ON THE REVERSION OF PHOSPHORIC ACID.

By THOMAS S. GLADDING, A.M.

(Continued from page 3.)

III. Experiments on Natural Soils.

THE soils used were light loams. One from the truck gardens of Long Island, N.Y., one from the cotton plantations of North Carolina, and one from the tobacco fields of Connecticut, taken from plots upon which fertilisers have been sown and large crops of the before-mentioned staples grown.

The soils were ground to pass through a 20-mesh sieve, and 100 grms. of each were weighed for each experiment.

160 grms. of an ammoniated superphosphate were digested in two litres of water and filtered; the quantity of phosphoric acid found by analysis in 50 c.c. of this filtrate was 0.284 g. This quantity was added to 100 grms. of each soil, prepared as before, and the mixture was stirred to a thin, wet, pasty condition, allowed to remain five days in thin layer exposed to the open atmospheric conditions, in the shade, in open vessels. At the end of this period they were weighed and divided into four equal parts for digestion in citrate of ammonia solution, at temperatures 40° and 65° C., and with water, to determine the amount not reverted.

In order to calculate the exact quantity of reverted dissolved by these digestions, the amount originally in each soil was estimated by previous digestions as follows:—

SOIL.	Amount Phos. Acid dissolved from— 25 g. by Citrate of Am.	25 g. by Temp. 40° C.	65° C.	Water.
1. Long Island garden ..	0.0193	0.0292		trace
2. North Carolina cotton ..	0.003	0.0076		"
3. Connecticut tobacco ..	0.0072	0.0163		"

Corrections have been made according to the above results, as follows:—

Soil Experiment 1.—Long Island Garden Soil.

25 grms. mixture digested with cold water—

Phos. acid added	0.071 grm.
" " dissolved	0.007 "
" " reverted	0.064 "

25 grms. mixture, digested with citrate of ammonia; temp. 40° C.—

Phos. acid added	0.071 grm.
" " dissolved	0.0532 "
Reverted phos. acid dissolved ..	0.0462 "

25 grms. mixture, digested with citrate of ammonia; temp. 65° C.

Phos. acid added	0.071 grm.
" " dissolved	0.0702 "
Reverted phos. acid dissolved ..	0.0632 "

Amount of phos. acid added actually reverted 0.064 grm.
Ditto, ditto, and not dissolved at 40° C., .. 0.0178 "

Soil Experiment 2.—North Carolina Cotton Soil.

25 grms. mixture, digested with cold water—

Phos. acid added	0.071 grm.
" " dissolved	0.0062 "
" " reverted	0.0648 "

25 grms. mixture, digested with citrate of ammonia; temp. 40° C.—

25 grms. of mixture digested with citrate of ammonia; temp. 65° C.—

Phos. acid added	0.071 grm.
" " dissolved	0.0698 "
Reverted phos. acid dissolved ..	0.0638 "

Amount of phos. acid added actually reverted, 0.065 grm.
Ditto, ditto, and not dissolved at 40° C. .. 0.019 "

Experiment No. 1 shows that citrate of ammonia solution at temperature of 65° C. dissolves all the phosphoric acid added to the soil, while at temperature of 40° C. it fails to dissolve 27.81 per cent of the phosphoric acid actually reverted by the soil.

Experiment No. 2 shows that citrate of ammonia solution at temperature of 65° C. dissolves all the phosphoric acid added to the soil, while at temperature of 40° C. it fails to dissolve 27.77 per cent of the phosphoric acid actually reverted by the soil.

Experiment No. 3 shows that citrate of ammonia solution at temperature 65° C. dissolves all the phosphoric acid added to the soil, while at temperature of 40° C. it fails to dissolve 29.23 per cent of the phosphoric acid actually reverted by the soil.

In order to obtain a thorough and uniform mixture of the solution of phosphoric acid with so large a volume of soil, the mass was made very wet and stirred; during two days its condition represented very wet lands; later, as more water evaporated, it took upon itself all the successive stages of drought, but at no time contained less moisture than was observed in the fields from the surface to depths varying several inches, during the summer season. Tests made with other portions of these mixtures showed that all the phosphoric acid was dissolved at both temperatures, if kept constantly saturated with water, owing to the ready solubility of all gelatinous precipitates at low temperatures.

Whether phosphoric acid exists in the soil in combination of lime only, or also with iron and alumina, has heretofore never been proven by any direct laboratory tests, because no method of separation was known for distinguishing these three phosphates in the presence of each other in the soil. The results of soil experiments 1, 2, and 3, show that advantage can be taken of this discovery to formulate a method of a laboratory qualitative test for reverted iron and alumina phosphates, under the above conditions. The fact that a strongly alkaline citrate of ammonia solution rapidly attacks insoluble iron and alumina phosphates, but dissolves even less of insoluble lime phosphate than when neutral, constitutes another test for distinguishing these phosphates.

Many investigators have sought a direct proof since the work of Thénard* on this subject, but I am not aware that any has been found.

That phosphoric acid becomes reverted or insoluble in water, when in contact with soil, has been demonstrated by many experiments by such noted scientists as Bronner,† Thompson and Huxtable,‡ Way,§ Liebig,§ Mulder,¶

Knop and Hussakowsky,* Salomon,† Millot,‡ Joulie,|| and Voelcker,§ and in our own country, by Drs. Johnson¶ and Shephard.**

Of these, a large number believed that it becomes combined largely with iron and alumina. Knop especially proved that phosphoric acid was fixed in greater amount, and more rapidly, when oxides of these bases were added to soils; and that soils containing large quantities had greater reverting properties than those containing less oxides of iron and alumina.

Thénard and Déhérain discussed elaborate theories to establish the chemical reaction by which plants could absorb phosphoric acid from its combinations with iron and alumina; but experience has taught the agriculturist that he cannot reason with certainty regarding these intricate processes.

That plants do absorb phosphoric acid from pure phosphate of iron and alumina by some means has been demonstrated beyond a doubt in recent field experiments by Drs. Peterson,†† Voelcker,‡‡ Pittbagen,||| Prof. Dietrich,|||| F. Oldenberg,|||| Renow,||| Dr. Birner,||| Prof. Maercker,§§ Hoffmeister and others.¶¶

Leaving the theoretical discussion of this question, the practical view of the case is best expressed in the following words from Prof. S. W. Johnson's work, "How Crops Feed," p. 374.

"The great beneficent law regulating these absorptions appears to admit of the following expressions: those bodies which are most rare and precious to the growing plant are by the soil converted into and retained in a condition, not of absolute, but of relative insolubility, and are kept available to the plant by the continual circulation in the soil of the more abundant saline matters."

The quantities of iron and aluminum oxides introduced into the mixtures of artificial soils, with which experiments 2, 3, 4, and 5 were performed, were chosen according to the average amount of these oxides in soils.

Analyses of 87 soils, collected from all the farming districts of New York State by Emmons,*** in 1846, show the average contents of iron oxide and alumina to be 7.79 per cent; of lime, 0.84 per cent.

The average of 20 representative soils, collected in New Jersey by Cook,††† shows, by analysis—Oxide of iron and alumina, 19.33 per cent; lime, 0.77 per cent.

And even in Ohio, where the geological formation is lime rock, the soil contains much more of these oxides than of lime. Average of 13 representative soils show by analysis,†††† oxide of iron and alumina, 3 per cent; lime, 1.25 per cent.

Very many soils contain less than 0.15 per cent of lime. The normal amount, it is safe to say, does not exceed 0.45 per cent. Lime is rapidly removed from soils by percolating waters. In formations of lime rock, huge caverns are formed by this process; whereas the iron and alumina of the rocks remain in the soils formed from them, with a consequent increase of the relative proportions between these bases and lime.

Knop,|||| Salomon,§§§ and others have shown that this loss of lime is also largely due to reactions in the soil, by which soluble compounds of lime are formed with nitric, sulphuric, muriatic, and humic acid.

Albert and Vollbrecht* experimented on soils containing a large amount of lime, and with others containing a small amount, with the result here given in abstract.

They mixed 10 grms. soil, containing 18 per cent carbonate of lime; 2.5 grms. superphosphate, containing 9.3 per cent phosphoric acid soluble in water, and 12.06 per cent reverted soluble at temperature 40° C. in neutral solution of citrate of ammonia.

Of the total phosphoric acid present, dried in the shade, there became insoluble in water, per cent:—

After Hours.			After Days.

In another experiment they mixed 10 grms. clay soil 2 grms. superphosphate above used:—

Of total phosphoric acid present, in the shade, there became insoluble in citrate of ammonia, temp. 40° C.—

After 3.	8.	14 Days.
8.2	12.1	—

In another experiment with a sandy soil, same mixture—

Of the total phosphoric acid present, in the shade, there became insoluble in citrate of ammonia, temp. 40°—

4	5.2	7.1
---	-----	-----

The authors, with Millot and Joulie,† concluded from these experiments that the amount of phos. acid not dissolved by citrate of ammonia solution at 40° C. had become insoluble phosphate of lime, and so Déhérain thought possibly oxide of iron and alumina produced insoluble phosphates of lime.

Had they digested these soils at the temperature of 65° C., these discrepancies would have disappeared, as is shown by my experiments on soils 1, 2, and 3 (P).

If all the reverted phos. acid present in these experimental mixtures had been in combination with lime, it would have been entirely re-dissolved at temperature 40° C. by the neutral citrate of ammonia solution, as is proved by experiment No. 1, where lime was the only base present.

Therefore it is impossible to conclude otherwise than that a portion of the phos. acid added was in combination as reverted phosphates of iron and alumina in these soils.

Thenard and Dehérain in 1858 believed that when even

insoluble phosphate of lime was applied to the soil, eventually the phosphoric acid became combined with iron and alumina, through the chemical agencies of soils.

The physical conditions of oxides of iron and alumina in soils do not seem to affect the principal result of these comparisons of temperature at which citrate of ammonia solution is used; the mineral, brown hematite, used in experiment No. 4, was chosen to represent the mineral oxides of iron formed by decomposition of rocks; though much more active forms of these oxides, such as proto-compounds, are supposed to be present in the chemical changes going on in soils. Bauxite, used in experiment No. 5, represents in the same manner the possible condition of alumina in soils. In short, I do not think that these minerals can be *more active* in their affinities for phosphoric acid than are those contained in soil.

(To be continued.)

ON THE DETERMINATION OF CHROMIUM SESQUIOXIDE.

By M. H. BAUBIGNY.

THE tendency of chromium sesquioxide to combine with other bases has caused the separation of chrome in this state to be abandoned whenever the liquid contains any bases other than the alkalies properly so-called. Hence chromium sesquioxide is now separated by being converted into chromic acid. The methods employed for this purpose are fusion with alkalies, alone or mixed with saltpetre, or the action of chlorine or bromine upon the mixture of oxides, suspended in an alkaline lye. Reynoso's permanganate method has been abandoned on account of its serious inconveniences.

Storer, in 1859, proposed the use of the following oxidising mixture:—Chromic oxide, or its salts, whether in the state of powder or of solution, is quickly oxidised at a gentle heat in presence of nitric acid into which potassium chlorate is projected. The conversion into chromic acid is rapid and complete.

This method is absolutely general. Not only is ignited chromic oxide converted almost instantaneously into soluble chromic acid, but even chrome-iron is attacked, and that so thoroughly that the residue, when tested by fusion with sodium carbonate and saltpetre, is found absolutely free from chromium.

When the chrome is once transformed into chromic acid its separation from the other oxides falls under the general case of the separation of acids and bases. When Storer's method has been used the presence of oxy-derivatives of chlorine prevents this operation from being effected by ammonia or its carbonate, unless the chlorous acid has first been expelled by heat, which under certain circumstances is a tedious process.

As examples the author gives the separation of chrome from alumina and from iron. In a concentrated solution of chromium sulphate and aluminium sulphate M. Baubigny transformed the chrome into chromic acid. This process is unattended with danger when conducted in an open vessel, simply covered with an inverted funnel to prevent loss by spitting. The strength of the acid is of little importance in case of soluble compounds, and the heat should not exceed 100°.

When the liquid is cold the alumina is thrown down by a very slight excess of sodium bicarbonate. After standing for an hour or two it is filtered and washed with water very slightly charged with bicarbonate. The alumina which is at first tinted yellow is rapidly decolourised; it is then partially dried and the filter supported by the funnel is kept at the surface of a large volume of water to remove the last traces of alkali. The precipitate is then dried and incinerated as usual.

The chrome is then easily separated as sesquioxide by saturating the bicarbonate with sulphuric acid, adding ammonia, and treating with a current of sulphuretted hydrogen. The reduction is easily and completely effected by raising the mixture to a boil, when it is merely necessary to filter and wash the chromic hydrate. To remove alkalies and alkaline salts the precipitate is dissolved in hydrochloric acid and precipitated by ammonia whilst hot.

The separation of chrome from iron (ferricum) is conducted on the same principles.

If chrome is precipitated as mercurous chromate (Rose's method) the presence of ammoniacal salts must be avoided.—*Bulletin de la Soc. Chimique de Paris.*

DETERMINATION OF MOLYBDENUM AND TUNGSTEN.

By BARON OTTO VON DER PFORDTEN.

I. Gravimetric Methods for Molybdenum.

THE reduction of molybdic acid to the state of metal is an improvement on the original method of H. Rose. The author has further simplified the methods of Rammelsberg and Debray. He finds that the reduction to metal can be effected in a crucible with a perforated cover, by means of a good gas-blast. He uses a platinum crucible and passes in a current of hydrogen through an earthen tube. In the analysis of ammonium molybdate he heats the sample in the crucible to 170° for some hours in an air-bath, thus avoiding spitting. If the temperature is raised higher, *e.g.*, to 200°, there is a slight loss by sublimation. The crucible is then heated gently in a slow current of hydrogen to superficial reduction. In order to guard against possible loss by sublimation the aperture of the gas-delivery pipe is wrapped in sheet platinum, running to a point below and fitting into the aperture of the lid, with which it is weighed. After the heat has been gradually raised, the complete reduction is effected in the highest heat of a good gas-blast in a strong current of hydrogen. The ignition takes about half an hour for 0.2 grm. of the quantity of metal expected. The reduction is complete when the weight of the crucible is constant, or when the contents take a uniform grey colour. A violet stratum shows that a little oxide is still present; it is then brought to the sides of the crucible by stirring, and the reduction is thus easily completed. The crucible is afterwards to be well cleansed by ignition in the air and by subsequent successive treatments with nitric acid and with ammonia.

This method is applicable for all neutral solutions containing molybdic acid, if combined with precipitation by mercurous nitrate. This process was first recommended by Berzelius for tungsten and was then applied to molybdenum by H. Rose. The cold, concentrated solution of a molybdate, exactly neutralised and freed from carbonic acid, is mixed with an excess of a clear concentrated solution of neutral mercurous nitrate and well stirred up in the beaker with a glass rod. The bulky yellow precipitate clots together and begins to deposit, and if enough of the reagent has been added and the mixture well stirred the liquid quickly becomes clear as water. After a few hours the precipitate may be filtered with the aid of the vacuum pump. Particles which, on stirring, adhere to the sides of the glass are rinsed with hot nitric acid into a platinum crucible and evaporated. The main precipitate, when dry, is separated as completely as possible from the filter and placed in the crucible. The portions adhering to the paper may be rinsed into the crucible with hot nitric acid and evaporated. Or the filter is carefully folded up, so that the particles may be reduced by the carbonaceous matter before molybdic acid can sublime

away, and the whole is incinerated on a platinum wire as usual. The reduction to metal is then effected as above.

For the analysis of acid solutions containing molybdic acid the reduction of molybdenum trisulphide to the disulphide is recommended as described by Liechti and Kempe. It requires much more time than the reduction to metal and the conclusion of the reduction is not so distinctly marked. The molybdenum disulphide obtained must not be ignited too strongly in the current of hydrogen.

The gravimetric determination of tungsten is much less difficult. The method of Berzelius—precipitation with mercurous nitrate as above described—is convenient and gives good results. Scheele's method,—evaporation of the solution with hydrochloric acid, exactly as for silica—is also to be recommended.

II. Volumetric Methods.

Both for molybdenum and tungsten a volumetric process can be founded upon the methods of reduction described above. In both cases complete reduction is necessary in a hydrochloric solution. The molybdenum compounds are titrated in the ordinary manner in presence of air; tungsten, on the other hand, is titrated with exclusion of air.

The execution of the process is substantially the same in both cases. The solution of the salt is mixed, for Mo, with 50 to 60, and for W with 70 to 80 c.c. of hydrochloric acid at 27 per cent. There are then added, for Mo, 8 to 10 grms., and for W 14 to 15 grms. of zinc in the form of rods and in as large pieces as possible; the iron present in the zinc, if any, is previously determined. The solution of the salt may contain 0.3 gm. MoO_3 , or 0.1 gm. WO_3 . In the latter case the solution is previously heated on the water-bath and the hydrochloric acid and zinc are then added. We thus escape the deposition of tungstic acid in a solid state. The reaction is in both cases brisk, with tungsten even violent, so that there is no occasion to accelerate it by the subsequent application of heat, which, with molybdenum, is sometimes useful towards the end of the process. When the solution of molybdenum has become yellow, and that of tungsten red, the flask is cooled,—in case of tungsten, with especial care.

The remainder of the procedure is different. The reduced solution of molybdenum is rinsed into a porcelain capsule containing about 40 c.c. dilute sulphuric acid and 20 c.c. of a solution of manganous sulphate, free from ferrous salt and containing 200 grms. per litre. The whole is then diluted with an equal volume of water, and at once a considerable number of c.c. of a dilute solution of permanganate are run in with a pipette. It is finally titrated, stirring strongly until a rose colour appears. From the quantity of permanganate consumed is deduced that consumed by the iron present in the zinc and in colouring the water. The solution of permanganate is standardised with potassium dichromate as directed by Volhard. The results are accurate.

The reduced solution of tungsten is rinsed at once quickly and carefully into a porcelain capsule in which there are an excess of permanganate, 70 to 100 c.c. dilute sulphuric acid, 40 c.c. solution manganous sulphate, but otherwise no water. Not until the flask has been rinsed out is the liquid diluted to 1 litre. In presence of such large quantities of hydrochloric acid the manganous sulphate exerts its power of transferring oxygen only in concentrated solutions. Quick work is essential. Into the liquid which still contains excess of permanganate there is run on an excess of ferrous sulphate, and the solution is finally titrated with permanganate until the rose colouration appears. A volumetric determination is less important for tungsten than for molybdenum.—*Liebig's Annalen*.

CHINESE METALLURGICAL OPERATIONS.

METHODS OF REFINING GOLD AND SILVER.

CHINA has often been spoken of as a sink down which the gold of the world is constantly poured. It is quite a mistake to suppose, however, that all the gold bullion imported by China is retained or consumed in that country; on the contrary, large quantities of gold are re-exported from Hong-kong and various ports of China, in the form of sheet gold or gold leaf, as it is generally called. This form of bullion must not, however, be confounded with the ordinary gold leaf used by gilders, which is very much thinner, and a different article altogether. The thick gold leaf to which we are now referring is manufactured principally for the Indian market, where it goes in payment for the cotton and other commodities imported from that country. Silver is more often cast into small ingots called shoes of sycee, and in this form may be said to be the standard currency of China. In the melting down of gold and silver for leaf gold and sycee of standard fineness, large quantities of crucibles are annually cracked and broken; and we purpose now to give a short description of the various ingenious processes by which the Chinese recover the fragments and minute globules of the precious metals, which, after repeated use, adhere in considerable quantities to these disused crucibles; also to say a few words on the subject of Chinese methods of refining gold and silver and the parting or separating of gold from silver, when the two metals have been melted together in the process of extraction. As the whole of these various manipulations are included in the smelting of the disused crucibles above referred to, it will be sufficient to give an outline of this process.

The goldsmith having accumulated a sufficient quantity of old crucibles to justify him in commencing operations, these crucibles—which are somewhat soft, and manufactured from a but slightly ferruginous, non-siliceous clay, resulting from the disintegration of a felspathic rock, found in the neighbourhood of Fatshan—are first carefully pounded in large iron mortars, then mixed with powdered oxides of lead, of varying and uncertain chemical composition, the result of previous operations. This mixture is then sifted, wetted with water, and puddled and punched in the large iron mortars previously referred to into a kind of a dough, which is worked up by the hand into little conical shaped pellets about 3 inches high by 2 inches in diameter at their base; they are then left to dry in the air under cover. The next process consists in smelting these pellets with the addition of lead; this is done in a small blast-furnace very similar in appearance to those figured in the ancient works of the old European alchemists. The lower or hearth part of the furnace is of a semi-spherical shape, and with the cover, which is made of the clay previously described, strengthened and held together by straps and bands of iron, forms an almost perfect globe, but slightly elongated downwards towards the hearth. The tuyere pipe is of earthenware and is inserted into a hole made through the cover. This pipe does not extend much below the middle of the furnace, and its aperture is thus considerably above the hearth. The furnace itself is about two and a half feet internal diameter by rather more in depth, and the cover is almost exactly semi-spherical. Previously to insertion of the charge the interior portion of the furnace is carefully smoothed and covered with a luting of a kind of black clay made of moulding sand, and a basin, sunk into the floor, opposite the tap hole of the furnace, is similarly prepared for reception of the molten alloy after termination of the process of smelting. The furnace having been prepared for reception of the charge as above described, charcoal in small pieces is inserted to about a foot in depth; then on this is piled the little conical shaped pellets previously described, from which the precious metals are to be extracted; then a layer of lead in small ingots, about seven inches long, flat on one side and semicircular on the other.

Then more charcoal and another layer of lead ingots, and finally the furnace is filled up with charcoal, fire is applied, and the blast urged; the flames and products of combustion escape from an opening in the top of the dome-shaped furnace cover, more fuel being from time to time added as the contents of the furnace become exhausted. When the process is judged to have proceeded sufficiently far—that is when all the little pellets of disused crucible clay are completely melted—the tap hole of the furnace is opened and its contents run out. When the alloy of lead, gold, and silver thus produced has been allowed to cool, it is removed from adherent slag and the next step taken is to oxidise the lead. This is effected in a primitive cupel and muffle furnace constructed as follows. First a quantity of oyster shells are calcined in a suitable furnace by burning with wood, the resulting ash or lime is powdered and sifted; a circular depression in the floor of the furnace room is then filled with this powdered ash, which is carefully rammed down and smoothed, leaving a circular depression or shallow basin-shaped cupel some four inches deep in the centre by two and a half feet in diameter. On this is placed some fragments of charcoal together with the lump of alloy resulting from the smelting operations previously described. The whole is then covered with a shallow basin-shaped cover, like a small segment of a large sphere; this, like the furnace cover, is made of earthenware held together with straps of iron; there are two openings in this cover in order to allow the progress of the operation to be watched, and also a semi-circular opening in its rim for insertion of a tuyere or blast pipe. Fire is then applied to the charcoal on the cupel, the openings in the cover are partially closed, and the whole is covered up with a pile of charcoal. The blast is now urged and the flames or heat from the charcoal on the cupel soon communicate with the heap of charcoal by means of the apertures in the but partially closed cover, between the rim of which and the cupel or hearth a small space is also purposely left. The charcoal on the cupel soon becomes exhausted and is not renewed, the heat being kept up by combustion of the heap of charcoal over the cover. This is one of the most wasteful and least economical metallurgical operations which the Chinese have, as it will be seen that the heap of charcoal being uncovered must radiate the greater portion of its heat into the surrounding atmosphere instead of communicating it to the contents of the cupel. The Chinese operator has a reason for this, however, as he noticed that when a second cover—that is, a cover to the heap of charcoal—was applied, too great a degree of heat was generated and a considerable proportion of his silver dissipated. There was also considerable difficulty in renewing the fuel and watching the progress of the operation. After a time, varying with the nature of the alloy, the whole, or a greater portion, of the lead is oxidised and absorbed by the ashes of which the cupel is composed; a few fragments of potassium nitrate are then thrown upon the surface of the alloy, in order, as the Chinese workman says, to dissipate the last traces of lead (literally "drive away the breath or spirit of the lead"). The whole is now allowed to cool. The next process is that of parting the gold and silver, which is, for so primitive a people as the Chinese, most remarkably ingenious. The button of alloy from the cupel is placed in a large earthenware crucible and melted in a small blast-furnace or forge, which is not provided with a cover, the smoke, &c., finding exit by means of a hood similar to that over the forges of our own European blacksmiths. When the alloy is thoroughly melted it is kept constantly stirred up with roll brimstone, which acts upon the silver, forming silver sulphide, leaving the gold untouched. The workmen know, by long experience, when the process has gone far enough, and when this is accomplished, the contents of the crucible are poured out into a mould and allowed to cool, the button of gold is knocked off from the mixture of sulphur and silver sulphide, the gold re-melted, and, when wholly fused, a very small quantity of potassium nitrate is thrown upon its surface, and

the contents of the crucible, which are now only pure gold and a little potassa, are cast into suitable ingot moulds, and the gold is then, after washing to free it from the potassa, ready for the market.

The mixture of sulphur and silver sulphide resulting from the previous operation is now placed in a large crucible and melted, heat is kept up until the free sulphur is all oxidised or burned away, a suitable proportion of lead is then added to the silver sulphide and kept for some time stirred up with it. This, again, is a very wasteful and unscientific proceeding, but still, considering the authors of the process, remarkably ingenious. The whole is then poured out into a mould, and when cold is placed upon a cupel as previously described, and the original proceeding as for extracting the alloy of gold and silver from the lead of the first operation gone through with, the brightened silver, after cooling, is re-melted, a little nitre thrown upon its surface in the crucible, and the now pure silver cast into ingots for the market.

Considering the complicated nature of these various operations, the quantity of lead lost is very small indeed, the quantity recovered being generally somewhere about two-thirds of the total weight employed in the operation. The lead is recovered by smelting the previously broken up and powdered cupel with its adhering litharge, and other varying oxides of lead, with charcoal in a smelting furnace, similar to that described as employed in the first operation. The resulting slag is a dark reddish or dingy coloured glass, and with the usual Chinese habits of economy where their own property is in question, is turned to account as colouring matter by the makers of artificial stone bangles, snuff phials, and various other ornaments and articles of coloured opaque glass or artificial stone ware. For this purpose the slag in question realises about thirty cents of a Mexican dollar per picul of one hundred and thirty-three and a third pounds. The silver from these operations is cast into shoes of sycee, and the gold beaten into thick leaves or sheets of a standard degree of fineness said to be ninety-eight touch, that is, two parts of alloy to ninety-eight of pure gold. The gold is presumably prepared for the market in this form to prevent the possibility of fraud, in the shape of blocks of base metal being inserted into the centre or interior of ingots ostensibly of pure gold.

The Chinese processes for the assay on the small scale of gold and silver bullion are invariably by cupellation as above described; hence from the volatile nature of silver rendering it easily dissipated by too great heat, the Chinese are almost invariably liable to err in their assays of silver bullion by loss of weight. The Chinese are themselves aware of this fact, and endeavour to correct it by making an allowance for the loss. This, however, is at best but guess work, as the amount of silver volatilised varies with the excess or otherwise of heat to which the alloy in the cupel has been subjected; a practised and skilful operator making perhaps scarcely any appreciable loss, where another in the same operation will volatilise considerably more than the amount which is, by rule, allowed for loss in assay. In their assays of gold, from the greater difficulty with which it can be volatilised, the Chinese are more likely to be accurate, but with gold there are other sources of error, making a Chinese assay at best but an approximation to accuracy.

The Chinese are, however, from long and constant practice, very expert in the use of the touch stone, that is, a piece of dark coloured stone on which they rub the gold and tell by the colour of its streak the degree of fineness; hence the expression, so often heard amongst the Chinese, of so many "touch," pure gold being spoken of as "one hundred touch."

Hong Kong, 1884.

Examination of Milk.—A. Jørgensen recommends Abbe's refractometer.—*Zeit. f. Anal. Chem.*

A RECALCULATION
OF
THE ATOMIC WEIGHTS.*

By FRANK WIGGLESWORTH CLARKE, S.B.,
Chief Chemist to the U.S. Geological Survey, Washington.

DIDYMIUM.

THE atomic weight of didymium has been determined by Marignac, Hermann, Zschiesche, Erk, and Cleve. Mosander's early experiments we may leave out of account.

Marignac† mixed a solution of the sulphate with a slight excess of barium chloride, filtered, weighed the precipitate, and estimated the excess of barium in the filtrate by the ordinary method. The first precipitate always contained didymium, and therefore weighed too much. By deducting the weight of the second precipitate, representing the excess of the barium chloride, from the weight of barium sulphate theoretically formable, the weight of the latter proportional to the quantity of didymium salt taken was found:—

$\text{Di}_2(\text{SO}_4)_2$.	BaCl_2 .	1st BaSO_4 .	2nd BaSO_4 .
3'633 grms.	3'902 grms.	4'412 grms.	0'084 grm.
3'862 "	4'227 "	4'679 "	0'075 "
3'330 "	3'552 "	4'027 "	0'088 "
1'386 "	1'477 "	1'681 "	0'014 "

These figures give us a ratio between the sulphates of didymium and barium which we may express as follows. Column A gives the $\text{Di}_2(\text{SO}_4)_3$ proportional to 100 parts of BaSO_4 , as calculated from the first precipitate of the latter. Column B gives a similar ratio calculated with the second BaSO_4 precipitate, this being deduced from the total BaSO_4 which the chloride used could form:—

A.	B.
82'344	84'685
82'539	82'626
82'692	85'545
82'451	84'425
82'247—Erk.	

Mean 82'455 $\pm$ 0'052

Mean 84'320 $\pm$ 0'414

To A I have added a single result of Erk's, to be described further along. It will be seen that although A is theoretically defective, its figures are much more concordant than those in B. In fact, the latter would almost vanish for the final general mean for the atomic weight of didymium:—

From A	Di = 143'929
" B	" 150'436

In a later paper‡ Marignac adopts two other methods for establishing the atomic weight of didymium. The carefully dehydrated sulphate was taken, the didymium was precipitated as oxalate, and the latter, ignited, yielded oxide. The following percentages of oxide were found:—

58'22
58'24
58'29
58'31
58'29

Mean 58'27 $\pm$ 0'015

The chloride of didymium was also studied. As the anhydrous salt could not be obtained in an absolutely definite state, Marignac prepared neutral solutions of it and determined the ratio between didymium oxide and silver chlo-

ride. The latter compound was first precipitated in the usual way, and filtered off: the excess of silver in the filtrate was removed by hydrochloric acid, and after that the didymium was thrown down as oxalate and weighed as oxide. The subjoined weights of AgCl and Di_2O_3 were found. In a third column I give the ratio between the two compounds, putting AgCl at 100:—

AgCl .	Di_2O_3 .	Ratio.
10'058 grms.	3'946 grms.	39'232
5'029 "	1'960 "	38'974
5'844 "	2'276 "	38'946

Mean 39'051 $\pm$ 0'061

Hence $\text{Di} = 143'637 \pm 0'263$.

Hermann's* determination of the atomic weight of didymium rests on a single experiment with the sulphate. By precipitation as oxalate and subsequent ignition, he found that this salt yielded 58'14 per cent of Di_2O_3 .

Zschiesche† also analysed didymium sulphate, which he dehydrated at 230°, and afterwards converted into oxide by calcination. I give his percentages, and also, in a fourth column, the percentage of oxide from the anhydrous sulphate as deduced from his figures:—

H_2O .	SO_3 .	Di_2O_3 .	Di_2O_3 in anhyd. salt.
23'19	32'97	43'83	57'070
23'03	32'39	44'58	57'919
23'00	32'56	44'95	58'006
23'547	31'938	44'515	58'225
22'550	32'870	44'570	57'554

The salt used in the first experiment probably contained lanthanum. Rejecting this, the mean of the figures remaining in the fourth column is 57'926 $\pm$ 0'094. Hence $\text{Di} = 141'007$.

Erk,‡ to whom reference has already been made, estimated didymium in the sulphate by precipitation as oxalate and calcination to oxide:—

$\text{Di}_2(\text{SO}_4)_2$.	Di_2O_3 .	Per cent. Di_2O_3 .
0'556 grm.	0'323 grm.	58'094
0'674 "	0'3915 "	58'087

Hermann's single result for this percentage, 58'14, agrees more nearly with Erk's series than with any other. It may therefore be averaged in with Erk's two experiments, giving a mean of 58'107 $\pm$ 0'012. Erk also obtained from 0'7065 grm. of sulphate 0'859 grm. BaSO_4 . This experiment has already been averaged with Marignac's earlier results.

The latest determinations of the atomic weight of didymium were published by Cleve|| in 1874. Strongly calcined didymium oxide was dissolved in nitric acid, the solution was evaporated with sulphuric acid, and the weight of the resulting sulphate was ascertained. I subjoin the weighings and the percentage of Di_2O_3 in $\text{Di}_2(\text{SO}_4)_3$:—

Di_2O_3 .	$\text{Di}_2(\text{SO}_4)_3$.	Per cent Di_2O_3 .
2'257 grms.	3'844 grms.	58'715
1'086 "	1'8485 "	58'750
1'1525 "	1'9615 "	58'756
1'3635 "	2'319 "	58'797
1'9655 "	3'3435 "	58'786
1'528 "	2'599 "	58'792

Mean 58'766 $\pm$ 0'0087

Hence $\text{Di} = 146'804$. If $\text{SO}_3 = 80$, $\text{Di} = 147'021$.

‡ Zschiesche's Zeitschrift, 6, 306. 1871.

|| K. Svenska. Vet. Akad. Handlingar, Bd. 2, No. 8. These figures were kindly transcribed for me by Professor Delafontaine of Chicago, as I had not access to a copy of the original memoir.

* Smithsonian Miscellaneous Collections. The Constants of Nature."

† Arch. des Sci. Phys. et Nat., (1), 11, 29. 1849.

‡ Ann. d. Chim. et de Phys., (3), 38, 148. 1853.

This determination is undoubtedly the best of all, and might properly be accepted to the exclusion of the others. Still, it is worth while to combine all the figures into one general mean. For the percentage of Di_2O_3 in $\text{Di}_2(\text{SO}_4)_3$ we have the following data:—

Marignac	58.270	$\pm$ 0.0115
Erk and Hermann .. .	58.107	0.0112
Zschiesche	57.926	0.094
Cleve	58.766	0.0087

General mean ..	58.451	0.0059
-----------------	--------	--------

For the atomic weight of didymium we have now three independent values:—

From per cent Di_2O_3 in $\text{Di}_2(\text{SO}_4)_3$..	Di = 144.604	$\pm$ 0.031
„ Marignac's chloride analyses ..	143.637	0.263
From Marignac's and Erk's BaSO_4 ratio—	Di = 143.929	0.189

General mean .. „	144.573	$\pm$ 0.0306
-------------------	---------	--------------

If $O = 16$, $\text{Di} = 144.906$.

The following additional note has been communicated by the author:—

Since this chapter was written, Brauner and Cleve have shown the presence of samarium in what were formerly considered pure didymium compounds. By the conversion of purified Di_2O_3 into $\text{Di}_2(\text{SO}_4)_3$, they arrive at new estimates for the atomic weight of Di. Brauner* in five experiments, finds the sulphate to contain a mean percentage of 58.515 of oxide. Hence $\text{Di} = 145.26$, if $\text{SO}_3 = 80$.

Cleve† gives two series, one of ten and one of seven experiments, the mean percentages being respectively 58.0905 and 58.0895. Hence, in mean, $\text{Di} = 142.33$ if $\text{SO}_3 = 80$. If $\text{SO}_3 = 79.874$, $\text{Di} = 142.121$.

PROCEEDINGS OF SOCIETIES

PHYSICAL SOCIETY.

June 28th, 1884.

Prof. F. GUTHRIE, President, in the Chair.

New Member:—Mr. W. H. Hensley.

Lord RAYLEIGH made a communication “On the Practical Use of the Silver Voltmeter for the Measurement of an Electric Current.” At a former meeting of the Society the method was explained by the author, but on the present occasion the apparatus was exhibited. The author considers this the best method of determining the strength of current in absolute measure. One ampère deposits 4 grms. of silver in an hour, therefore a quarter to half an hour is sufficient to give 1 to 2 grms., quantities which can be measured with accuracy. Any current, from one-tenth to 4 or 5 ampères, can be measured successfully in this way. With very weak currents there is a difficulty in weighing the deposits: with very strong, dense currents the deposit is apt to be irregular. The author deprecates the use of acetate of silver, pure nitrate or pure chlorate giving the best results. The cathode of his apparatus is a platinum bowl; the anode a silver sheet wrapped with clean filter-paper sealed over it to keep any loose silver from dropping on the cathode. The anode is immersed in the solution of silver salt, and at the end of several hours (if great accuracy is required) a measurement of the weight of silver deposited is made by weighing the bowl cathode in a chemical balance.

* Sitzungsber. Akad. Wein, June, 1882.

† Bulletin de la Soc. Chimique, 39, 289, 1883.

Dr. FLEMING enquired whether it was not better to weigh the loss of weight suffered by the anode, as is sometimes done.

Lord RAYLEIGH had not found this plan so good, the anode being apt to disintegrate and lose weight not by electrolytic action.

Prof. GUTHRIE remarked that with small electrodes peroxide of silver is formed, and that the inferiority of acetate of silver might be due to formation of subacetate.

Lord RAYLEIGH then made a communication on a “Colour-mixing Apparatus founded on Refraction.” This apparatus had been described at a former meeting of the British Association, and consists of a double refracting prism, a lens, dispersing prism, and screen, by which an overlapping of spectra can be obtained, and thus a mixture of colours. In comparing different eyesights with it, Lord Rayleigh found that the majority of persons are more sensitive to red than he himself.

In answer to Mr. W. BAILY, Lord RAYLEIGH had not observed any difference between the two eyes of the same person, except what might be due to fatigue and freshness.

Dr. GUTHRIE enquired if the author had discovered any racial characteristics of colour-blindness.

Lord RAYLEIGH had not observed any so far.

Dr. GUTHRIE stated that though colour-blind to red, he believed he was more than usually sensitive to blue.

Dr. STONE and Mr. STANLEY referred to known cases of blindness to green as well as red.

Dr. LODGE asked if persons abnormally sensitive to red could see further down the spectrum.

Lord RAYLEIGH believed they could see the spectrum brighter near its limits, at all events.

Mr. GLAZEBROOK briefly described a modification of Lord Rayleigh's apparatus, by which the distance on the spectrum which anyone can see could be measured.

Mr. C. V. BOYS read a paper on “A Phenomenon of Electromagnetic Induction.” Between the poles of an electromagnet a small disc of copper is hung by a bifilar suspension. If the magnetic field is uniform, and the disc at an angle to the lines of force, then on making the magnet it is jerked parallel with the lines of force. If it is a changing field, and the disc perpendicular to the lines of force, it is repelled on making the magnet, and attracted on breaking by the nearest pole. This phenomenon, which was observed by Faraday, was shown by Mr. Boys to be useful for determining the intensity of a magnetic field by measuring the throw of the disc on magnetising and demagnetising. It might also be employed to measure the resistance of bodies in the form of plates, from their diameter, moment of inertia, and observed throw. Any structural difference of resistance in different directions in the body might be determined by its means. Mr. Boys illustrated his remarks with curves of results obtained by experiment.

Lord RAYLEIGH considered that the effect of self-induction on the result was not likely to be serious.

Mr. J. HOPPS read a paper “On the Alteration of Electrical Resistance in Metal Wires produced by Coiling and Uncoiling.” His experiments were made with an inclined plane, the angle of which could be varied, and a car carrying bobbins, which was drawn up or let down the plane by the wires experimented on. It appeared that coiling and uncoiling tends to produce hardness in a wire. Coiling produces an increase of resistance, and uncoiling a decrease in the resistance of a wire.

Mr. R. T. GLAZEBROOK, M.A., F.R.S., read a paper “On the Determination in Absolute Measure of the Electrical Capacity of a Condenser, and on a Method of Finding by Electrical Observations the Period of a Tuning-Fork.” The paper described experiments conducted according to a method given in Maxwell (Vol. ii., § 776), for measuring the capacity of a condenser. Mr. J. J. Thomson showed (*Phil. Trans.*, 1883, Part iii.) that Maxwell's formula is only approximate, and gave the correct formula, which was used in the author's experiments. In these tuning-forks were used of frequencies approximately 16,

32, 64, and 128 to a second, the frequencies being determined by careful comparison with the clock by Lord Rayleigh's method, and the corresponding values found for the capacity were 0.333, 0.334, 0.3335, and 0.3337 m.f. The mean is 0.3337 m.f., and the experiments do not show any variation in the capacity, as the time of charging varies from $\frac{1}{4}$ th to $\frac{1}{16}$ th of a second. The condenser was furnished by Messrs. Latimer Clark, Muirhead, and Co. The method also gives a ready and accurate means of determining the pitch of a tuning-fork, for if the capacity of the condenser used is known the frequency (n) can be determined. The author has used the method successfully for this purpose.

Lord RAYLEIGH objected to mercury contacts in such experiments, and Dr. STONE said he had found iron and mercury contacts good.

Prof. HERBERT MCLEOD exhibited a Sunshine Recorder made by placing a water lens in front of an old camera box. Sensitised paper is placed in the bottom of the box, so that the focussed ray strikes on it, and as the sun moves traces a curved line or band on the paper. Several of these records were shown to the meeting.

The Society adjourned till November 28th.

ROYAL INSTITUTION OF GREAT BRITAIN.

General Meeting, July 7, 1884.

The Hon. Sir WM. R. GROVE, M.A., D.C.L., F.R.S.,
Manager and Vice-President, in the Chair.

Mr. J. Wimmshurst was elected a Member of the Royal Institution.

Two Candidates for membership were proposed for election.

The Managers at their meeting appointed Professor Arthur Gamgee, M.D., F.R.S., Fullerton Professor of Physiology for three years.

The presents received since the last meeting were laid on the table and the thanks of the Members returned for the same.

ROYAL DUBLIN SOCIETY.

At the June Monthly Meeting of this Society, held at the Society House, Kildare-street, the following papers were read in the Natural Science Section:—

"On the Possibility of the Formation of Coloured Solar and Lunar Halos, Produced by the Suspension of Volcanic Dust," by the Rev. Dr. HAUGHTON, F.R.S. This paper was in connection with the eruption of Krakatoa, in August, 1883.

Prof. C. R. TICHBORNE read a paper on "An Argenterous Galenetic-Blende found in Ovoca." The author wished to bring before the notice of the Society a mineral of which very little was known. It had been found in the east district of Ovoca, and was called there "Kilmacooite," from the name of the place where it was found. There can be little doubt that this mineral was identical with one which had been discovered in the Island of Anglesea. No other locality seemed to be known where it had been procured. In Anglesea it was called "Blue Stone."

An analysis performed by the author gave the following results:—

*Silver	0.024
Zinc	25.27
Lead	25.18
Iron	5.51
Manganese	trace
Antimony	0.21
Arsenic	0.08
Copper	2.50

* Equal to nearly 8 ozs. (troy) per ton.

Alumina	0.60
Magnesium, with traces of calcium	0.02
Sulphur	23.71
Silica, &c.	16.896

This mineral may be said, therefore, to consist of—

Sulphide of zinc	37.68
Sulphide of lead	29.07
Sulphide of silver	0.0275

The amount of pyrites varies. The substance does not belong to the mineral proper. It was examined in the spectroscopic for the rarer metals, but with a negative result.

The specific gravity is 4.73, and it is harder than blende or galena. The ore is very hard to break, and blasting has to be resorted to to raise it. About 1000 tons can be sighted. It is very homogeneous, forming a close-grained saccharoid mass, but which, from the author's experiments, seems to be an intimate mechanical mixture of microscopic crystals of blende and galena.

Its value consists in the very considerable amount of silver present. In the year 1865 Ireland was supplying about 2½ per cent of the silver raised in the United Kingdom, or 14,000 ounces per annum. It has sadly fallen off since then; therefore the find of this ore should be of some importance.

Mr. S. H. KINAHAN read "Some Notes upon the Recent Earthquake in Essex."

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcvi., No. 22, June 2, 1884.

Experimental Researches on the Influence of a Current of Purified Air at Ordinary Temperatures, or at 65°, upon the Fermentation of Saccharine Juices. —M. P. Calliburgès.—The author passed a current of air, freed from all suspended corpuscles, through 30 litres of grape-juice. The fermented liquid obtained, when examined after the lapse of thirteen months, was perfectly clear and free from cotton-like sediment. It contained 18.40 per cent of alcohol by volume.

An Attempt at a Mercurial Galvanometer.—J. Carpentier.—As far back as January, 1881, the author constructed an apparatus similar to that recently presented to the Academy by M. Lippmann, and experimented with it before witnesses.

Spitting of Gold and Silver in the Vapour of Phosphorus.—P. Hautefeuille and A. Perrey.—Whilst endeavouring to reproduce the curious silver phosphides described by Pelletier in 1792, the authors have been led to study the action of the vapour of phosphorus upon silver and upon gold. In this action there are produced phenomena of the same order as those described by Dumas. Observations have also been made which show more precisely the influence of the change of the physical state of bodies upon the statics of chemical combinations. At the temperature at which it softens silver rapidly absorbs oxygen: at a heat a little below its melting-point it readily absorbs the vapour of phosphorus, at a tension below the atmospheric pressure. Phosphorus renders silver more fusible. At a heat equal to its softening-point, and in a current of an inert gas, silver retains a large proportion of the oxygen absorbed; at the temperature at which the phosphorised silver remains melted it retains a large proportion of the phosphorus absorbed. On solidifying in the air silver abandons a portion of the oxygen taken up: on solidifying in the vapour of phos-

phorus it abandons the whole of the phosphorus. Gold absorbs the vapour of phosphorus at a temperature below its melting-point, retains it at a higher temperature, and spits on cooling. Phosphuretted gold loses its phosphorus at a temperature of 400° to 500° . Most other metals form permanent compounds with phosphorus.

Action of Mercury Sulphide on Potassium Sulphide.—A. Ditte.—This paper does not admit of useful abstraction.

Combination of Gold Chlorides with Phosphorus Chlorides.—L. Lindet.—The author has obtained a double protochloride of gold and phosphorus ($\text{Au}_2\text{ClPCl}_3$) and a corresponding per-compound, $\text{Au}_2\text{Cl}_3\text{PCl}_5$.

No. 23, June 9, 1884.

Existence of Manganese in Animals and Plants, and its Part in Animal Life.—E. Maumené.—Wheat contains from $\frac{1}{1000}$ th to $\frac{1}{100}$ th of its weight of metallic manganese. The bulk of the metal exists as the salt of an organic acid. The bran and the starch do not contain any. Rye, rice, and barley contain much manganese. It is also found in potatoes, beets, carrots, lentils, peas, lettuce, parsley, and—in infinitely small traces—in apples and grapes, though the leaves of the vine are tolerably rich in manganese. It is found in a larger proportion in cocoa, in a still larger in coffee, and most of all in tea. In the 50 to 60 grms. of ash obtained from 1 kilo. of tea are found 5 grms. of metallic manganese. On the other hand, manganese is not found in oranges, lemons, garlic, onions, &c. Human blood does not always contain it. Very small traces are found in the milk, the urine, the bones, and the hair. It is almost entirely eliminated in the solid excrements, whence it must be regarded as a mere accidental constituent of the animal system, not essential to life. Medical science must renounce the use of manganese as a substitute for iron. Tea, coffee, and tobacco require an abundance of manganese in the soil.

New Dynamo-electric Machine.—A. Damoiseau and G. Petitpont.—The machine devised by the authors is described as producing about double the work performed by existing machines.

Permeability of Silver for Oxygen Gas.—L. Troost.—The author proves that pure oxygen and the oxygen of atmospheric air are capable of passing through the sides of a heated tube of silver, whilst a mere trace of nitrogen penetrated the metal. Carbonic monoxide and dinoxide also permeate silver, though more slowly than does oxygen. The author suggests that pure oxygen may be obtained from the air on this principle. The temperature of the metal must not exceed 800° .

Action of Copper Sulphide upon Manganese Sulphide.—A. Ditte.—A thermo-chemical paper, not capable of useful abstraction.

Solubility of certain Halogenous Salts.—A. Etard.—The author has examined the solubility of sodium bromide and iodide, potassium chloride, bromide, and iodide, and calcium chloride of different temperatures.

Certain Colloidal Substances.—E. Grimaux.—Schweitzer's solution when submitted to dialysis leaves within the porous vessel a body of a colloidal character, which is decomposed by the addition of distilled water, depositing flakes of cupric hydrate. Very minute quantities of magnesium, calcium, aluminium, and copper sulphates, and of very dilute acetic acid precipitate this solution; sodium chloride and potassium sulphate are without action. Copper hydrate is also precipitated by a temperature of 40° to 50° , but the precipitate re-dissolves slowly on cooling. The solution of cellulose in Schweitzer's reagent after three or four days dialysis loses most of its colour. All the ammoniacal copper nitrite and the excess of water pass into the exterior liquid. The remaining solution of cellulose is less coloured; on the addition of water it gives a gelatinous precipitate which re-dissolves in a few drops of ammonia, forming a

perfectly transparent liquid of little colour. The author has also examined the condensed pyruvic ureids, the amido-aspartic colloid, and soluble silica, which he obtains without dialysis by saponifying the methyl silicate of Friedel and Crafts with water.

Synthesis of Pyridic Hydrides.—Oechsner de Coninck.—The author, setting out from β -lutidine and β -collidine, has obtained a small quantity of a dihydride-collidine. By the action of sodium and absolute alcohol upon β -lutidine and β -collidine he has obtained the hexa-hydride of β -lutidine, as a colourless, mobile liquid, differing little in appearance from the pyridic alkaloids.

On Tribenzoyl-mesitylene.—E. Louise.—The author has obtained a new acetone, symmetrical tribenzoyl-trimethyl-benzene. It melts at 215° – 216° . It is almost insoluble in cold alcohol, dissolves more readily in boiling alcohol, ether, and benzol, but its best solvent is a mixture of chloroform and acetone.

Crystalline Colchicine.—A. Houdès.—Colchicine appears in the form of prisms grouped in colourless mamellæ; it is intensely bitter, turns litmus-paper slightly blue, is sparingly soluble in water, glycerin and ether, but readily in alcohol, benzol, and chloroform. It combines with certain organic acids, but is decomposed by such as act more energetically, and also by the mineral acids. The author proposes to examine how this precipitate differs from that of Oberlin.

Losses of Nitrogen during the Fermentation of Dung.—H. Joulie.—From a series of careful experiments the author finds that a prolonged fermentation of dung involves a loss of nitrogen, which reached 20 per cent in his trial-heaps, but which may be higher in actual practice. This loss is entirely due to the decomposition or the volatilisation of the ammonia contained in the urine, and bears consequently upon the most active and the most easily assimilable portion of the dung heaps. The addition of calcium phosphate does not perceptibly modify the extent of the loss. That calcium carbonate and sulphate, both, largely increase the loss of ammoniacal nitrogen and lessen its fixation upon the organic matters.

NEW CARBON BATH FOR THE EGGERTZ COLOUR TEST.

By J. OLIVER ARNOLD, F.C.S.

THE Eggertz colour test for estimating carbon in steel is perhaps used more extensively commercially than any other analytical process. This is particularly the case in Bessemer steel works, where every blow is tested to ascertain its percentage of carbon; the number of estimations thus amounts even in a small works to 25 daily.

In carrying out the analytical process, which is too well known to require description, it is of course necessary to preserve the identity of each blow number, and this is effected by dissolving the steels in a square shallow copper water-bath, provided with a lid perforated with holes in which the tubes are inserted in a slanting position, the first hole indicating the starting-point of the day's blows.

This form of bath is objectionable from several points of view:—

- It soon gets dirty from the fumes of the laboratory, evaporation of water, and the action of the Bunsen flame.
- The slanting position of the tubes often causes the solution to dry on their sides.
- The water in the bath is out of sight, and may easily evaporate to dryness without notice, when the whole batch of carbons would be ruined.
- The identity of the tubes may be readily lost by a slip of memory as to how they were originally placed.
- The bath frequently leaks, and has to be repaired.

The author has consequently designed a bath which two years' constant use has proved to have none of the disadvantages connected with the old form of bath.

The bath consists of a cylinder of glass 5 ins. high by 5 ins. in diameter, closed at one end to contain the water;

this is heated on an iron plate or sand-bath nearly to boiling-point (90° — 95°). On the top is a perforated cover of glazed white earthenware; this cover contains 17 holes, numbered 1 to 15 in burnt-in black figures, and the other two holes are marked S for the standard steels.

The tubes containing the steels and nitric acid are suspended in the water to the proper depth by slipping on the tube a rather tightly-fitting cylinder of india-rubber $\frac{3}{4}$ in. long; this india-rubber serves the double purpose of keeping the ends of the tubes off the bottom of the bath, bumping thus being avoided, and of preventing the bobbing up of the tubes by floatation (see figure).

The apparatus being of glass and glazed earthenware enables it to be washed perfectly clean every day. The tubes are suspended vertically in the water to any desired depth.

The clear numbering enables the selection of any given blow about which "a hastener" has been received without chance of error, and the progress of the solution of the steels in the tubes can be watched without removing them.

Except from mechanical breakage the apparatus is practically indestructible. Wooden covers were tried at first, but were found to be dirty, and to crack in a few weeks from the effect of steaming. In cases where the daily carbons exceed 15, a second and third bath may be employed, the numbering following on, or one large bath could be made; this, however, might prove inconveniently large.

In cases where only a few odd carbons are required a smaller bath perforated for 6 steels and a standard would suffice. The baths used by the author were made to his instructions by Messrs. Cubley and Preston, of Sheffield.

Sheffield, July 11, 1884.

ON VITREOUS AND ORDINARY AMORPHOUS SILICA.

By DAVID LINDO.

It is known that when crystallised silica is fused, it forms a vitreous mass which can be drawn into fine threads; on cooling, it remains transparent, but is no longer crystalline.

In "Watts's Dictionary," 3rd Supplement, experiments made by Monier and Ullik are recorded, which seem to have resulted in the conversion of ordinary gelatinous hydrate of silica into a transparent gelatinous variety. This, on drying and heating, may have resulted in anhydrous vitreous silica, though the behaviour of the bodies described does not quite coincide with this view.

It is said that evaporating an aqueous solution of silica as obtained by Graham's process of dialysis results in the formation of a transparent jelly which dries to a vitreous mass. The existence of anhydrous vitreous silica as a distinct allotropic modification of this body, and the methods of obtaining it, seem, however, to have occupied little attention, the chief aim having been to obtain definite hydrates of silica by drying the jellies at various temperatures.

According to text-books, silica, as obtained in the analysis of silicates, has the aspect of a white earthy powder. If the contents of the dish are stirred when crusts begin to form, and the stirring continued until the mass is dry, the silica will always present the appearance described above to the unaided eye; under the microscope with reflected light it will appear either:—

1st. In the form of amorphous, dead white masses, which in very thin layers are slightly translucent—ordinary amorphous silica.

2nd. As a mass entirely composed of perfectly trans-

parent brilliant particles with sharp edges and angles—vitreous silica.

3rd. As a mixture of these two varieties.

If the melt has been acted on by strong acid without dissolving it first in water, or if very little water has been used to effect solution, the silica will be precipitated in the ordinary gelatinous form, and on evaporating to dryness, with or without stirring, the silica obtained will be ordinary amorphous.

If the melt has been dissolved in a considerable quantity of water, so that on adding the strong acid more of the silica is precipitated, on evaporating to dryness, with or without stirring, all the silica will be obtained in the vitreous form.

If the melt has been dissolved in a moderate quantity of water, so that on adding the acid part of the silica is precipitated and a portion held in solution, the silica on evaporating to dryness will be found partly vitreous and partly ordinary amorphous.

If an acid solution of the melt containing all the silica dissolved is evaporated to dryness without stirring, the silica will form a transparent jelly, and on continuing the heat to dryness, the vitreous silica will be obtained in transparent particles large enough to be visible as such to the unaided eye, having the appearance when washed and dried of coarsely powdered glass. It contains water, which can only be expelled completely by strong ignition.

If a small quantity of ordinary amorphous silica is mixed with a drop of water and examined by transmitted light with the microscope, it will be found to consist of flakes which appear granular and have a yellowish brown colour. Thin layers, without the addition of water, present the same appearance. I have observed this colour with all samples examined, including some prepared by myself with great care, and which I have reason to believe were quite pure.

Vitreous silica examined in the same way appears colourless. Ignited intensely over the blast it appears unaltered, and samples so ignited retain their transparency after being exposed to the air for several weeks. Some samples retained their hygroscopic property in a marked degree after several intense ignitions each of five minutes duration; other samples lost this property completely after the first ignition, gaining nothing in weight though kept under a bell-glass with a vessel of water for several days. I failed to detect impurity by testing, or any difference in appearance by the microscope in those samples that lost their hygroscopic property so readily; yet to the presence of traces of foreign matter I am still inclined to attribute this peculiarity which the samples retained when again ignited.

Vitreous silica formed in the midst of various salts would be more likely to retain traces of impurity than the ordinary amorphous kind. I have seldom succeeded in depriving a sample of the latter of its hygroscopic property by a single ignition over the blast; that is, a sample obtained from the decomposition of water glass.

As regards the very light flaky amorphous silica obtained by passing fluoride of silicon into water, the case may be different. A sample of this tried absorbed no moisture after five minutes' ignition over the blast. On examination under the microscope it was found converted for the most part into transparent particles which may have been crystalline. I have not succeeded by several ignitions over the blast in producing this change in ordinary amorphous silica prepared from water-glass, though probably more intense heat would have done it. Since Jenzsch has shown amorphous silica of sp. gr. 2.6 exists; increase of density is no proof that the amorphous has passed into the crystalline form.

The Specific Weight of Paraffin.—E. Sauerlandt.—The specific gravity of the oil ranges from 0.869 to 0.943.—*Zeit. f. Anal. Chem.*

THE ACTION OF THE AIR UPON SOLUTIONS OF TANNIN AND ON THE DETERMINATION OF TANNINS.

By M. ANTONY GUYARD.

It is stated in all the text-books that dilute solutions of tannin absorb oxygen from the air, becoming transformed into gallic acid and giving off carbonic acid. We read also that these same solutions are metamorphosed with the same phenomena under the double influence of the contact of air and of ferments, and lastly that the gallic fermentation is effected without the participation of air.

This last assertion seems to be the only true one in conformity with the general laws of fermentation.

The author, in a series of very precise experiments to which unlimited time was devoted, has succeeded in showing that the oxygen of the air has no action upon solutions of tannin.

The apparatus employed consisted of a U-tube with bulbs containing 10 c.c. of a solution of 10 grms. of pure tannin per litre of water.

This tube was connected on one side with a tube filled with pumice moistened with sulphuric acid, and on the other with a Liebig's bulb tube containing a solution of potassa and communicating with three tubes containing solid caustic potassa and calcium chloride. This system of tubes was intended to be weighed, and was arranged in such a manner that neither moisture nor carbonic acid could escape.

This system was connected on the one hand with tubes 1 metre in length and 0.01 metre in diameter filled with solid potassa, calcium chloride, and soda lime, adapted to a large aspirator, and on the other to a similar series of tubes filled with cotton-wool, solid potassa, calcium chloride, and soda lime, communicating with a washing bottle containing a solution of potassa, and intended to deprive it of every trace of water and of carbonic acid.

Whatever was the time employed in these experiments, day and night, and whatever was the volume of air passed into the tannic solution, there was never observed either loss or gain in the system of tubes when weighed; besides it was always impossible to detect the least alteration of the tannic solution or even a sign of gallic transformation.

Solutions of only half the above strength and others two or three times stronger showed the same absolute indifference.

The oxygen of the air, therefore, exerts no action upon dilute solutions of tannin, and the conversion into gallic acid is effected only under the action of atmospheric dust or of ferments, possibly with, but more probably without, the concurrence of oxygen.

In presence of an alkali, purified air acts, on the contrary, with great energy. If we weigh, we may even determine the tannin as M. Terreil does in his apparatus, but the procedure of this chemist is applicable only in limited atmosphere.

By means of the apparatus described above and in presence of an unlimited quantity of purified air, we can cause the alkaline solution of tannin to absorb as much oxygen as we wish, and induce a true combustion of such a nature that the process of M. Terreil, thus modified, is not capable of application to the determination of tannin.

A very useful reagent in the examination of tannins is lead acetate, acidulated with acetic acid. Lead tannate is insoluble in this reagent, whilst lead gallate is perfectly soluble. As gallic acid frequently accompanies tannin, these two bodies may thus be advantageously separated. On afterwards eliminating the lead by means of sulphuric acid and filtering, we have on the one hand a solution of pure tannin, and on the other a solution of gallic acid. Permanganate then serves for the titration of both of these acids when separated.—*Bulletin de la Soc. Chimique de Paris.*

ON THE REVERSION OF PHOSPHORIC ACID.

By THOMAS S. GLADDING, A.M.

(Concluded from page 18.)

FEW deposits of mineral phosphates exist free from oxide of iron and alumina. Vast stores of phosphoric acid, provided by nature for agricultural use, are represented by the following names of deposits:—

Commercial Names.*	Per cent contents Oxide Iron and Alumina.

* "Spon's Encyclopedia."

The last is now sold in the market, coloured a pronounced reddish tint by the oxide of iron it contains. It is evident that superphosphates made from such minerals are undervalued when the reverted phosphoric acid is estimated at a temperature of 40° C.; because, as is fair to conclude from experiments 2, 3, 4, and 5, the oxides, dissolved by the sulphuric acid, subsequently combine in the superphosphate with their equivalent of phosphoric acid, and the reverted phosphates of iron and alumina thus formed are *not all dissolved at the temperature of 40° C.*, whereas a slight increase in temperature dissolves them entirely, without unduly attacking the *insoluble* mineral, as is proven by my experiments on raw phosphates.

Millot* showed the result of contact of these oxides with soluble phosphates in a superphosphate, prepared from coprolites of the Ardennes. All the phosphoric acid was soluble in water when it was freshly made; but after two years 90 per cent of the phosphoric acid was insoluble in water. Millot washed this with hot water until all the gypsum was removed, and found the residue to be *free from lime*, and to consist of phosphate of iron.

The experiments of Dr. E. Heyden† show how very rapidly and completely reversion takes place under conditions more nearly similar to those when fertilisers are applied to fields. He filtered solutions containing an equal amount of phosphoric acid through four separate soils, 2500 c.c. of the solutions to each 1250 grms. of the soils.

	Amount reverted, Grms.	Amount soluble, Grms.	Per cent not reverted.
Soil A, surface soil (within 8 ins. of surface)	0'137	0'0057	4'16
Soil A, subsoil (between 8 ins. and 16 ins.)	0'147	0'0026	1'76
Soil B, surface soil (within 8 ins. of surface)	0'165	0'0053	3'21
Soil B, subsoil (between 8 ins. and 16 ins.)	0'153	0'0019	1'24

* *Comptes Rendus*, t. lxxviii., p. 1131; t. lxxxii., p. 522.
† *Annalen der Landwirtschaft*, Bd. 45, s. 189.

Dr. Stohmann* showed by his experiments that from a DILUTE solution of salts, filtered through a given mass of soil, a larger per cent was removed than from a more concentrated solution.

1000 lbs. of superphosphate, containing 100 lbs. of soluble phosphoric acid, sown upon an acre of land, represent a distribution of only 0'0005 grm. to every 26'7 grms. of soil, which is the weight of a mass 1 square inch in surface and 3 inches deep. In the experiments of Heyden, just quoted, 0'150 grm. of phosphoric acid were used to 1250 grms. of soil. Thus, in actual field practice, a solution is employed which, proportionately to the soil, is seven times more dilute than that which Heyden experimented with, and about 120 times more dilute than those used in my experiments.

It is probable, therefore, that the superphosphate becomes reverted *on the spot* where it is sown. If spread broadcast, it lies near the surface; if harrowed or ploughed under, it is brought a few inches deeper.

Liebig† analysed samples of soil at the Experimental Station, at Rothamsted, which had received dressings of superphosphates for twenty-two years in succession, and found three-fourths of the phosphoric acid in the first 9 inches of soil.

It is evident, from the *marked* and *positive* results of the foregoing experiments, that the only *equitable* method of valuation of the *reverted phosphoric acid* of a *superphosphate* must be based upon these facts.

I assert, therefore, that the true method of valuation is that which dissolves reverted phosphates of the same degree of solubility as those which are formed when a soluble superphosphate is mixed with the soil.

That the value of a superphosphate is determined, not alone by its condition in the storehouse, but by its condition within a reasonable time after being sown upon the fields.

That phosphates, soluble in water, become entirely reverted within a few hours, in some cases; in others to the extent of over 90 per cent. This has been shown by my experiments with artificial and natural soils, and there is no lack of testimony by most eminent authorities in verification of these results.

That a superphosphate which was valued by a method in which the temperature was 40° C., if re-analysed by the same temperature, after several days' contact with the soil, after allowing for the amount previously in the soil, would show an apparent loss of 20 to 30 per cent available phosphoric acid, as has actually been shown by experiments 1, 2, and 3.

The following method of analysis of superphosphates recognises the principles demonstrated in this and the previous paper, and contains in addition a detailed manipulation which long experience has fully recommended to our confidence.

Method of Analysis of Superphosphates.

Preparation of Sample.—Pass the sample through a twelve-mesh sieve.‡

Moisture.—Dry 5 or 10 grms. at 100° C.

Total, Phosphoric Acid.—Weigh 2 grms., brush into a 200 c.c. flask, add 50 c.c. nitric acid;‡ boil gently for fifteen minutes, cool and fill to mark, mix, filter through a dry filter-paper into a dry receiver, take 50 c.c. of filtrate, place in a beaker, add 25 c.c. concentrated ammonia, then nitric acid to acidity. To the hot liquid add molybdic solution, let stand for one hour at about 65° C., filter, wash with nitrate of ammonia solution, dissolve on paper with hot ammonia solution, and wash with same. Run in magnesia mixture from a burette at the rate of one drop a second, stirring constantly. Let stand several

* *Henneberg's Jour. f. Landwirtschaft*, 1862. (Translation).

† *Roy. Ag. Soc. Jour.*, 1881.

‡ If too wet, a portion of the sample must be air-dried and then sifted, and an allowance made by calculation for loss of moisture.

§ Several cubic centimetres of HCl must be added here and in solution of the insoluble when working with difficulty soluble iron and alumina phosphates.

hours, filter, wash with ammonia solution, dry, ignite to whiteness, and weigh.

Soluble Phosphoric Acid.—Weigh 2 grms., rub up in a mortar with a soft rubber-tipped pestle,* digest in 25 c.c. of cold water; decant clear liquid on a filter-paper, filtering into a 200 c.c. flask; add 25 c.c. of water to residue, digest for several minutes, and again decant. Repeat for five or six times, and finally bring all upon the filter-paper and wash till flask is filled to the mark; mix, take 50 c.c., and estimate P_2O_5 as in the total.

Insoluble Phosphoric Acid.—Wash the residue upon the paper into a 200 c.c. flask, with 100 c.c. citrate solution, cork the flask with a common cork, digest in a water-bath at constant temperature of $65^\circ C.$ ($150^\circ F.$) for thirty minutes. Filter the warm solution quickly† and wash with cold water. Return paper and contents to the same 200 c.c. flask, add 50 c.c. nitric acid, boil for fifteen minutes, and estimate the P_2O_5 as in the total.‡

Reverted Phosphoric Acid.—The sum of the soluble and the insoluble phosphoric acid subtracted from the total will give the reverted.

Memoranda.

Citrate Solution.—This is a neutral solution of citrate of ammonia of sp. gr. 1.09.

Molybdic Solution.—This is made up as usual to contain 5 per cent. MoO_3 . Of this, use 60 c.c. to every 0.100 gm. P_2O_5 . (The filtrate should be tested by addition of phosphate of soda to see that an excess of precipitant is employed.)

Magnesia Mixture.—Made up as follows:—

110 grms.	crystallised magnesium chloride,
300 "	ammonium chloride,
400 "	concentrated ammonia,
1500 "	water.

Use 10 c.c. to every 0.100 gm. P_2O_5 .

(15 c.c. added to 100 c.c. ammonia solution must remain clear after standing twenty-four hours.)

Ammonia Solution.—This consists of 1 part strongest ammonia to 3 parts water.

Nitrate of Ammonia.—This is a 10 per cent nitrate of ammonia solution, slightly acidified with nitric acid.

Laboratory of Stillwell and Gladding,
New York.

A RECALCULATION

OF

THE ATOMIC WEIGHTS.¶

By FRANK WIGGLESWORTH CLARKE, S.B.,
Chief Chemist to the U.S. Geological Survey, Washington.

THE YTTRIUM GROUP.

The atomic weights of the metals in this group can only be said to have been determined approximately. Not only do great difficulties attend the purification of the material used for study and the separation of the earths from each other, but there have been and still are grave doubts as to the actual nature of some of the latter. The figures for scandium, yttrium, and ytterbium seem to be tolerably good; those for decipium, philippium, thulium, erbium,

and terbium are little more than estimates; for samarium we have no data whatever. All the atomic weights in this group are based upon analyses or syntheses of sulphates; and from analogy to the cerium metals all of these elements are regarded as forming sesquioxides.

SCANDIUM.

Cleve,* who was the first to make accurate experiments on the atomic weight of this metal, obtained the following data. 1.451 gm. of sulphate, ignited, gave 0.5293 gm. of Sc_2O_3 . 0.4479 gm. of Sc_2O_3 , converted into sulphate, yielded 1.2255 gm. of the latter, which, upon ignition, gave 0.4479 gm. of Sc_2O_3 . Hence, for the percentage of Sc_2O_3 in $Sc_2(SO_4)_3$ we have:—

36.478
36.556
36.556

Mean 36.530

Hence, if $SO_3 = 80$, $Sc = 45.044$.

Later and better results are those of Nilson,† who converted scandium oxide into the sulphate. I give in a third column the percentage of oxide in sulphate:—

0.3379 gm.	Sc_2O_3 gave 0.9343 gm.	$Sc_2(SO_4)_3$.	36.166 p.c.
0.3015	"	0.8330	36.194
0.2998	"	0.8257	36.187
0.3192	"	0.8823	36.178

Mean 36.181
± 0.004

Hence $Sc = 43.980 \pm 0.015$; or, if $O = 16$, then $Sc = 44.081$. If $SO_3 = 80$, then $Sc = 44.032$. These values are doubtless very nearly correct.

YTTRIUM.

For yttrium we need consider only the determinations of Popp, Delafontaine, Bahr and Bunsen, and Cleve.

Popp,‡ evidently worked with material not wholly free from earths of higher molecular weight than yttria. The yttrium sulphate was dehydrated at 200° ; the sulphuric acid was then estimated as barium sulphate; and after the excess of barium in the filtrate had been removed, the yttrium was thrown down as oxalate, and ignited to yield oxide. The following are the weights given by Popp:—

Sulphate.	$BaSO_4$.	Y_2O_3 .	H_2O .
1.1805 gm.	1.3145 gm.	0.4742 gm.	0.255 gm.
1.4295 "	1.593 "	0.5745 "	0.308 "
0.8455 "	0.9407 "	0.3392 "	0.1825 "
1.045 "	1.1635 "	0.4195 "	0.2258 "

Eliminating water, these figures give us for the percentages of Y_2O_3 in $Y_2(SO_4)_3$ the values in column A. In column B I put the quantities of Y_2O_3 proportional to 100 parts of $BaSO_4$:—

A.	B.
51.237	36.075
51.226	36.064
51.161	36.058
51.209	36.055

Mean 51.208 ± 0.011 Mean 36.063 ± 0.003

From B, $Yt = 101.880$. The values in A will be combined with similar data from other experimenters.

In 1865 Delafontaine|| published some results obtained from yttrium sulphate, the yttrium being thrown down as oxalate and weighed as oxide. In the fourth column I give the percentages of Y_2O_3 reckoned from the anhydrous sulphate:—

* *Comptes Rendus*, 89, 419.

† *Ibid.*, 91, 118.

‡ *Ann. Chem. Pharm.*, 131, 179.

|| *Ibid.*, 134, 108.

* This serves simply to break up lumps. No grinding or trituration of sample is made either in extraction of soluble or reverted phosphoric acid.

† This is best accomplished by use of a filter-pump, or by use of a plaited filter-paper. After the citrate solution has run through, the first paper may advantageously be rolled up, placed upon a second paper, and washed. The use of citrate solution for washing is discarded as being equivalent to a further treatment.

‡ The organic matter from the paper does not interfere in the least with the estimation. We have never found soluble silicic acid in any phosphate in sufficient quantity to give a precipitate and thus interfere with the above method.

|| Smithsonian Miscellaneous Collections. The Constants of Nature."

Sulphate.	Yt ₂ O ₃ .	H ₂ O.	Per cent Yt ₂ O ₃ .
0'9545 grms.	0'371 grm.	0'216 grm.	50'237
2'485 "	0'9585 "	0'565 "	49'922
2'153 "	0'827 "	0'4935 "	49'834
Mean 49'998 ± 0'081			

In another paper* Delafontaine gives the following percentages of Yt₂O₃ in dry sulphate. The mode of estimation was the same as before:—

48'23
48'09
48'37

Mean 48'23 ± 0'055

Bahr and Bunsen,† and likewise Cleve, adopted the method of converting dry yttrium oxide into anhydrous sulphate, and noting the gain in weight. Bahr and Bunsen give us the two following results. I add the usual percentage column:—

Yt ₂ O ₃ .	Yt ₂ (SO ₄) ₃ .	Per cent Yt ₂ O ₃ .
0'7266 grm.	1'4737 grm.	49'304
0'7856 "	1'5956 "	49'235

Mean 49'2695 ± 0'0233

Cleve's‡ results are published in a joint memoir by Cleve and Hoeglund, and are as follows:—

Yt ₂ O ₃ .	Yt ₂ (SO ₄) ₃ .	Per cent Yt ₂ O ₃ .
1'4060 grms.	2'8925 grms.	48'608
1'0930 "	2'2515 "	48'545
1'4540 "	2'9895 "	48'637
1'3285 "	2'7320 "	48'627
2'3500 "	4'8330 "	48'624
2'5780 "	5'3055 "	48'591

Mean 48'605 ± 0'0096

This series is unquestionably the best of all. From it, if SO₃=80, Yt=89'485.

Combining all these data, we have the subjoined general mean for the percentage of Yt₂O₃:—

Popp	51'208 ± 0'011
Delafontaine, 1st ..	49'998 0'081
" and ..	48'230 0'055
Bahr and Bunsen ..	49'2695 0'0233
Cleve	48'605 0'0096

General mean ..	49'637 0'0069
Rejecting Popp..	48'705 0'0087

From the general mean of all Yt = 97'616. From the mean, after excluding Popp's work, Yt=89'816 ± 0'067. Or, if O=16, Yt=90'023.

The following additional note has been communicated by the author:—

Since the foregoing re-calculation was first published a later and better series of experiments by Cleve|| has appeared. The method was the same as before, but the yttria used was wholly free from terbia. In the mean of twelve syntheses the percentage of yttria in the sulphate was found to be 48'503. Hence Yt=88'9, or, if O=16, Yt=89'104. If SO₃=80, Yt=89'02.

YTTERBIUM.

For ytterbium we have one very good set of determinations by Nilson.§ The oxide was converted into the sulphate after the usual manner:—

Yb ₂ O ₃ .	Yb ₂ (SO ₄) ₃ .	Per cent Yb ₂ O ₃ .
1'0063 grms.	1'6186 grms.	62'171
1'0139 "	1'6314 "	62'149
0'8509 "	1'3690 "	62'155
0'7371 "	1'1861 "	62'145
1'0005 "	1'6099 "	62'147
0'8090 "	1'3022 "	62'126
1'0059 "	1'6189 "	62'134

Mean 62'147 ± 0'0036

Hence Yb = 172'761 ± 0'038. If O = 16, then Yb = 173'158. If SO₃ = 80, Yb = 173'016. The true number cannot be far from 173.

ERBIUM.

Since the earth which was formerly regarded as the oxide of this metal is now known to be a mixture of two or three different oxides, the older determinations of its molecular weight have little more than historical interest. Nevertheless, the work done by several investigators may properly be cited, since it sheds some light upon certain important problems.

First, Delafontaine's* early investigations may be considered. A sulphate, regarded as erbium sulphate, gave the following data. An oxalate was thrown down from it, which, upon ignition, gave oxide. The percentages in the fourth column refer to the anhydrous sulphate. In the last experiment water was not estimated, and I assume for its water the mean percentage of the four preceding experiments:—

Sulphate.	Er ₂ O ₃ .	H ₂ O.	Per cent Er ₂ O ₃ .
0'827 grm.	0'353 grm.	0'177 grm.	54'308
1'0485 "	0'4475 "	0'226 "	54'407
0'803 "	0'3415 "	0'171 "	54'035
1'232 "	0'523 "	0'264 "	54'028
1'1505 "	0'495 "	—	54'760

Mean 54'308 ± 0'0915

Bahr and Bunsen† give a series of results, representing successive purifications of the earth which was studied. The final result, obtained by the conversion of oxide into sulphate, was as follows:—

0'7870 grm. oxide gave 1'2765 grms. sulphate.
61'653 per cent oxide.

Hoeglund,‡ following the method of Bahr and Bunsen, secured these results:—

Er ₂ O ₃ .	Er ₂ (SO ₄) ₃ .	Per cent Er ₂ O ₃ .
1'8760 grms.	3'0360 grms.	61'792
1'7990 "	2'9100 "	61'821
2'8410 "	4'5935 "	61'848
1'2850 "	2'0775 "	61'853
1'1300 "	1'827 "	61'850
0'8475 "	1'370 "	61'861

Mean, 61'8375 ± 0'0063

Humpidge and Burney|| give data as follows:—

Grms.	Grms.	Per cent.
1'9596 Er ₂ (SO ₄) ₃ gave	1'2147 Er ₂ O ₃	61'987
1'9011 "	1'1781 "	61'965

Mean, 61'976 ± 0'0074

Combining all four series we get the subjoined general mean for the percentage of oxide in sulphate. In Bahr and Bunsen's single experiment is given the probable error of one experiment in Hoeglund's series:—

* Arch. des Sci. Phys. et Nat., (2), 25, 119. 1866.

† Ann. Chem. Pharm., 137, 21. 1866.

‡ K. Svenska. Vet. Akad. Handlingar., Bd. 1, No. 8.

§ Bull. Soc. Chim., 39, 120. 1883.

|| Comptes Rendus, 91, 56. 1880.

* Ann. Chem. Pharm., 134, 108. 1865.

† Ibid., 137, 21. 1866.

‡ K. Svenska. Vet. Akad. Handlingar., Bd. 1, No. 6.

|| Journ. Chem. Society, February, 1879, p. 116.

Delafontaine	54.308 ± 0.0915
Bahr and Bunsen	61.653 ± 0.0178
Hoeglund	61.8375 ± 0.0063
Humpidge and Burney..	61.976 ± 0.0074

General mean	61.860 ± 0.0046
Rejecting the first ..	61.880 ± 0.0046

From the mean of all, $E_r = 170.379 \pm 0.082$; or, if $O = 16$, $E_r = 170.770$. From Bahr and Bunsen's determination, $E_r = 168.683$; and from Humpidge and Burney's highest, $E_r = 171.428$.

The foregoing data were all published before the composite nature of the supposed *erbia* was fully recognised. It will be seen, however, that three sets of results were fairly comparable, while Delafontaine evidently studied an earth widely different from that investigated by the others. Since the discovery of ytterbium, some light has been thrown on the matter. The old *erbia* is a mixture of at least three earths, to one of which, a rose-coloured body, the name of *erbia* is now restricted. For the atomic weight of the true erbium Cleve* gives three values, but without data concerning weighings or methods. Doubtless the oxide was converted into sulphate, and the calculations were made with $SO_3 = 80$:—

166.00
166.21
166.25

Mean, 166.153

With $SO_3 = 79.874$, this becomes 165.891, and if only $O = 16$, 166.273. These figures are undoubtedly the nearest yet reached to the true value. According to Thalén,† who reasons from spectroscopic evidence, the erbium of Hoeglund was largely ytterbium.

SAMARIUM.

For samarium we have data by Brauner,‡ and also by Cleve.|| Brauner, without giving details, says that the atomic weight of samarium may be put at 150.7. Cleve, by his usual method, converts the oxide into the sulphate, and finds the following percentages of Sm_2O_3 in $Sm_2(SO_4)_3$:—

59.180
59.175
59.201
59.190
59.190
59.183

Mean 59.1865

Hence $Sm = 149.801$; or, if $O = 16$, $Sm = 150.145$.

NOTICES OF BOOKS.

The Blowpipe in Chemistry, Mineralogy, and Geology. Containing all Known Methods of Anhydrous Analysis, many Working Examples, and Instructions for making Apparatus. By Lieut.-Colonel W. A. Ross, R.A. (retired), F.G.S., Member of the German Chemical Society, &c. With 120 Illustrations by the Author. London: Crosby Lockwood and Co.

THE improvements which Colonel Ross has effected in blowpipe analysis are not unknown to many of our readers, and are quietly finding their way into general practice both in England and on the Continent. The substance of this work has, it seems, already appeared in the *English Mechanic*. The author has especially

adapted his teachings to the intelligent artisans of our cities. He explains carefully the meaning of the technical terms which it is impossible to help employing, and gives instructions to the student how to construct his own apparatus, or, where this is impracticable, where to procure it at the least possible price. He evidently considers, as do the Germans, that Science is best acquired by investigation, and that the use of the blowpipe is one of the easiest and cheapest means of investigation.

With the principle here laid down we fully agree. Actual, careful, patient work is the only method by which any science can be truly acquired. The student who goes conscientiously through the course of experimentation here laid down will gain a better insight into organic chemistry and mineralogy than if he had "got up" any of the best text-books of the day, and passed any number of examinations in their contents.

The author's methods need not be here discussed, as they have been already considered with reference to his two former works, "Pyrology" and "Alphabetical Manual of Blowpipe Analysis." We read, however, with more surprise than satisfaction, the following footnote:—"I understand that 'The City and Guilds of London Institute' have quite recently, by the advice of an irresponsible chemist, cut out blowpipe analysis, as worthless, from their *Curriculum*. It is still untaught at the Royal School of Mines." Comment is here surely needless.

From another note we learn that "Berzelius only compiled or edited the first part of the work on the blowpipe which bears his name, the real author being undoubtedly his teacher, Dr. Gahn. It is now well known, also, that Gahn was the real author of the work on the blowpipe attributed to and appropriated by Bergmann."

Experimental Proofs of Chemical Theory for Beginners.

By W. RAMSAY, Ph.D., Professor of Chemistry in University College, Bristol. London: Macmillan and Co.

It is not easy to give in brief space a correct idea of the nature and object of this little book. The author in it describes a course of experiments forming the preliminary work of all students beginning chemistry in his laboratory. The course consists of the measurement of heat, weighing, experiments on the relation of the volume of the gases to temperature and pressure; the weight of a litre of air; the analysis of air; the determination of the specific gravities of oxygen and of nitrogen, of hydrogen chloride, of watery vapour, and of ammonia.

The chapter on atoms and molecules, in which an account is given of the theories of Dalton, Gay-Lussac, and Avogadro, is ably written. Here, of course, the student encounters much that is not experimentally demonstrable, and of course has to be told that "it is believed." The hypothesis of Sir William Thomson on the shape of atoms and molecules is dismissed as "of little moment to the chemist, who has to deal with changes and with quantities rather than with forms."

The eighth and ninth chapters discuss respectively quantivalence and the equivalents of the metals. Here certain experiments on the determination of equivalents are introduced.

The tenth chapter introduces the student to the determination of specific heats, and their employment in ascertaining the atomic weights. We next come to the determination of atomic weights by the aid of replacement. The last chapter discusses the periodic law, with due acknowledgment of the priority of Mr. Newlands.

As to the practical advantages of teaching chemistry, or chemico-physics, on Mr. Ramsay's plan, it might be rash to decide without actual observation. The author thinks that "it is easier to start a number of students in this manner than in the usual course preliminary to qualitative analysis." He also states that "after such a course as this it is easy for a student of ordinary intelligence to acquire a knowledge of qualitative analysis, and it is noteworthy that the detection of unknown substances

* *Comptes Rendus*, 91, 382.

† *Poggend. Beiblätter*, 5, 122, 1881.

‡ *Journ. Chem. Soc.*, June, 1883.

|| *Comptes Rendus*, 97, 94.

is accomplished much more rapidly and accurately after such preliminary training."

Text-Book of Descriptive Mineralogy. By HILARY BAUERMANN, F.G.S. London: Longmans and Co.

WE have here a descriptive treatise on mineralogy, though only the more important species, scientifically or economically speaking, are described in detail.

The subject of nomenclature is considered at some length. The author remarks that "names founded on physical or chemical peculiarities are, as a rule, among the most uncouth and inconvenient, and as they are not unfrequently founded upon false analogies, some trivial character, or one that may be common to many other minerals being selected as a specific distinction, a knowledge of their etymology is not always of advantage as an aid to the memory." Mr. Bauermann holds, very judiciously, that in the case of minerals worked as ores the ordinary commercial names should always be used where possible. "Thus for all purposes copper-pyrites, tinstone, and zinc-blende are preferable to chalcopyrite, cassiterite, and sphalerite."

The author's classification is substantially the same as that followed in the second edition of Rammelsberg's work. The statements of localities are generally on a level with the most recent discoveries. The only mineral of commercial importance which we miss is bauxite, which certainly does not figure in the index. The illustrations, being printed from the blocks used in Brooke and Miller's work, are excellent, and contribute greatly to the value of the work.

Corpulence and its Treatment on Physiological Principles.

By Dr. W. EBSTEIN. Translated from the sixth German edition, by Prof. A. H. KEANE, B.A. London: H. Grevel.

SOME time has passed since Banting's pamphlet on the reduction of corpulence moved the comic and the literary papers to laughter. Since then we have had several attempts in the same direction, and a proprietary medicine has even flourished for a time under the title of "anti-fat." Dr. Ebstein, in the treatise before us, aims at combatting the tendency to corpulence in a more rational manner. He distinguishes in the outset between corpulence and obesity, the former state, though inconvenient, being still not incompatible with health, and even with activity, whilst obesity is a formal disease, almost always accompanied by anæmia, and very frequently by gout and diabetes. It is somewhat humiliating to find how observers—professional as well as lay—differ, both as to the causes and the consequences of so common a phenomenon. Some trace corpulence to excess in eating and drinking, or to an injudicious selection of food; others lay the blame on inactivity, on the deficiency of light, on a damp atmosphere, on heredity, &c. There is a similar difference of opinion as to the effects of corpulence upon mental activity. Cantani is quoted as representing the influence of fatness on mental energy as highly injurious, whilst Grissoles and Albert insist that the corpulent have on unsubstantial grounds been taxed with incapacity for intellectual exertion, and J. P. Frank observes that there is no lack of "intelligent fat paunches."

The author raises the question whether corpulence is due simply to fat formed from the food consumed or to self-made fat. He doubts the conclusions drawn by Lebedeff from his dietetic experiments upon dogs, which, receiving linseed oil in their food, deposited in their bodies not ordinary dog-fat, but a substance closely resembling linseed oil. There can, it would seem, be no doubt that stall-fed beasts deposit more fat than they consume as such. Hence the excess, at all events, must be formed either from the albuminous compounds or from the carbohydrates. Recent experimentalists find that no fat is

formed directly from the carbohydrates, though they cause fat to be separated and deposited from the albumen. The carbohydrates, namely, protect a portion of the albumen from total decomposition, what thus escapes being the fat, so rich in carbon. It appears that a too plentiful consumption of albumen favours the development of corpulence, even when not accompanied by an excessive use of the carbohydrates.

The author divides the possible methods of treatment for corpulence into two great classes, the medical and the dietetic, the latter being subdivided into such as aim at effecting the purpose by a mere change of diet, and such as propose a general alteration in the mode of life.

The strictly medical system is abandoned as at once dangerous and useless. Violent purgatives, diuretics, iodine, caustic potassa, and even vinegar, are no longer prescribed by physicians, though the latter is still employed by silly young ladies who are desirous of looking "delicate."

The change of diet recommended by the author is to be so regulated that no abnormal cravings for food may be experienced, and, though there is a diminution of weight and bulk, no decrease of the power for work must be perceptible.

A striking point in his suggestions is that he does not, like Banting and Cantani, absolutely prescribe the consumption of fats. On the contrary, he reminds us of a fact known already to Hippocrates, that fats reduce the craving for food and for an excess of drink. He excludes, however, the carbohydrates,—sugar, sweets of every kind, potatoes in every form. The daily consumption of bread is limited to 3 to 3½ ounces, and the vegetables allowed are the cabbage tribe, the legumens, spinach, and asparagus.

Although corpulence is less frequently met with in England than was formerly the case,—owing doubtless to the fact that an easy mind becomes more and more a rarity,—this work will be extremely useful not merely to the medical profession, but to those of the general public who have room to dread obesity.

The Extra Pharmacopœia of Unofficial Drugs and Chemical and Pharmaceutical Preparations. By W. MARTINDALE, F.C.S. With References to their Use abstracted from the Medical Journals, and a Therapeutic Index of Diseases and Symptoms. By W. WYNN WESTCOTT, M.B. Lond., Deputy Coroner for Central Middlesex. Third Edition. London: H. K. Lewis.

THE first edition of this little work appeared a year ago. Hence the fact of a third impression having already been found necessary proves that it must meet some distinctly felt want. In fact the rapidity of discovery, in pharmacy no less than in the other applications of chemistry, tends to render pharmacopœias more or less obsolete or imperfect. Hence the necessity for a work like the one before us.

We find here accordingly an alphabetical list of newly introduced remedies, with remarks on their physiological action. Then follows a table of histological preparations used for staining, hardening, and mounting microscope objects. Next comes the index, with a table of doses; and finally a therapeutic index of diseases and symptoms, the remedies for each being arranged alphabetically.

From the form and size of the book we should judge that it is intended as a pocket companion.

The Behaviour of Certain Amidic Acids with Lyes of Potassa and Baryta, and with Magnesia.—E. Bosshard.—The author proves experimentally that asparagine, leucine, and tyrosine, glutamic acid, &c., are at all attacked by dilute alkalis and alkaline earths, the action is so trifling as not to come in account in ordinary analytical operations.—*Zeit. f. Anal. Chem.*

CORRESPONDENCE.

MEMORIAL TO DUMAS.

To the Editor of the Chemical News.

SIR,—I have received from M. Pasteur, President of the Committee, a letter informing me that it is proposed to erect a statue to the memory of Dumas, at Alais, his native town. The name of Dumas is so prominent in the history of our science that no words of mine are needed in support of such a proposition, and I merely express the hope that many English chemists will be willing to contribute to this memorial. Subscriptions will be received by the Secretaries of the Chemical Society, Burlington House, Piccadilly.—I am, &c.,

W. H. PERKIN.

HEAT OF FORMATION OF ORGANIC COMPOUNDS.

To the Editor of the Chemical News.

SIR,—As I am a warm admirer of Prof. Ramsay's experimental work, I may perhaps be permitted to point out the cause of the apparently anomalous results at which he has arrived in calculating the heats of formation of organic compounds. It is a very simple one: the heat of formation of water, $(H_2O) = 68,360$, happens to be equal to the heat of formation of carbonic acid from carbonic oxide, $(CO_2O) = 68,370$.

Let us examine Dr. Ramsay's calculations:—

The heat of formation of formic acid, *not from its elements*, but from carbonic oxide and water (CO, H_2O) , is found to be $-27,820$.

The heat of formation of the same acid *from hydrogen and carbonic acid* is found to be $-27,830$.

That two such different reactions should give out the same amount of heat is no doubt startling; but if E = heat of formation of formic acid from its elements, the first number should be—

$$E - (C, O) - (H_2, O).$$

and the second—

$$E - (C, O) - (CO, O).$$

And since $(CO, O) = (H_2, O)$ these must be equal.

When, however, acetic acid is formed (1) from carbon and water, (2) from carbonic oxide and hydrogen, the numbers are found by Dr. Ramsay, as one would expect, to be different.

If we examine calculation No. 3, and compare it with No. 2, we shall see that it differs only in this, that the heat of formation of 36 grms. of water has been subtracted, and that of 56 grms. of carbonic oxide from "gaseous carbon" put in its place. Now since the latter number is assumed to be equal to the heat of combustion of 56 grms. carbonic oxide, and this is, as we have seen, equal to the heat of formation of 36 grms. of water, it is not altogether surprising that calculations 2 and 3 should give results differing by exactly 20 units.

It is therefore evident that Dr. Ramsay has not as yet found any data which will enable us to say what the heat of volatilisation of carbon really is.—I am, &c.,

H. FORSTER MORLEY.

University College, London.

COMMERCIAL ANALYSES.

To the Editor of the Chemical News.

SIR,—May I ask some reader practically versed in the analysis of artificial manures if he can throw any light upon the following matter?

A sample of bone manure the exact value of which it was important to determine was carefully taken, thoroughly

mixed, divided into three parts, and sent to three eminent London analysts. Their several analyses as to phosphates and ammonia were as follows:—

Dr. A. ..	Soluble phosphates ..	21.20
	Insoluble phosphates ..	4.10
	Ammonia	undetd.
Dr. B. ..	Soluble phosphates ..	24.17
	Insoluble phosphates ..	5.73
	Ammonia	1.69
Dr. C. ..	Soluble phosphates ..	24.81
	Insoluble phosphates ..	5.52
	Retrograde phosphates ..	1.83

Is there any way of accounting for the large discrepancy of the results?—I am, &c.,

F.C.S.

IRON IN CHLOROPHYLL.

To the Editor of the Chemical News.

SIR,—I have to thank Professor H. McLeod, F.R.S. (CHEMICAL NEWS, vol. xlix., page 265), for calling my attention to a mistake which runs throughout my article on this subject (CHEMICAL NEWS, vol. xlix., page 237). On referring to my "Laboratory Notes," what I intended to convey to chemists was, that the alcoholic filtrate was shaken up with its own volume of ether and with about two volumes of water, and *not* "the deposit."

The supplementary note of Dr. Schunck, in the same number of the *Proceedings of the Royal Society*, I had not previously seen before Professor McLeod published his letter, because Dr. Schunck's memoir "On the Constitution of Chlorophyll" was torn out of the *Proceedings* by a scientific friend and sent to me, knowing that I had been working for some time on chlorophyll, and am still continuing these researches.—I am, &c.,

A. B. GRIFFITHS, Ph.D., F.C.S.,

Membre de la Société Chimique de Paris, &c.

The Heath, Bromsgrove, Worcestershire,
July 10, 1884.

SUNSHINE RECORDER.

To the Editor of the Chemical News.

SIR,—In the report of the last meeting of the Physical Society the account of the sunshine recorder I described, but did not exhibit, is inaccurate.

The instrument consists of a camera fixed with its axis parallel to that of the earth, and with the lens northward, and there is placed opposite to the lens a round-bottomed flask silvered inside. The light reflected from the sphere passes through the lens, and acts on the sensitive paper.

I do not know how the idea of the water lens got into the reporter's mind, unless it is because I said that the sensitive paper employed was the ferro-prussiate paper used by engineers, and which is fixed by merely washing with water.—I am &c.,

HERBERT MCLEOD.

Cooper's Hill, July 15, 1884.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Zeitschrift für Analytische Chemie.
Vol. xxiii., Part 2.

Determination of Boric Acid in Boro-silicates.—C. Bodewig.—This paper will be inserted in full.

Detection of Nitric Acid in Presence of other Acids which may mask its Reactions.—Antonio Longi.—The detection of nitrates is often tedious and uncertain when they occur in a complex mixture containing at the same time iodides and bromides, also chlorates, bromates, iodates, chromates, &c. The author proposes the following method:—The solution in question, if acid, is neutralised with sodium carbonate and then treated with sulphurous anhydride until it retains a permanent odour of this gas. When the reduction of the oxy-acids is complete, so that ammonium salts are no longer converted into nitric acid, the liquid is gently heated to expel a portion of the excess of sulphurous acid, and sodium carbonate is gradually added until the reaction is faintly alkaline. On boiling, chrome and other heavy metals are thrown down. The precipitate, if any, is filtered off and the liquid is acidified with acetic acid, filtering again if necessary. The liquid is now mixed with a little acetic acid and pure lead peroxide, and boiled until, on a further addition of the same reagents, vapours which affect starch-paper no longer escape. The liquid is let cool, filtered, the lead in solution is precipitated by means of sodium sulphate, filtered again, and the filtrate is evaporated to dryness on the water-bath. The residue is dissolved in water, filtered if necessary, and tested for nitric acid with the usual reagents.

Simple Method for the Quantitative Determination of Nitric Acid.—Dr. E. Wildt and A. Scheibe.—This memoir cannot be reproduced without the accompanying illustration.

Quantitative Determination of Quartz in Rocks and Soils.—J. Hazard.—The author's method depends on the decomposition of certain silicates when treated with dilute sulphuric acid under strong pressure. Muscovite, biotite, garnet, tourmaline, talc, hornblende, hypersthene, diaspore, and pyroxene are completely decomposed. Among the feldspars only anorthite and labradorite are dissolved, whilst orthoclase, albite, and oligoclase remain completely unattacked. The author recommends the following procedure: the rock, finely pulverised, is sealed up in a glass-tube with 2 parts of oil of vitriol and 1 part of water, and exposed in an air-bath to a temperature of 250° for six hours. When the tube is opened the contents are rinsed into a capsule, any particles adhering to the sides of the tube being removed, if necessary, by means of a glass rod fitted with a short caoutchouc tube. Before filtering, the acid is suitably diluted. After the residue has been slightly washed, the filter, with its contents, is placed in moderately dilute potassa, digested on the water-bath for an hour; the solution again diluted with water, filtered off, and the residue washed first with dilute potassa, and then with dilute hydrochloric acid. The filter, after being well dried, is incinerated along with its contents in a platinum capsule, and the silica, alumina, and lime are determined in the ordinary manner.

The Qualitative Detection and Quantitative Determination of Arsenic, Sulphur, and Phosphorus, and of Certain Metals occurring in small quantities in the Copper of Commerce.—O. Kuhn.—Reserved for insertion in full.

Modification of Kipp's Sulphuretted Hydrogen Apparatus.—C. Reinhardt.—Requires the accompanying illustration.

Examination of Certain Musts of 1883 for Acid and Sugar.—W. Schäfer.—The nature of this paper appears sufficiently from its title.

Challenge to H. Skalweit.—R. Kissling.—The writer calls upon H. Skalweit, editor of the *Repertorium für Analytische Chemie*, either to substantiate or to withdraw a statement made in that journal touching the determination of nicotine in tobaccos.

Researches on the Detection of Adulterations in Portland Cement.—R. Fresenius and W. Fresenius.—The authors recommend the examination of samples as

regards their specific gravity, their loss on ignition, their behaviour with water, and especially the alkalinity of the aqueous solution, their behaviour with dilute acids, with permanganate, and with gaseous carbonic acid.

The Performance of Micro-chemical Operations.—A. Streng.—In observing the results of chemical reactions under the microscope there is often a difficulty in limiting the action of a reagent to some constituent of a rock. Streng uses for this purpose perforated covers of thin glass, which he prepares as follows:—Ordinary covers are plunged in melted wax, and the wax is then scraped off from a spot about $\frac{1}{4}$ to 1 m.m. in diameter. Upon this spot is placed a drop of strong hydrofluoric acid, which is renewed until the glass is corroded through, when the coating of wax is then entirely removed. The part of the thin glass round the aperture is then coated with melted Canada balsam, let cool, and the thin glass is then laid with the balsam side downwards on the section of the mineral in such a manner that the aperture is exactly over the constituent which is to be examined with a reagent. The balsam is then melted by passing a hot knitting needle over the thin glass. When it cools again it forms a boundary round the part to be examined. The reagent is then applied with a pencil, and acts of course only at the exposed spot. As a micro-chemical reagent for soda the author utilises the formation of uranium-sodium acetate. He places a granule of a soda-salt (supposed) upon the port-object and adds a drop of a strong solution of uranium acetate. There are then form around the granule small well-defined pale-yellow tetrahedrons of the double salt.

The Correction of Weighings with Reference to a Vacuum.—J. P. Cooke.—From the *CHEMICAL NEWS*.

The Determination of the Specific Weights of Gases.—C. Chancel.—From the *Comptes Rendus*.

Determination of the Specific Weights of Gases at High Temperatures.—H. Goldschmidt and V. Meyer.—From the *Berichte der Deutsch. Chem. Gesellschaft*.

Modified Methods for Determining Vapour Densities.—H. Schwarz.—This paper requires the two accompanying figures.

A Simplification of the Dumas Method of Determining Vapour Densities.—B. Pawlewski.—This memoir cannot be reproduced without the accompanying illustration. For the same reason a number of papers on improved thermo-regulators, air- and water-baths, and other apparatus, can merely be mentioned.

Improved Thermo-regulators.—W. T. Richmond, H. B. Wilson, M. Thomas, Lothar Meyer, and H. Vogel.

A Water-Drying Oven.—H. Vogel.

Apparatus for Fractionated Distillation at Reduced Pressure.—L. T. Thorne.

A Boiling Tube for Fractionated Distillation.—C. Winssinger.

Apparatus for Evolving Pure Carbonic Acid.—A. Muencke.

Apparatus for Collecting, Heating, and Weighing Precipitates.—A. A. Breneman.—From the *CHEMICAL NEWS*.

Platinum Apparatus for Collecting, Weighing, and Burning the Carbon separated from Steel.—Addison B. Clemence.—From the *CHEMICAL NEWS*.

A Lamp for Heating Tubes.—W. Ramsay.—From the *CHEMICAL NEWS*.

A Stop-Cock for Store-Bottles.—H. Vogel.—A glass tube, bent at right angles, is fixed with its short horizontal limb in a perforated cork fitting into the tubulure near the bottom of the bottle. If the tube is turned so that the second limb points vertically upwards the bottle is closed, but if it is turned horizontally the liquid runs off.

A Clamp for Holding the Tubes in Determining Melting-Points.—A. Kölliker.

The Use of White Light in Wild's Polaristrobometer.—These two papers require the accompanying illustrations.

A Liquid of High Specific Gravity and Great Refractive Power.—C. Röhrbach.—The author uses a solution of barium-mercury iodide.

The Behaviour of Glycerin with Certain Ethereal Solutions.—C. Mehu.—Glycerin dissolves a number of bodies, e.g., ferric chloride and bromide, gold chloride, uranium nitrate, mercury chloride, and methyl-violet, better than does ether. If the ethereal solutions are shaken up with glycerin, these substances are withdrawn from the ether, though not in all cases to the last trace. The presence of glycerin in a watery solution prevents these substances partially or entirely from being withdrawn on shaking up with water.

The Preparation of Pure Hydrobromic Acid.—W. Grüning.—The author heats 100 grms. of coarsely powdered potassium bromide and 280 grms. phosphoric acid (spec. gr. 1.304) in a flask holding about $\frac{1}{2}$ litre. At first there passes over water, then aqueous acid, and finally pure acid. The yield is about 80 per cent of the calculated quantity.

Preparation of Platinum Chloride.—L. Opificius.—A mixture of ammonium chloro-platinate and metallic platinum is treated with nitro-hydrochloric acid, heating slowly and raising the temperature very gradually to a boil. On evaporating the solution there remains a residue which forms a clear solution with alcohol.

The Cause of the Reddening of Carbolic Acid.—Hager ascribes this phenomenon to the presence of ammonium nitrite in the atmosphere, and Meyke to lead in the glass of the bottles in which it is kept.

Preparation of a Stable Solution of Copper for Determinations of Sugar.—M. Sonnerat.—The author recommends that the solution should be prepared in the cold to avoid the tendency to spontaneous reduction.

Preservation of Standard Solutions of Permanganate.—F. Simond advises that the bottles should be coated externally with black varnish.

Standardising Alkalimetric Solutions and Permanganate.—W. Hampe.—The author recommends oxalic anhydride as being easily procured in a state of absolute purity.

The Use of Diphenylamin and Aniline in Qualitative Analysis.—E. Kopp has already used diphenylamin for the detection both of nitric and nitrous acid. C. D. Braun uses aniline for the same purpose. I. According to R. Böttger, aniline is adapted for the detection of chlorates. C. Laar has examined the reaction of chloric acid with diphenylamin and the coloured reactions of other oxidising agents with diphenylamin and aniline. The solution of diphenylamin must be prepared with concentrated sulphuric acid. The strength of the solution of diphenylamin must correspond to that of the chlorate. The experiment is performed either on a larger scale in a wide test-tube, or on the small scale in a watch-glass. In the first case 1 c.c. of the chlorate solution is poured upon about 10 c.c. of the diphenylamin solution. The line of contact takes a fine blue, which, on shaking, spreads through the entire liquid. In the second case about 1 c.c. of the diphenylamin solution is placed in the watch-glass and a drop of the solution is cautiously applied by means of a glass rod. In about half a second a radical system of rings of a splendid blue colour spreads over the surface, inclosed in a narrow greenish ring, characteristic of chloric acid as compared with nitric acid, which gives a circle inclosed in a pale blue ring. II. Coloured reactions of other oxidising agents with diphenylamin and aniline. The solutions of diphenylamin and aniline are prepared by dissolving 1 part of the base in 99 parts of the undiluted acid. Hypochlorous acid, bromic and iodic acid, give, with diphenylamin, blue colourations. With aniline hypochlorous acid gives a violet blue; bromic and iodic

acid or violet; perchloric acid colours neither of the reagents. Vanadic, chromic, and permanganic acids yield, with diphenylamin, a blue, and with aniline, at first, orange, followed by violet. Molybdic acid gives a faint blue with diphenylamin only. Arsenic, tungstic, and oxalic acids give no reactions. Ferric salts give with diphenylamin a blue colour, passing partly into green, partly into violet. Potassium ferricyanide alone gives with aniline a faint orange, which gradually becomes mixed with violet. Copper, mercury, tin, and platinum salts gave no coloured reactions. With hydrogen and barium peroxides diphenylamin gives a blue, but manganese and lead peroxide a greenish. With aniline, the two former peroxides give no reaction, and the two latter a blue, which appears gradually.

Applications of Hydrogen Peroxide in Analytical Chemistry.—A. Classen and O. Bauer.—Already noticed.

Separation of Gallium from Other Elements.—Lecoq de Boisbaudran.—From the *Comptes Rendus*.

The Absorption-Spectrum of Uranous Salts.—O. Zimmermann.—From *Liebig's Annalen*.

The Establishment of a Method for the Direct Determination of Carbonic Acid in Presence of Alkaline Sulphides, Sulphites, and Hyposulphites.—M. Hönig and E. Zatzek.—The authors have in the first place studied the behaviour of the above-mentioned sulphur compound with permanganate. The alkaline hyposulphites in an acid solution are imperfectly oxidised by permanganate, either in the cold or at a boiling heat. The sulphur acid, poorer in oxygen, which accompanies sulphuric acid is, in the author's opinion, hyposulphuric acid, which alone is not affected by permanganate even at a boiling temperature, and is converted into sulphuric acid only by the free halogens. In a neutral solution the oxidation is more complete, but is still imperfect. In alkaline solutions the hyposulphites are completely converted into sulphates, even in the cold. The alkaline sulphites, in neutral and alkaline, though not in acid solutions, are completely oxidised by permanganate at common temperatures. Alkaline mono- and poly-sulphides are substantially completely peroxidised at a boiling-heat. The authors give the following process for the direct determination of carbonic acid in presence of alkaline sulphides, sulphites, and hyposulphites. The substance in question is placed in a flask holding 300 c.c., and fitted with a caoutchouc stopper having two perforations. Through the one passes a funnel tube, fitted with a cock, and reaching down nearly to the bottom of the flask. Through the other aperture it is connected air-tight with the following pieces of apparatus:—1. A Liebig's bulb-tube, containing a dilute solution of permanganate, slightly acidified. 2. A U-tube, filled with calcium chloride. 3. A Liebig's bulb-tube, filled with potassa-lye (spec. gr. 1.27), and weighed. 4. A U-tube, filled with calcium chloride. After the whole has been joined together, and the connections have been found air-tight, a solution of permanganate containing 5 grms. per litre is allowed to flow down the funnel-tube, shaking occasionally until the solution takes a permanent dark-red. The acid necessary for the decomposition of the carbonate—dilute sulphuric, nitric, or acetic, but never hydrochloric—is next introduced. The cock of the funnel-tube is closed, and the decomposition of the carbonate and expulsion of the carbonic acid are effected by the application of heat, very gently at first, but afterwards raised to a simmer. The heat is then withdrawn, the cock opened, and the funnel-tube placed in connection with a washing-bottle, filled with potash-lye, when air is aspirated through the apparatus for 30 to 45 minutes. The increase of weight in the Liebig's bulb-tube containing potassa gives directly the weight of the carbonic acid. The total sulphur present in the sulphur compounds can be determined in the same portion of the sample. After the determination of the carbonic acid the contents of the decomposition-flask and of the Liebig's bulb-tube containing permanganate, are rinsed into a beaker. The excess of

permanganate is destroyed by the addition of hydrochloric acid and the application of heat, which at the same time re-dissolves any precipitate. The liquid is boiled to expel chlorine, and the sulphuric acid is determined in the ordinary manner. Of course, only nitric or acetic acid must have been used to decompose the carbonate.

A Reaction for Sulphuretted Hydrogen.—H. Caro and E. Fischer.—The aqueous solution supposed to contain sulphuretted hydrogen is mixed with about 1-50th of its bulk of fuming hydrochloric acid, a few fragments of para-amido-dimethyl-aniline sulphate are added, and as soon as they are dissolved 1 or 2 drops of a dilute solution of ferric chloride. If sulphuretted hydrogen is present the liquid shortly takes a pure blue colour. The reagent may be obtained from commercial helianthine or orange III., which is reduced by grinding it up with 5 parts of water and an excess of ammonium sulphide and heating it on the water-bath. The amido-dimethyl-aniline thus formed is separated from the water by shaking up with ether. The ammonium sulphide taken up by the ether is removed by shaking up with a little lead carbonate made into a paste with water, filtering, and mixing the ether cautiously with an ethereal solution of strong sulphuric acid. The neutral sulphate separates out as a nearly colourless mass. The ether is decanted off and the salt heated on the water-bath with 4 to 5 parts of absolute alcohol until it is converted into fine white needles. These are filtered when cold, washed with alcohol, pressed, and dried on the water-bath.

A Reaction for Gallie Acid.—Sydney Young.—From the CHEMICAL NEWS.

Preparation of Sclerotic Acid.—Valerian Podwissot-sky.—The author's process is not stated.

On Coloured Reactions of the Alkaloids.—Karl Hock, and Karl Arnold, and K. Mandelin.—The authors give the reactions of the coloured liquids in a series of tables which do not admit of abridgment.

Spectroscopic Examination of Coloured Ethereal Oils.—Karl Hock.—All the blue oils have the same absorption spectrum and are therefore not capable of being distinguished.

The Composition of Natural Fats.—J. A. Wanklyn and W. Fox.—From the CHEMICAL NEWS.

Action of Bromine upon Cellulose and Starch.—A. P. N. Franchimont.—If moisture is entirely excluded, bromine acts neither upon cellulose nor starch.

Influence of Various Reagents upon the Formation of Sugar.—W. Dettmer.—Carbonic acid and small proportions of citric, phosphoric, and hydrochloric acid, accelerate the formation of sugar, while it is retarded by larger proportions. Small doses of concentrated potassa entirely prevent the formation.

The Solubility of Aniline in the Solution of an Aniline Salt.—A. Lidow.—An aqueous solution of aniline hydrochlorate at 50 per cent dissolves aniline in almost all proportions. Such solutions are sometimes sold as aniline oil, which they much resemble in colour and odour.

**ST HELEN'S ENGINE, BOILER, AND BRIDGE WORKS
AND FOUNDRY,
LANCASHIRE**

**BAILEY'S LABORATORY MILL
(CARR'S PATENT),**

With Wedgwood-ware Pan and Runner. For Hand or Power.
*Suitable for Levigating Chemicals, Drugs, Powders, Minerals, Paints,
and for General Laboratory Purposes.*

Approved by some of the most eminent Chemists, and awarded
the Silver Prize Medals of the Manchester and Liverpool, and the
Middleton Agricultural Shows.

The chief feature in this machine is, that although it can be
turned with ease, it has immense frictional power for levigating pur-
poses. This is caused by the runner being driven at a much greater
speed than the bowl. The surfaces are clean, smooth, and durable.
Dia. of Bowl, 18 ins. Price, £11 nett cash, delivered to Man-
chester. This Levigator is also suitable for triturating and mixing
Medicines, Vegetable Powders, Ointments, Paints, Sugar, Salt,
Spices, Herbs, Mineral Ores, &c., and will grind the coarsest emery
into a nearly impalpable powder in a few seconds. The Pan can be
tilted for emptying.

VOL. L. No. 1287.

CHEMICAL PHENOMENA OF THE RESPIRATION OF PLANTS.

By Dr. T. L. PHIPSON, F.C.S., &c., London.

1. THE experiments on *Protococcus palustris* and other unicellular algae, published by me last year in the CHEMICAL NEWS (vol. xlviii., p. 205), have been continued, with others made on *Achillea*, *Solanum*, *Veronica*, *Vinca*, *Galium*, and some ferns. What is said here of the chemical phenomena observed with *Protococcus pluvialis*, *P. palustris*, *Myrocystis minor*, and unicellular algae generally, applies to the various species of phanerogams belonging to the genera just mentioned, to ferns, and probably to all plants except *Fungi*. On account of the great number of observations made since last year I can only give a very brief and rough account of them here at present.

2. Many years ago I was aware that plants could not decompose CO_2 , as was supposed in text-books on vegetable physiology. I had already satisfied myself on this point at Brussels in 1855, when I found that carbonic acid in excess killed the plants, caused them to turn yellow, and that in smaller quantities alone it gave rise to no evolution of oxygen in the sunlight.

3. The history of the question may be briefly set down as follows:—More than a hundred years ago Bonnet, of Geneva, discovered that plants in water exposed to sunlight evolved air. Dr. Priestley, about 1780, showed that this air was oxygen, Ingenhousz then found that daylight or sunlight was essential, and Sennéber showed that carbonic acid was no less essential. H. de Saussure found that the phenomena took place in air as well as in water, i.e., that plants absorb CO_2 from the air and evolve oxygen, in fact, converting almost entirely the CO_2 into its own volume of oxygen. Much later still (1845) Professor Boussingault again placed it beyond doubt that it was only in water charged with carbonic acid that plants can evolve oxygen in the sunlight.

4. My experiments go a step further: I have found that something else (besides carbonic acid) is necessary, and that carbonic acid alone will yield no oxygen in these circumstances.

5. In my last paper in the CHEMICAL NEWS (1883) I showed a simple apparatus by which unicellular algae, supplied constantly with fresh spring-water and exposed to sunlight, gave a constant evolution of oxygen gas. When the CO_2 of the spring-water is exhausted fresh spring-water is let into the apparatus, whilst the old water is run off, and the evolution of oxygen continues.

6. When the CO_2 of the spring-water was exhausted it seemed natural to supply more CO_2 and not more water. In other words, if carbonic acid could be constantly supplied, it appeared that the evolution of oxygen would prove continuous. This was tried: CO_2 was supplied to the water after three or four days' sunning had exhausted its power of causing the algae to give off oxygen. The faculty of evolving oxygen was certainly restored, but not to any great extent, and it became less and less manifest with successive additions of carbonic acid.

7. The spring-water was boiled and then impregnated with pure carbonic acid gas (about 0·10 volume), when it was found that the *Protococcus* gave off little or no gas at all. A further quantity of CO_2 was supplied. No result. The experiment was repeated several times, with fresh quantities of spring-water and with other plants. Same results. The conclusion arrived at was that in spring-water which has been thoroughly boiled for five minutes, then rapidly cooled and supplied, when cold, with small or

large quantities of carbonic acid, plants are incapable of evolving oxygen in the sunlight.

8. It was therefore evident that something else is required by the plant, and that this "something else" is destroyed by boiling the spring-water for five minutes. It is binoxide of hydrogen that is required. It exists, and its presence can be demonstrated, in all spring-water, and it is as essential to the life of the plant as carbonic acid is. As I hinted in my former paper, the phenomenon generally termed "respiration" of plants is due to the reaction which occurs in the plant-cell between CO_2 and HO_2 . (It may be expressed theoretically thus:—

In this manner oxygen is evolved, whilst ternary compounds are formed in the plant-cell.

9. When spring-water is boiled the air collected (after absorption of the carbonic acid) contains 30 to 33 per cent of oxygen instead of 21 per cent. This difference is chiefly due to oxygen in the state of binoxide of hydrogen. The amount will vary, of course, with different waters and in different circumstances, but probably 6 to 8 per cent of the oxygen yielded by spring-water is in the state of binoxide of hydrogen.

I hope to make known in another paper how binoxide of hydrogen is put in evidence in spring-water, and its quantity approximately ascertained. To-day I must be content with stating that peroxide of manganese (MnO_2) in spring-water exposed to strong sunlight can be made to "breathe" like the unicellular algae.

10. Unicellular algae in spring-water which has been impregnated with carbonic acid after boiling (and so deprived of its little charge of HO_2), and having abundant contact with the air, will, after several days' exposure to the sun, evolve slight quantities of oxygen, showing that in these circumstances HO_2 is slowly formed again in the water that has been deprived of it.

11. These observations appear to me to throw quite a new light on the phenomenon of plant respiration, and as the entire growth of the plant depends upon this function, it is probable that in agriculture binoxide of hydrogen will take a higher rank than nitrogen. The science of manuring will consist in providing the soil with materials which by their oxidation will induce the highest possible formation of binoxide of hydrogen and carbonic acid.

12. It is no less evident that these researches will also induce direct experiments in the laboratory with binoxide of hydrogen and carbonic acid, with the view of forming organic substances artificially.*

A GENERAL METHOD OF TOUGHENING GOLD (AND SILVER) IN THE MELTING CRUCIBLE.

By Dr. JAMES C. BOOTH, of the U.S. Mint, Philadelphia.

GOLD and silver differ from other elements, except those of the platinum group, in their feeble affinity for oxygen, and by means of this property we can separate the noble metals from others by fusion in the fire, in which heat removes oxygen from gold and silver and attaches it to the others. To this first class we may add a second, embracing iron, nickel, copper, tin, bismuth, and lead, whose oxides may be reduced to metal by being heated with fuel, or without reduction can be melted with fluxes or slag. A third class, arsenic, antimony, and sulphur, are reduced and volatilised, or are fluxed off with alkali and oxides of the second class.

To illustrate the subject practically, I shall describe an operation of toughening brittle gold which I recently per-

* I have expressly avoided any allusion to temperature in the above though it plays quite as important a part as light in the phenomena under consideration; but I reserve my observations on this subject for another time.

formed at the United States Mint at Philadelphia. Some brittle gold, having been accidentally melted with a quantity of well-refined and tough gold, was found to have rendered the whole mass very brittle, with a highly crystalline fracture, and therefore useless for coinage. I determined to avoid loss of time, and the greater cost of refining by acid, and to toughen it wholly by fluxing. This was accomplished on 75,162 $\frac{1}{4}$ ounces (= 5154 lbs. av.) in 1 $\frac{1}{2}$ days, at a trifling cost, and with scarcely apparent loss. The 75,000 ozs. were divided into 14 melts of about 5400 ozs. each, and each melt separately toughened. The ingots, easily broken into pieces by striking them on the edge of a wooden box, were put into the crucible with soda-ash and anhydrous, fused borax, in the ratio of one or two ounces to a melt until the crucible was nearly full. It then appeared as a quiet mass of metal covered with a rather viscid slag, disposed to swell and puff. A few crystals of saltpetre, say one or two ounces, were then dropped successively into the centre of the metallic surface, and as they melted, their spreading out over the whole surface was aided by the concentric motion of the bottom of a small crucible. The moment the visible oxidising action began to slacken, the melter skimmed off, by a small black-lead dipping crucible, the fluxed matter as rapidly as was consistent with the care necessary to avoid taking up metal. The remainder in the melting-pot was the toughened metal.

There are several points worth noting in the operations just described. 1. One part of the foreign matter was sufficient to impart brittleness to 75,000 parts of good standard gold (st. gold = 900 gold + 100 copper, &c.). 2. By a slight oxidising process the metal causing brittleness was collected and removed at a trifling cost in 1 $\frac{1}{2}$ days, without appreciable loss of gold. 3. Still more remarkable is the fact that the 14 melts of gold, in their brittle state, proved by assay to be of true standard, 900 gold + 100 alloy (usually 90 copper + 10 silver), after their brittleness had been changed to toughness by fluxing and skimming, were still 900 gold + 100 alloy inappreciably altered. So delicately executed is the act of toughening, that although 10 per cent of the metal is easily oxidised copper, yet the ratio of copper after fluxing is the same. 4. Another point worthy of remark is that the toughening proceeds from the top downward, to the depth of 9 to 12 inches of its own accord, although it is stirred towards the close of the operation to render the melt uniform throughout.

I do not wish the inference to be drawn that every case of toughening brittle gold is as successful or simple as the above. When the metal contains a larger proportion of foreign matter, the operation of fluxing, nitreing, and skimming may have to be repeated, perhaps more than once. While the crucible is on the fire, the perfection of the toughening may be readily ascertained in 2 or 3 minutes by casting a thin strip, $\frac{1}{4}$ to $\frac{1}{2}$ inch thick, and doubling it under the hammer or rolling it, the cracking of the strip in this case, if any, or its snapping asunder, informing the experienced eye of the degree of completeness in the toughening operation.

When the bullion appears to be baser—to contain a larger amount of foreign matter than in the example specially quoted in this paper, and experience can often make an approximate guess at the degree of baseness as well as at the nature of the elements causing it, then the only change made in the toughening consists in using a larger amount of soda and borax, and a still larger proportion of nitre. Two points are to be noted in the use of a large amount of this more oxidising flux:—1. That some of the graphite of the crucible at the level of the liquid is cut away, injuring the crucible and weakening the oxidising power of the nitre. 2. That since the larger bulk of fluxing matter increases the time of skimming, some of the oxidised foreign matter, in the presence of a large amount of metal, and surrounded by graphite, tends to revert to the metallic state.

To obviate these difficulties or objectionable features,

after going through the stronger oxidising process, as above described, the oxidation is suddenly fixed by the rapid addition to the floating slag of sand, lime, or bone-ash, which is stirred with the slag and thickens or stiffens it, so as to allow more deliberate skimming of the whole mass without fear of re-oxidation. I have tried the three thickeners above named, which seem to act rather mechanically than chemically, and, of the three, prefer sand. Where thickeners are employed on standard gold, there is greater liability to an increase in fineness of the standard by the removal of oxide of copper, together with the oxidised embrittler, so that brittle gold of 900 after toughening may be 900.5 or even 901.

The toughening of the above 75,000 ozs. effected in fourteen meltings (fourteen crucibles full) of over 5000 ozs. each in standard gold, resulted in less than a crucible full of skimmings. The skimmings are worked down to metal and poor slag as follows. They are quietly melted and cooled slowly, so as to form a *king* of metal at the bottom of the crucible, and a glassy or cindery slag above. The last is ground and separated by sifting and washing into metallic grains and poor cinder. The grain and king are again fluxed and treated as before, either by themselves or as usual with other light residues. Thus the impurities of gold (and silver) are successively worked out, by concentrating them in a small bulk and weight of metal, and purifying it with a greater diminished risk of loss of gold than if we attempted to purify a large mass at one operation. In the case detailed in this paper the impurities were concentrated by a single operation of purifying in a king of about (8) eight ozs. From the purification of this king, we have ground for asserting that the impurity causing brittleness in the whole 75,000 ozs. was a small fraction of an ounce, probably $\frac{1}{1000}$ or less, of the original weight.

As a concluding note to this paper, I must state that a great deal of skill is required to avoid loss of gold in executing the process herein detailed; that the melter must have unusual powers of observation and long practice to acquire the necessary skill, and I deem it but justice to state that Mr. F. C. Garrigues, my foreman, especially in the melting department of the Mint, possesses the requisite skill and practice, and that he performed the operations above described.—*Journal of the American Chemical Society.*

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING JUNE 30TH, 1884.

By WILLIAM CROOKES, F.R.S.

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford.

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To the Water Examiner, Metropolis Water Act, 1871.

London, July 6th, 1884.

SIR,—We submit herewith the results of our analyses of the 175 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily from June 2nd to June 30th inclusive. The purity of the water, in respect of organic matter, has been determined by the Oxygen and the Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to

oxidise the organic matter, and the quantities of free oxygen present in the whole of the samples submitted to analysis.

The results set forth in these several Tables, taken together, show that the June supply of water to the Metropolis has differed but little in character from the supplies of the preceding months.

During the past six months we have examined 1071 samples of water drawn from the mains of the seven companies taking their supply from the Thames and the Lea, and have been able to register these many samples as being, without a single exception, clear, bright, and efficiently filtered. Judged by the eye, they had all of them the further claim to be described as being, even when in considerable bulk, colourless. Subjected to more exact examination in this particular, their degree of brownish tint proved to be exceedingly low, so as in no case to preponderate over the proper blue tint of the water. According to the scale adopted by ourselves, based on a comparison of the tint of the water with the tints of certain brown and blue mineral solutions of definite strength, the mean ratios of brown to blue tint observed in the Metropolitan supply during the past six months were as 15·3 to 20 in January, as 12·8 to 20 in February, as 9·5 to 20 in March, as 6·7 to 20 in April, as 8·5 to 20 in May, and as 13·1 to 20 in June. The whole of the 1071 samples were further examined for organic matter by the permanganate process, and for dissolved oxygen by the Schutzenberger process, with similarly satisfactory results.

Of the 148 samples of water submitted to complete analysis—or one sample daily, exclusive of Sundays and holidays—42 samples were furnished by the New River and East London Companies, in chief measure from the Lea; while the remaining 106 samples were furnished by the five Companies taking their supply from the Thames. As regards the quantities of organic carbon, and consequently of organic matter present in these Thames-derived samples, the mean result for January, exceptionally low for this season of the year, was 0·118 part of organic carbon in 100,000 parts of water. The mean result for February was 0·140 part, for March 0·165 part, for April 0·139 part, for May 0·104 part, and for June 0·114 part of organic carbon in 100,000 parts of the water; while the highest result furnished by any single sample examined during the last two months was 0·129 part, equivalent to about a quarter of a grain of organic matter per gallon.

It was explained in the Report of the Royal Commission on Water Supply, that a minute proportion of organic matter, variable in amount with season, is a normal constituent of river water; that there is no reason whatever to consider this proportion of natural organic matter as in any way prejudicial to health; and that there is absolutely no chemical evidence to indicate that the small proportion of organic matter present in the water supply of London is different, either in quantity or kind, from the natural organic matter of the river, as met with for instance at Lechlade, 120 miles above the intake of the Companies. Still, in view of the importance which is sometimes attached, though as we maintain unwarrantably, to the not inconsiderable variations in the always minute proportion of organic matter present in the London supply, it is satisfactory to note that at periods of summer heat and drought like the present, the natural agencies at work to keep down the proportion of organic matter existing in the water of the river are at their maximum of activity. It results in this way, that the water supply of London is at its best just at those seasons, like the present, when any failure in the quality of the supply might be considered likely to be of exceptionally serious import.

We are, Sir,

Your obedient Servants,
WILLIAM CROOKES,
WILLIAM ODLING,
C. MEYMOTT TIDY.

A RECALCULATION OF THE ATOMIC WEIGHTS.*

By FRANK WIGGLESWORTH CLARKE, S.B.,
Chief Chemist to the U.S. Geological Survey, Washington.

COLUMBIUM.†

THE atomic weight of this metal has been determined by Rose, Hermann, Blomstrand, and Marignac. Rose† analysed a compound which he supposed to be chloride, but which, according to Rammelsberg,|| must have been nearly pure oxychloride. If it was chloride, then the widely varying results give approximately $Cb = 122$; if it was oxychloride, the value becomes nearly 94. If it was chloride, it was doubtless contaminated with tantalum compounds.

Hermann's§ results seem to have no present value, and as for Blomstrand's,¶ I am not able to get at a copy of his original memoir. The results of the latter chemist are thus summed up in Becker's "Digest." Three chlorine estimations in the pentachloride give, in mean, $Cb = 96·67$. Eleven weighings of columbic acid from the same compound make $Cb = 96·16$. Other experiments on sodium columbate lead Blomstrand to regard 95 as the most probable value.

Marignac** made about twenty analyses of the potassium fluoxycolumbate, $CbOF_3 \cdot 2KF \cdot H_2O$. 100 parts of this salt give the following percentages:—

Cb_2O_5	Extremes 44·15 to 44·60	Mean 44·36
K_2SO_4	" 57·60 .. 58·05	
H_2O	" 5·75 .. 5·98	
F	" 30·62 .. 32·22	

From the mean percentage of Cb_2O_5 , $Cb = 93·217$. If $O = 16$, this becomes 93·431.

From the mean between the extremes given for K_2SO_4 , $Cb = 93·812$. If $O = 16$, this becomes 94·027.

As Deville and Troost's†† results for the vapour density of the chloride and oxychloride agree fairly well with $Cb = 94$, we may adopt this value as approximately correct.

TANTALUM.

The results obtained for the atomic weight of this metal by Berzelius,†† Rose,||| and Hermann,§§ may be fairly left out of account as valueless. These chemists could not have worked with pure preparations, and their data are sufficiently summed up in Becker's "Digest."

Marignac¶¶ made four analyses of a pure potassium fluo-tantalate, and four more experiments on the ammonium salt. The potassium compound K_2TaF_7 was treated with sulphuric acid, and the mixture was then evaporated to dryness. The potassium sulphate was then dissolved out by water, while the residue was ignited and weighed as Ta_2O_5 . 100 parts of the salt gave the following quantities of Ta_2O_5 and K_2SO_4 :—

Ta_2O_5 .	K_2SO_4 .
56·50	44·37
56·75	44·35
56·55	44·22
56·56	44·24

Mean 56·59 ± 0·037

Mean 44·295 ± 0·026

* Smithsonian Miscellaneous Collections. The Constants of Nature."

† This name has priority over the more generally accepted "niobium," and therefore deserves preference.

‡ *Poggend. Annal.*, 104, 439. 1858.

|| *Ibid.*, 136, 353. 1869.

§ *Journ. f. Prakt. Chem.*, 68, 73. 1856.

¶ *Acta Univ. Lund.*, 1864.

** *Archives des Sci. Phys. et Nat.*, (2), 23, 258. 1865.

†† *Comptes Rendus*, 56, 891. 1863.

‡† *Poggend. Annal.*, 4, 14. *Lehrbuch*, 3, 1209.

||| *Ibid.*, 99, 80. 1856.

§§ *Journ. f. Prakt. Chem.*, 70, 193. 1857.

¶¶ *Arch. des Sci. Phys. et Nat.*, 26, 89, serie 2. 1866.

From these figures, 100 parts of K_2SO_4 correspond to the subjoined quantities of Ta_2O_5 :—

127.338
127.960
128.178
127.848

Mean 127.831 $\pm$ 0.120

The ammonium salt, $(NH_4)_2TaF_7$, ignited with sulphuric acid, gave these percentages of Ta_2O_5 . The figures are corrected for a trace of K_2SO_4 which was always present :—

63.08
63.24
63.27
63.42

Mean 63.25 $\pm$ 0.047

Hence we have four values for Ta :—

From potassium salt, p.c. Ta_2O_5 ..	Ta = 183.033 $\pm$ 0.343
" " " K_2SO_4 ..	" 181.619 0.242
" " " Ta_2O_5 ..	" 182.361 0.411
" ammonium salt p.c. Ta_2O_5 ..	" 182.149 0.456

General mean 182.144 0.166

Or, if O = 16, Ta = 182.562.

If we assume K = 39, O = 16, F = 19, S = 32, and N = 14; the percentage of K_2SO_4 from K_2TaF_7 gives Ta = 181.912; and the analyses of the ammonium salt make Ta = 182.020. Evidently, 182 is not far from the true value.

CHINESE IRON FOUNDRIES AND RICE PAN CASTING.

ALTHOUGH the Chinese, as a race, are incapable of the deep thought and extreme mental effort required to elaborate the intricate details of modern scientific machinery, or to plan those bold enterprises and extensive systems of road and hydraulic engineering which are the pride and glory of the British civil engineer, yet, *per contra*, it must be conceded that for finicking, tedious, patient ingenuity of a certain sort, the Chinaman stands almost without a rival. As a notable example of this same patient plodding ingenuity, shown by the Chinaman in some of his trades and industries, may be instanced the manufacture of the very thin cast-iron rice pans which may be seen in almost any cook house in the Colony of Hongkong. The principal seats of this industry are at the towns of Sam-tiu-chuk, in the Kwei-shin district of the Wei-chow prefecture, and at the busy populous manufacturing town of Fatsshan, situated in the Nam-hoi district of the Kwang-chow prefecture. This latter town is distant but some twelve miles, in a south-westerly direction, from the provincial capital of Canton, and has, from the extent and importance of its trade and manufactures, notably its great trade in iron goods, tools, and hardware, been aptly termed the Birmingham of China. The previously mentioned town of Sam-tiu-chuk is inhabited principally by Hakkas, and is one of the principal towns of the sparsely populated and mountainous district of Kwei-shin. The iron used is obtained by smelting the magnetic oxide, which is found in large masses in the mountains surrounding the town. The ore is broken up and smelted with charcoal in a primitive smelting furnace or cupola some eight feet high; the cupola is cone shaped, having its apex or smaller diameter at the bottom; the single tuyere pipe is of earthenware, the opening for emission of the blast being placed downwards. The furnace itself is of earthenware, or rather puddled and dried clay, kept from falling to pieces

and strengthened by hoops and longitudinal straps of iron; the whole is lined with clay several inches thick; the internal diameter at the bottom may be about two feet or perhaps a little more, and at the top about three feet and a half, inside depth about six feet. The blast is produced by a rude yet most ingeniously contrived bellows, formed of a wooden box some five feet long by three feet in horizontal and a foot and a half in vertical section. This box is divided longitudinally into two compartments, each eighteen inches square in vertical section, in each of which compartments a piston works; the valves are so arranged that one piston is effective in the up, the other in the down or rather return stroke, for the machine is arranged horizontally. It will be seen, however, from this arrangement, as there is no air chamber, that the blast is not perfectly continuous, there being a slight cessation at the end of each stroke before the return stroke can be effective. The fuel used is charcoal, and the furnace being first heated by starting a fire with fuel alone is then filled up with alternate layers of charcoal and ore in small fragments. The blast is urged, and after a sufficient time has elapsed the molten metal is drawn off from a tap hole at the bottom in the usual manner and cast into ingots, which, when intended for export, are afterwards re-heated in an open forge and beaten into blooms of about six pounds in weight; these may occasionally be seen for sale in the iron dealers' shops in Hongkong, and when made from genuine native iron fetch a very high price indeed, as much as four dollars per picul or even more being sometimes paid for the best quality made from the black or magnetic oxide. The Fatsshan iron, which to a great extent comes from Ying-tak (a town on the West River) is smelted from hematite (the red oxide) but mixed to a considerable extent with gangue, rarely pure, and of varying and uncertain chemical composition. The iron smelted from this latter ore, although far more valuable in the native estimation than foreign imported iron, yet does not realise so high a price in the market as the other.

For making the very thin rice pans which are cast without handles, pure native iron alone can be used; as being smelted with charcoal, it has the property, when melted, of being more fluid than iron smelted with coal; or it may be that the iron itself being uncontaminated with sulphur, or phosphorus, possesses the property of greater fluidity on this account. The moulds in which the pans are cast require weeks of tedious and patient labour to bring them to perfection. They are composed of two parts—an upper and a lower—and are made of carefully puddled clay, the upper portion about an inch and a half and the lower somewhat thicker; the lower or under half is full of round holes about half an inch in diameter, which pierce about two thirds the thickness of the mould; these holes are made in order to allow the clay to dry thoroughly; the moulds are turned true on a revolving potter's table of the usual pattern, and when quite dry receive a final coating of fine moulding sand, and are made perfectly smooth. The two portions of the mould are then luted together with clay and placed in a large round oven some six feet or more in diameter. The pans are cast bottom upwards, each mould having a runner but no riser; the upper portion of the mould has three little legs in order to support it when drying previously to the two moulds being luted together. After being placed in the oven, which is some two and a half feet deep, the moulds are surrounded with charcoal, which is fired, and the ovens closely covered with a curiously constructed earthenware, or rather dried clay cover, kept together, as in the case of the furnaces or cupolas previously mentioned, with bands and straps of iron. The process is so timed that by the time the moulds are at a bright red heat or almost white heat, the iron in the cupola is melted, and ready for tapping; the molten metal is then run out into ladles made for the purpose, and quickly poured into the moulds. When these are all filled, the cover of the oven is re-adjusted, and the whole left to anneal or cool gradually.

The great secret about this process, which enables the

Chinese founders to cast their iron pans of such large diameter, yet so thin and light as to be scarcely thicker than a sheet of paper, appears to be the use of highly heated moulds, and pure iron smelted with charcoal. When the ovens and their contents have cooled down, which takes about two days, the luting attaching the upper portion of the mould to the lower is carefully removed, and the moulds being separated the pan can be extracted; when the operation has been successful, the same mould can, with a little touching up, be used several times. The pans now have each attached to its bottom a runner or lump of iron, of greater or less size, which, from the extreme thinness of the pans, making them but little less brittle than earthenware, requires the greatest care in its removal; these runners are carefully sawn off, the use of the more expeditious cold chisel being more likely to cause fracture than the slower but steadier saw; the edges are smoothed down, and the pan is ready for the export market. Handles are attached to these pans by the retail dealers, who bore holes near the rim of the pan, and attach small ribbons of iron for the purpose of handles.

The pans made at Fatshan differ from the preceding in being cast with handles attached near the rim to the inner surface of the pan, which necessitates the breaking of the mould at each casting, it being rare for the same mould to be serviceable a second time. The Fatshan pans are also usually cast much thicker and heavier than those of Sam-tiu-chuk, and occasionally as large a proportion as one-third of foreign cast-iron, generally Kentledge or ordinary pig-iron, is mixed with the native iron for casting. In other respects the process followed at both places is the same. The Fatshan pans being thicker are the more durable of the two, while the thinner Kwei-shin pans are more popular with poor people because being thinner a less quantity of fire-wood is required to heat them through. The manufacture of iron rice pans is in Kwangtung province a Chinese Government monopoly, which is farmed out by the Salt Commissioner, and by him licenses are granted to the local iron founders on payment of a heavy fee. Considerable care has to be used in packing the pans for export, in order to prevent breakage, which, however, frequently occurs when any considerable number of pans are shipped to Australia or other distant ports. An attempt was made some years back to cast rice pans in Hongkong, but the locality chosen, Shau-ki-wan, being an unhealthy one, many of the workmen died, others left the place sickly and fever stricken, and the concern from this cause mainly proved a failure. It may, however, be possible that had a longer time, say a year or more, been allowed to elapse for the newly filled ground to settle down, and the freshly cut hill side adjacent to finish giving off its malarious exhalations, the place would not have been so unhealthy, and in that case the result might not have been so disastrous to all concerned as it unfortunately proved itself to be.

T. I. B.

Hongkong, 19th March, 1884.

PROCEEDINGS OF SOCIETIES.

SOCIETY OF CHEMICAL INDUSTRY.

Newcastle-on-Tyne, July 9th, 1884.

Address delivered at the Third Annual General Meeting by the Retiring President, WALTER WELDON, F.R.S., &c.:

I trust that it will not be unfitting that the observations which it is now my duty to offer should be devoted exclusively to that one of the chemical industries of which the district in which we are now met is so important a centre, which was first practised in England within four miles of this building, and with which it happens that I am more familiar than with any other. Eighteen months ago,

before the London Section of our Society, I sketched the then present condition of that industry, and indulged in some speculations as to its future. "Many things," however, "have happened since then"; and among them have been changes, alike in the actual condition of the older branch of the soda industry, and in the data for estimating the probable future of that industry at large.

Since I collected, towards the end of 1882, the statistics with respect to the soda industry which I presented to our London Section in January last year, the ammonia process has continued its victorious advance, and the production of Leblanc soda has still further diminished. That further diminution in the production of Leblanc soda was indeed inevitable; but, whereas one expected that it would involve the closing of more Leblanc soda works; temporarily, at any rate, this result has been avoided by combinations among Leblanc soda makers to reduce production. These combinations have been regarded as simply combinations to force up the price of certain products; but there is no room to doubt that the rise which has taken place in the price of the products in question, as a consequence of these combinations, must necessarily have taken place by this time if those combinations had not been formed. The manufacture of chlorine and Leblanc soda, without profit, and in many cases at a loss, could not have gone on much longer. It must soon have resulted in the forced withdrawal of the weaker manufacturers from a hopeless struggle; and the effect upon prices of diminished production brought about in this way would of course have been the same as that of diminished production brought about by mutual agreement. The stronger of the manufacturers might well have preferred a continuance of the struggle until all the weaker had gone to the wall; but the consumer has certainly no cause to complain of an arrangement (the faint flavour of socialism about which renders it none the less acceptable in at least my eyes) by which—instead of the complete closing of more works and the ruin of their owners, the other works remaining in full activity and reaping the whole benefit of the reduced production thus occasioned—on the one hand, the reduced production which must have been brought about in some way; and, on the other, the benefit of the higher prices resulting from it, are shared, as equally as may be, among the proprietors of all the works which were still in operation when that arrangement was made.

While, however, the makers of soda by the Leblanc process are to-day in the position, to which they had so long been unaccustomed, of being able, not only to make both ends meet, but also, I trust, to make one end somewhat overlap the other—what of the future of that process? Regarded merely as a means of manufacturing soda it has served its time. Per given quantity of soda yielded by it, it is more than 70 per cent more costly than the ammonia process; and thus its only claim to continue to live consists in the fact that it yields hydrochloric acid. So far as one can yet see the world must continue to be supplied with chlorine. At present, the immediate raw material of the chlorine manufacture is always hydrochloric acid; and for our supply of that raw material we are entirely dependent on the Leblanc process. Is this state of things destined to continue? Is the Leblanc process likely to remain our only means of obtaining hydrochloric acid? And, above all, must the production of hydrochloric acid always be, as now, an essential condition precedent of the production of chlorine?

How to obtain, in a useful state, the chlorine, at present thrown away as calcium chloride, of the salt which is decomposed by the ammonia process, is a problem which has long occupied many minds. When it became known, in the course of last year, that Mr. Mond had patented a process to that end, it was widely felt that the solution of this problem had probably been reached; and Mr. Mond's very ingenious process certainly would, under given conditions, enable the manufacturer of ammonia soda to utilise both the constituents of the salt which he decomposes. Mr. Mond himself, however, has never regarded

this process as other than a process for the future. It is a process which would involve that the ammonia employed in the manufacture of ammonia soda, instead of being continually regenerated and used again as at present, should be used as a reagent in that manufacture only once, and should then be sold as ammonium sulphate; and hence the conditions for its extensive application obviously do not at present exist.

† The form of Mr. Mond's process is due to a fact of which, until he discovered it, chemists were not aware. We know that when sodium chloride is heated with an equivalent of sulphuric acid, as in the first operation of the Leblanc process, the sulphuric acid reacts on only one-half of the sodium chloride, the products of its reaction thereupon being HCl and hydrogen sodium sulphate; but that afterwards, at a higher temperature, that hydrogen sodium sulphate reacts on the other half of the sodium chloride, another HCl being evolved, and the whole of the sodium present being converted into normal sulphate. It has been generally supposed that if ammonium chloride were substituted for sodium chloride things would go in a similar way; but Mr. Mond has found that this is not the case. He has found that when ammonium chloride and acid ammonium sulphate are heated together no reaction takes place between them at whatever temperature. Below a certain temperature nothing happens; above that temperature, all that happens is that ammonium chloride volatilises. That this fact remained to be discovered in 1883 surely shows that, in the search for new organic compounds in which chemists for so many years past have been so absorbed, the pursuit of inorganic chemistry has been somewhat unduly neglected.

When the residual liquor of the ammonia soda process has been treated for the distillation off from it of such part of its ammonia as is combined with carbonic acid, together with such of it, if any, as may be in the free state; what remains is a nearly saturated mixed solution of ammonium and sodium chlorides. On evaporating this mixed solution, its sodium chloride, being the less soluble of the two salts contained in it, falls, and may be fished out, leaving eventually a mother-liquor consisting of solution of ammonium chloride only. Mr. Mond's proposed process consists in separating in this way the sodium chloride of the mixed solution in question; in then evaporating the mother-liquor to dryness, so as to obtain solid ammonium chloride; and in then treating this solid ammonium chloride by enough sulphuric acid to form ammonium acid sulphate, $\text{H}_2\text{NH}_4\text{SO}_4$, the chlorine of the ammonium chloride going off as HCl. The residual acid ammonium sulphate is then either to be treated by vapour of free ammonia, and so converted into normal ammonium sulphate for sale as such, or it is to be used, instead of free sulphuric acid and normal ammonium sulphate, in the manufacture of richly ammoniacal phosphatic manures.

If one wished to convey an idea of the stupendous scale upon which ammonia soda is now manufactured, I think one could not do it better than by pointing out some of the conditions which would be necessary to the application of this process to the whole of the ammonium chloride produced by a single ammonia soda maker, Mr. Mond himself. It is no secret that Mr. Mond manufactures fully 50,000 tons of ammonia soda per annum. To treat the whole of the ammonium chloride corresponding to this quantity of ammonia soda by that form of the process in question in which the acid ammonium sulphate at first produced should be afterwards converted into normal ammonium sulphate by means of free ammonia, would require, not only that he should manufacture per annum 128,000 tons of ammonium sulphate, but also that he should command a constant supply of one-third more ammonia than the total quantity at present produced in all Great Britain and Ireland; while to treat that vast quantity of ammonium chloride by the form of his process in which the acid ammonium sulphate immediately produced should be employed to react on calcium phosphate, he must manufacture per annum a quantity of manures

containing 64,000 tons of ammonium sulphate, which quantity of manures could not, I believe, be less than 350,000 tons, or 40 tons for every hour in the whole year, and the production of which would require a supply of ammonia equal to two-thirds of the total quantity at present produced in all the gas works of the United Kingdom. It would involve the annual consumption of a quantity of ammonia,—the production of which in gas works at present requires the distillation of five millions of tons of coal, and the concentration of which, as gas-liquor, upon any one spot, would require that gas-liquor should come pouring in there at the rate of from a ton to a ton-and-a-half per minute, night and day, weekdays and Sundays, all the year through.

Obviously—and, as I have said, I know that this is Mr. Mond's own view—this process cannot be extensively applied so long as we continue dependent for our supply of ammonia mainly on the distillation of coal for the manufacture of illuminating gas; and cannot, indeed, be applied on any serious scale at all except in proportion as means are realised of obtaining as ammonia the nitrogen of coal used as fuel, and as those means are practised in the immediate neighbourhood of ammonia soda works. Such means doubtless will be realised; but very much will happen before the supply of ammonia becomes so abundant as to permit the ammonia soda maker to use his principal reagent only once and then to sell it; and when that time at length arrives I think he will have no temptation to treat his ammonium chloride by sulphuric acid, but if he desires to sell his ammonia, after having used it only once, will probably best find his account in selling it in the form in which his soda process yields it. Meanwhile, I believe that Mr. Mond is not only not preparing to put this process into operation, on any scale whatever, but has no immediate intention of doing so.

An idea for the obtainment of hydrochloric acid in connection with the ammonia process, which has found more favour in many eyes than I think it deserves, and has recently been the subject of very much experiment, is one involving a modification of the ammonia process itself, by the substitution of sodium sulphate for sodium chloride as its starting-point. The idea is to first decompose salt by sulphuric acid, and so obtain hydrochloric acid and sodium sulphate, as in the Leblanc process at present, and then to treat that sodium sulphate by ammonia and carbonic acid. The experiments which have been made in this direction at least place beyond doubt—what before was widely disbelieved—namely, that a sulphate of soda ammonia process, whatever its commercial merits or otherwise, is in itself perfectly practicable. The lower solubility, in water at ordinary temperatures, of sodium sulphate than of sodium chloride, has been supposed to be an obstacle to the realisation of such a process; but there is no inconvenience in employing, in the operation of decomposing sodium sulphate by bicarbonate of ammonia, a temperature of about 34°C. , and at that temperature sodium sulphate is more soluble than sodium chloride: so that it is quite practicable to obtain, by treating by CO_2 an ammoniacal solution of sodium sulphate, more bicarbonate of soda than can be obtained by the corresponding treatment of an equal volume of ammoniacal brine. It has also been supposed that only one-half of the sodium sulphate treated by ammonia and carbonic acid would undergo decomposition, the second half of it going to form, with the ammonium sulphate resulting from the reaction of bicarbonate of ammonia on the first half of it, double sulphate of sodium and ammonium; but experience has proved that this is not so. Nor does the regeneration of ammonia by means of lime from the ammonium sulphate of the mother-liquor of a sulphate of soda ammonia process present any difficulty. The operation can not be performed, owing to the formation in it of solid and bulky calcium sulphate, in precisely the same manner as the corresponding operation of the present form of the ammonia process; but means have been found of effecting it with an ease and completeness which leave nothing to be desired. It has been found, too,

that that calcium sulphate can be readily separated from so much of the residual solution, containing a good deal of sulphate of soda, in which it is at first suspended, that, —the separated solution being used to dissolve the next quantity of solid sodium sulphate entering the process—the loss of sodium sulphate in a sulphate of soda ammonia process need be only extremely small. It seems quite clear, therefore, that such a process would present no practical difficulty whatever.

But, *cui bono*? To merely substitute for the Leblanc method of decomposing sodium sulphate its decomposition by bicarbonate of ammonia, would surely be a game not worth the candle. In the Leblanc process, as in so many other things, *c'est le premier pas qui coûte*. It is the first operation of the Leblanc process which makes that process so costly. It is the cost of his sodium sulphate which places the maker of Leblanc soda at such a disadvantage as compared with the maker of ammonia soda. If sodium sulphate cost the former no more than salt costs the latter, it is Leblanc soda, and not ammonia soda, which would be the cheaper of the two; since the cost of manufacturing Leblanc soda from sodium sulphate is appreciably less than the cost of manufacturing ammonia soda from salt. The treatment of sodium sulphate by ammonia and carbonic acid would at least not be less costly than the treatment of sodium chloride by the present form of the ammonia process; and hence to merely substitute for the Leblanc method of decomposing sodium sulphate the method of decomposing it by bicarbonate of ammonia would be to substitute for the later operations of the Leblanc process a series of more costly operations, having no advantage beyond one of scarcely appreciable commercial value, that of yielding a more concentrated product.

While, however, the only advantage of a process which should consist in manufacturing sodium sulphate as in the Leblanc process at present, and then decomposing that sodium sulphate by bicarbonate of ammonia, would thus be one which would not be worth the cost of obtaining it; a process, based on the decomposition of sodium sulphate by bicarbonate of ammonia, has recently been devised, which stands upon a very different footing. In the process to which I now refer the sodium sulphate to be afterwards decomposed by bicarbonate of ammonia would be obtained, and hydrochloric acid at the same time, without consumption of sulphuric acid, except to make up mechanical loss, by means of one and the same quantity of sulphuric acid continually regenerated and used again.

This remarkable process is the invention of three members of the firm of Gaskell, Deacon, and Co., of Widnes: Mr. Carey, Mr. Holbrook Gaskell, junr., and Dr. Hurter. These gentlemen have found a means of so decomposing ammonium sulphate as to obtain, not only its ammonia in the free state, but also its sulphuric acid, if not as free sulphuric acid, at any rate in a state in which it can decompose sodium chloride.

Chemists have long known that when ammonium sulphate is heated to a certain temperature one-half of its ammonia is set free and flies off, the other half of it remaining behind as hydrogen ammonium sulphate. Messrs. Carey, Gaskell, and Hurter have discovered that if a mixture of equivalent quantities of ammonium sulphate and sodium sulphate be heated to fusion, and steam be injected into the liquid mass, the whole of the ammonia of the ammonium sulphate is disengaged in the free state: its sulphuric acid combining with the sodium sulphate to form hydrogen sodium sulphate, which alone remains behind.

Upon this most interesting reaction there may obviously be based a soda process which should begin by obtaining sodium sulphate and hydrochloric acid by the reaction of "bisulphate of soda" on sodium chloride, the normal sodium sulphate so obtained being then decomposed by bicarbonate of ammonia, with production of bicarbonate of soda and ammonium sulphate, such ammonium sulphate being then so treated as to regenerate, by one and the same operation, both ammonia for use again and bisulphate of soda for use again.

The question of whether or not this most original and beautiful process can be reduced to practice must obviously depend, mainly if not solely, upon the degree of readiness with which the new reaction upon which it is based can be carried to such completeness as to avoid any serious loss of ammonia. I am unacquainted with the experimental results on this point which have so far been obtained; but it is easy to see that that reaction might be somewhat slow, and, therefore, somewhat costly, and yet the process based upon it be one of very serious importance.

Charging against the hydrochloric acid yielded by Messrs. Carey, Gaskell, and Hurter's process the cost of those operations of their process which are in excess of the operations which the ammonia soda maker performs at present, one may count that the cost of their soda would be practically the same as that of ammonia soda as at present manufactured from brine. Their process would start from solid salt, which is, of course, more costly than brine; but, in some localities, at any rate, the value of the lime which is required for the decomposition of the ammonium chloride of the present form of the ammonia process, but which would not be required in Messrs. Carey, Gaskell, and Hurter's process, would fully compensate the greater cost for raw materials of the latter than of the former.

The operations, the cost of which would thus have to be charged against Messrs. Carey, Gaskell, and Hurter's hydrochloric acid, are those: firstly, of evaporating to dryness the mixed solution of ammonium sulphate and sodium sulphate constituting the mother-liquor of the bicarbonate of soda obtained by treating an ammoniacal solution of sodium sulphate by carbonic acid; secondly, of treating the residue of that evaporation, after addition to it of more sodium sulphate, for the regeneration of ammonia and the production of bisulphate of soda; and, thirdly, of then furnacing that bisulphate of soda with an equivalent quantity of salt.

The quantity of water which would have to be evaporated, in the first of these three operations, per ton of sodium carbonate manufactured, may be put, I believe, at five-and-a-half tons. It would be the water of a mixed solution of ammonium sulphate and sodium sulphate, and as these are both salts which, like sodium chloride, absorb heat during solution in water, and so give out heat during the inverse operation,—the two together in the proportions in which they would be present in the solution in question, to just about the same extent as sodium chloride,—it ought to be possible to evaporate those five-and-a-half tons of water by means of the one ton of fuel which suffices for the evaporation of more than that quantity of water from brine. For the third operation, which would correspond to the second half of the first operation of the Leblanc process, less than half-a-ton of fuel should be ample. The labour upon these two operations would obviously be but slight, so that the cost of both operations together, for fuel and labour, per ton of sodium carbonate manufactured, could scarcely, I think, exceed eleven or twelve shillings.

The quantity of hydrochloric acid which corresponds to the quantity of sodium chloride corresponding to a ton of sodium carbonate, counted as aqueous acid of 27 per cent, is 2'548 tons. There are some Leblanc soda works in which the proportion of the total HCl evolved therein, which is obtained as aqueous acid of useful strength, is fully 95 per cent. Assuming this proportion of the HCl evolved in Messrs. Carey, Gaskell, and Hurter's process to be obtained in an useful form, the process would yield, per ton of sodium carbonate manufactured by it, a quantity of aqueous acid corresponding to 2'42 tons at 27 per cent.

The value of this quantity of hydrochloric acid I estimate at £2 8s., and I arrive at that value for it in this way. The difference between the cost of ammonia soda and that of Leblanc soda, plus hydrochloric acid, per quantity of Leblanc soda equivalent to a ton of ammonia soda, now averages, I believe, in England, about £2 15s.

These £2 15s. I take to be the value, in the sense of the actual cost, not of the quantity of hydrochloric acid, of useful strength, which is usually obtained concurrently with that quantity of Leblanc soda, but, what is by no means the same thing, of the greatest quantity of such acid which is obtained, per such quantity of soda, in any instance within my knowledge. This quantity,—for we must remember that the Leblanc soda maker has to produce more sodium sulphate, and, consequently, more hydrochloric acid, than merely the quantity equivalent to the alkali he finally obtains,—is 95 per cent of the quantity corresponding to about twelve-and-a-half per cent more sodium sulphate than the quantity of sodium sulphate equivalent to a ton of sodium carbonate, and is thus, counted as acid of 27 per cent, almost exactly two-and-three-quarter tons: £2 15s. for which quantity is just £1 per ton, or £2 8s. for the 2½ tons which I have taken to be obtainable, by the process under consideration, per ton of sodium carbonate manufactured thereby.

Taking it, then, that the minimum present cost of aqueous hydrochloric acid of 27 per cent is £1 per ton; that Messrs. Carey, Gaskell, and Hurter's process could yield, per ton of sodium carbonate manufactured by it, 2½ tons of such acid, thus worth at least £2 8s.; and that, of the three operations the cost of which would have to be charged against those 2½ tons of hydrochloric acid, twelve shillings would pay for two: there would thus remain £1 16s., the balance left after the deduction from which sum of the cost of effecting Messrs. Carey, Gaskell, and Hurter's reaction on about 2 tons 12 cwt. of a mixture of ammonium sulphate and sodium sulphate, would be the measure of the advantage of their process over the Leblanc process.

It is so difficult to conceive that the cost of effecting the reaction in question upon the quantity of materials which I have mentioned could be anything like £1 16s., that for this process of Messrs. Carey, Gaskell, and Hurter's I could not but anticipate a most important future; were it not for the results of a renewed attempt which has for some time past been in progress to realise the old idea of decomposing the ammonium chloride of the present form of the ammonia process by magnesia, and then so treating the resulting magnesium chloride as to obtain its chlorine in a useful form and at the same time to regenerate magnesia for use again. In this method of procedure there would be one operation less than in Messrs. Carey, Gaskell, and Hurter's process: the operation of evaporation, which would be practically the same in both processes, being followed in Messrs. Carey, Gaskell, and Hurter's process by two operations, in the first of which there would be treated, per ton of sodium carbonate manufactured, about 52 cwts. of mixture of sodium sulphate and ammonium sulphate, and in the second about 68 cwts. of mixture of sodium chloride and hydrogen sodium sulphate, while, in what may be called the magnesia process, the operation of evaporation would have to be followed by simply the one operation of decomposing about eighteen-and-a-half hundredweight of magnesium chloride. To which must be added the far graver consideration, that while Messrs. Carey, Gaskell, and Hurter's process can yield the chlorine of salt treated by it only as hydrochloric acid, a large part of the chlorine of magnesium chloride can be obtained directly in the free state.

It is MM. Pechiney et Cie., of Salindres, in the South of France, who have had the boldness to attack again the problem,—upon which so many earnest workers had spent in vain their utmost efforts during many years,—of how to obtain, as magnesium chloride, the chlorine of the salt decomposed by the ammonia process; and their genius and skill have enabled them to reach results which compel the conviction that the industrial realisation of the decomposition by magnesia of the ammonium chloride of the ammonia process is now only a question of time.

If, then, the manufacturer of ammonia soda shall become able, as he certainly will become able, to obtain as magnesium chloride the chlorine which he at present

throws away as calcium chloride, how is that magnesium chloride to be dealt with? When an aqueous solution of magnesium chloride is subjected to evaporation, vapour of hydrochloric acid begins to be disengaged so soon as the quantity of water present has fallen to six equivalents, per equivalent of magnesium chloride. Fifteen or sixteen years ago, at the Gerard's Bridge Works of Messrs. J. C. Gamble and Son, of St. Helens, very considerable quantities of solution of magnesium chloride, concentrated to that point, were treated in muffle furnaces. The magnesium chloride was readily enough decomposed, but the furnaces were rapidly destroyed—by reason of the concentrated solution fed into them penetrating their beds—and causing the beds to “rise.” The Gerard's Bridge experiments on the decomposition of magnesium chloride were therefore abandoned; but not until they had proved that the difficulties in the way of decomposing that compound industrially by heating it in an atmosphere of vapour of water, were simply mechanical difficulties.

Seeking, during many years subsequently, means of treating by heat and air, under industrial conditions, chlorides of various metals, I was at length led, in 1881, to the idea of adding to a concentrated solution of a chloride or mixture of chlorides, oxide of the same metal or metals, and then treating by heat and air solid masses of the resulting mixture; and since early in 1882, MM. Pechiney et Cie. have been earnestly engaged in endeavouring to realise this method of working: especially as applied to magnesium chloride, enormous quantities of which they obtain as a by-product of the manufacture of salt from sea-water, and also to manganese chloride. In the case of magnesium chloride, the product of the addition to its aqueous solution of magnesium oxide is, of course, not a mere mixture, but the compound, magnesium oxy-chloride. I had found in the laboratory that this body, heated in contact with air under certain conditions, gives off an appreciable part of its chlorine in the free state; and the larger experiments which have since been made at Salindres leave no doubt that fully half the chlorine of magnesium chloride may be obtained directly as free chlorine by converting the magnesium chloride into oxy-chloride, and then heating that oxy-chloride, under certain conditions, in presence of air. What this means is that a manufacturer of ammonia soda, able to decompose his ammonium chloride by magnesia, will be able, by evaporating, per ton of ammonia soda manufactured, a quantity of solution of magnesium chloride containing about five-and-a-half tons of water, and then heating in presence of air a mixture of about eighteen-and-a-half hundredweight of magnesium chloride with about eight hundredweight of magnesia, to obtain the quantity of free chlorine corresponding to very nearly a ton of bleaching-powder,—being the quantity of chlorine the present cost of which, as I shall show in a moment, is close upon £6,—and, in addition, a quantity of hydrochloric acid corresponding to something over a ton of aqueous acid of 27 per cent. The chlorine obtained by heating magnesium chloride in contact with air is of course diluted by other gases; but MM. Pechiney et Cie. have in operation an extremely simple mechanical bleaching-powder chamber, the complete absorption in which of the chlorine of a mixture of chlorine and other gases presents no difficulty.

(To be continued.)

The Probability of a Transformation of Strychnine in the Animal Organism.—P. C. Plugge.—The author is engaged with the examination of strychnic acid—an oxidation product of the base. Strychnic acid is a monobasic acid, not bitter, and in doses of 16 to 20 milligrams. has no poisonous action upon frogs, pigeons, and rabbits. With sulphuric acid and potassium bichromate it gives a splendid red-violet colour, which then becomes red and fades away. (Strychnine gives first a blue-violet colour, which afterwards turns to a red-violet.)—*Zeitschrift für Analytische Chemie.*

CORRESPONDENCE.

THE ACTION OF ARSENIOS ANHYDRIDE UPON GLYCERIN.

To the Editor of the Chemical News.

SIR,—The compound recently described by Mr. Herbert Jackson (CHEM. NEWS, vol. xlix., p. 258)—

was discovered by H. Schiff in 1867 (*Bull. Soc. Chim. de Paris*, (N.S.), vol. viii., p. 99).

Like Mr. Jackson I re-discovered this compound shortly before I heard of Schiff's paper.—I am, &c.,

EDWARD E. BERRY.

8, Belle Vue, Cotham, Bristol,
July 27, 1884.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcvi., No. 24, June 16, 1884.

Description of a New Evaporation and Distillation Apparatus for the Pneumatic Treatment of Saccharine Liquids.—P. Calliburgès.—This apparatus cannot be intelligibly described without the accompanying figures.

On Certain Colloidal Compounds, derived from Ferric Hydrate.—E. Grimaux.—The solutions in question are compounds of glycerin, ferric hydrate, and alkalies or alkaline carbonates. Their composition has not been determined, as the jellies which they yield on coagulating are decomposed on prolonged washing, and leave merely ferric hydrate. Their reactions show that they are easily dissociated by water into glycerin and insoluble compounds richer in ferric hydrate. Mannite and erythrite behave similarly to glycerin.

Detection of Nitric Acid and Nitrates in Vegetable Tissues.—A. Arnaud and L. Padé.—Cinchonamine nitrate is almost absolutely insoluble in water acidulated with any acid whatever. If into the solution of a nitrate we pour a small quantity of a salt of cinchonamine previously dissolved in water acidified with hydrochloric acid nitrate of cinchonamine is thrown down. It appears probable that the nitrates may be determined in this manner, as the nitrate of cinchonamine is completely insoluble in an acid solution, and its composition is definite and constant ($\text{C}_{19}\text{H}_{24}\text{N}_4\text{O}_3\text{H}$). The detection of nitric acid may be advantageously effected by this method.

Soldering Aluminium.—M. Bourbouze.—The author asserts that hitherto it has been found impracticable to solder aluminium either to itself or to other metals. He proposes to coat those parts which are to be joined together either with an alloy of tin and zinc, or of tin and aluminium.

Purification of Arseniferous Zinc.—L. L'Hôte.—The author throws into the melted zinc 1 to 1½ per cent of anhydrous magnesium chloride. On stirring there are given off white fumes of zinc chloride which carry off the arsenic. If the metal is granulated in cold water, it is found completely free from arsenic. The same process removes antimony, which is rarely present in the zinc of commerce.

No. 25, June 23, 1884.

Universal Presence of Nitrates in the Vegetable Kingdom.—M. Berthelot.—The author has, for a year, been especially engaged with an examination of the nitrates present in the tissues of certain plants, with their origin, and the part which they play in vegetable physiology. His experiments tend to establish the existence of a new vegetable function, giving rise to the formation of nitrates in certain vegetable tissues, and during a determined period of vegetation. It results from the action of certain celluloses acting doubtless after the manner of the nitric ferment of MM. Müntz and Schloësing.

On Certain Phenomena of Occlusion.—P. Schützenberger.—The author refers to the fact that oxygen prepared from a mixture of potassium chlorate and manganese dioxide carries along with it a considerable quantity of chlorine and oxides of chlorine. Such oxygen, though well washed with water and kept for two or three weeks in a metal gas-holder in presence of a considerable volume of water, still retains, so to speak, a reflection of the odour of chlorine, and attacks caoutchouc tubes like ozone. Still such oxygen may be allowed to bubble slowly for hours through a solution of silver nitrate, or through water faintly coloured with blue litmus, or with sodium indigotate, without producing the reactions of chlorine, or hydrochloric acid, or of one of the oxygen acids of chlorine. If, on the contrary, the current of oxygen, before being submitted to these reagents, is passed through a narrow platinum tube at one point, the presence of chlorine is distinctly shown; the indigo is bleached and the silver nitrate is precipitated. The author thinks that this is a case where the one gas is occluded in the other. He gives, also, a case when watery vapour is occluded by potassium chromate, which may occasion errors when the latter compound is used in organic analysis. Oxygen is also sometimes retained in an abnormal state by copper oxide.

Novel Method for the Synthesis of Nitrogenous Organic Compounds. Total Synthesis of Xanthine and Methyl-xanthine.—Arm. Gautier.—The regulated polymerisation of hydrocyanic acid in presence of water yields xanthine and methyl-xanthine. If, in the above reaction, the water is replaced by the various mono- or poly-atomic alcohols, the acetones, aldehydes, phenols, &c., we obtain an almost indefinite series of new compounds.

On Potassium and Barium Glyoxal-bisulphites.—M. de Forcrand.—A thermo-chemical paper, which does not admit of useful abridgment.

On Colloidal Ferric Salts.—E. Grimaux.—The salts described are potassium ferri-tartrate, the ferric arseniate and arsenite.

Researches on the Xylenes.—A. Colson.—The author has resumed the comparative study of the alcohols derived from these carbides. He describes in the present paper the diatomic alcohols, orthoxylenic glycol (the phthalic alcohol of Hessert), with the orthoxylenic bi-bromide and bi-chloride.

The Natural Saltpetres of Chili and Peru, as concerns Rubidium, Cæsium, Lithium, and Boric Acid. Inferences relative to the Beet-root Lands of North France.—M. Dieulafoy.—M. Grandeau in 1863 pointed out the richness in rubidium of the salts from the beet-root of North France. He shows at the same time the absence of cæsium and lithium. The author has examined 14 salts prepared from the beet-roots of Lower Normandy, from land never manured with foreign saline matter, and finds in them neither rubidium nor cæsium, whilst the spectrum of lithia was often intense. Latterly he has examined a sample of the mother-liquor from refining nitre in Chili. In opposition to the results of Kirchhoff, Bunsen, and Grandeau, the author found these waters rich in rubidium, very poor in lithium, and probably free from cæsium. Soils which are dressed yearly with crude nitre receive a considerable proportion of rubidium. The law of association of rubidium and cæsium with lithium, proposed by Kirchhoff and Bunsen, which seemed to be contradicted by the absence of lithium in beet-root, is now confirmed.

Zeitschrift für Analytische Chemie.
Vol. xxiii., Part 2.

Determination of Nitrogen in Organic Substances.—A number of processes are given, the more important of which have been already noticed.

The Determination of Starch in Articles of Food.—C. Faulenbach.—The author begins the conversion into sugar by means of diastase. When all the starch is dissolved he filters off the cellulose and completes the conversion into sugar by means of hydrochloric acid.

Precipitation of Glucose by Basic Lead Acetate.—P. Lagrange.—From the *Comptes Rendus*.

Determination of Cane Sugar by Polarisation after Inversion.—P. Casamajor.—From the *CHEMICAL NEWS*.

Determination of Carbonic Acid in Air.—A. Muntz and E. Aubin.—From the *Comptes Rendus*.

Analysis of Milk.—A notice of processes which have appeared in the *CHEMICAL NEWS* and the *Analyst*.

The Rapid Determination of Salicylic Acid in Beverages.—A. Remont.—From the *Comptes Rendus*.

The Adulteration of Cheese.—A. Langfurth.—The author examines the quantity of decinormal soda-lye respectively required for saturating equal weights of the fatty acids of natural and of factitious cheeses.

Examination of Wall Papers.—A. Gawalowski.—The author fills a large wide-mouthed bottle with clippings of the paper, and sets upright in it three large test-tubes, one half-filled with luke-warm water, another half-filled with carbonic acid water, and a third half-filled with ordinary vinegar. The glass is now closed, and two slips of filter-paper wedged in between the neck and the stopper, —the one steeped in lead acetate and the other with silver nitrate. The whole is let stand for some days. If the lead-paper is blackened, the author considers the paper injurious as emitting sulphuretted hydrogen. If the silver paper remains black after it has been steeped for two hours in a 10 per cent solution of potassium cyanide, the paper is condemned as giving off hydrogen arsenide.

The Detection of Petroleum added to Oil of Turpentine.—H. C. Armstrong.—From the *Journal of the Chemical Society*.

The Detection of Carnauba Wax.—E. Valenta.—Table showing the melting-points of carnauba wax, commercial stearic acid, ozokerite, paraffin, and of various mixtures.

Examination of Tallow.—O. Wolckenhaar.—A statement of the specific gravities and melting-points of ox and mutton-tallow.

Analysis of Oils.—Papers by Bach, David, and Krechel, which do not admit of useful abstraction.

Scheme for the Analysis of Soaps.—A. R. Leeds.—Already noticed.

Examination of Acetate of Lime.—F. Goebel.—The author employs a soda-lye of which 1000 c.c. exactly neutralise 100 grms. acetic acid and a phosphoric acid equivalent to the soda-lye. A weighed portion of the sample is mixed in an evaporating basin with a measured excess of the phosphoric acid and evaporated to dryness on the water-bath. The residue is re-dissolved in water and again evaporated, repeating the operation until no odour of acetic acid is perceptible. It is then dissolved in water and the excess of acid is titrated with soda-lye, using phenol-phthaleine as indicator. The phosphoric acid required for saturating the bases is calculated as acetic acid. The result thus obtained is too high, since the caustic lime and carbonate of lime, always present in the commercial salt, figure here as acetate. We determine, therefore, in a fresh portion of the original sample the quantity of hydrate and carbonate of lime by titration with hydrochloric acid, equivalent to the soda-lye employed, using litmus as indicator. The result is calcu-

lated as acetic acid and subtracted from the former amount.

Valuation of Yeast.—E. Meissl.—The author's method turns on the determination of the carbonic acid evolved from a standard saccharine solution.

Detection of the Eosines.—R. Benedikt.—Already noticed.

Separation of Aniline, Paratoluidine, and Orthotoluidine.—L. Lewy.—The hydrochlorates of these bases are mixed with sodium phosphate. There are formed, sparingly, soluble aniline and paratoluidine phosphate along with soluble acid, orthotoluidine phosphate, and free orthotoluidine. After this decomposition, the two first mentioned salts are kept in solution by the application of heat, the only supernatant layer of orthotoluidine is syphoned off, and the salts of aniline and paratoluidine are allowed to crystallise out. The mother-liquor contains the acid orthotoluidine phosphate. On separating the bases by means of soda the sodium phosphate is recovered.

Determination whether a Photographic Emulsion has been Boiled too long.—Otto Pfenniger.—Solution of tannin is added; the emulsion turns a reddish-brown if it has been boiled too long.

Rapid Valuation of Hydraulic Cements.—E. Landrin.—From the *Comptes Rendus*.

Determination of Carbon Disulphide in the Sulphocarbonates.—A. Muntz and E. Falieres.—From the *Comptes Rendus*.

Detection of Resin in Ethereal Oils.—A. Belohoubek.—The author mixes a drop of the ethereal oil in a dry test-tube, at first with one drop of petroleum ether, then with two, and gradually with several. If resin is present a white precipitate, or at least an opalescence, appears.

A Test for the Ethereal Oil of Juniper.—G. Thoms.—The author mixes a drop of the oil with 5 c.c. alcohol, and a drop of official tincture of iodine. If the oil is pure the yellow colour of the liquid disappears in a few seconds on shaking.

Hager's Microscopic Method for the Detection of Arseniate in Sodium Phosphate and Nitrate.—The author has once detected arsenic acid in sodium nitrate and leaves it an open question whether this impurity occurs more frequently. He rubs several crystals to powder, and heats 0.05 grm. along with 0.15 grm. in a small, short dry test-tube, until an escape of gas can no longer be detected. Upon the residue he pours about 1 c.c. dilute arsenic acid, adds then a few granules of oxalic acid and 0.5 c.c. of water, lets dissolve, and puts 1 to 2 drops upon a thin glass slip. He evaporates to dryness over a petroleum lamp and heats for a few moments until white fumes arise. Under the microscope there appear colourless crystalline deposits, and, if arseniate is present, black, opaque ramifications and margins.

The Solubility of Calcium Phosphate in Urine.—B. J. Stokvis.—The phosphatic precipitate formed on boiling urine free from albumen consists of basic calcium phosphate, containing occasionally traces of calcium phosphate and carbonate, but entirely free from magnesium compounds. On cooling, it re-dissolves, whilst the original neutral phosphate is re-formed.

Determination of Chloroform in the Blood.—MM. Gréhaut and Quinquaud.—From the *Comptes Rendus*.

A Simple Apparatus for Determining Urea with Sodium Hypobromite.—W. H. Greene.—From the *Comptes Rendus*.

Sulpho-diazo-benzol as a Reagent for Bilirubine.—P. Ehrlich.—The author has tested the bile pigments, bilirubine, bilifuscin, biliprasine, bililumine, and urobiline, with recently prepared solutions of diazot-benzol. The so-called Ehrlich's reagent, containing 1 grm. sulpho-anilic acid, 15 c.c. hydrochloric acid, and 0.1 grm. sodium nitrite in 1 litre of water. Bilirubine alone gave charac-

teristic colour phenomena. Its solution in chloroform, mixed with 1 or 2 vols. of the reagent and then with alcohol enough to form a homogeneous liquid, gives a play of colours for about a minute. The yellow colour turns to a red, and on the gradual addition of strong hydrochloric acid passes through violet to an intense splendid blue. This blue pigment is permanent, but displays its beautiful blue colour only in strongly acid liquids; in presence of strong alkalis it is a greenish-blue, and in neutral, feebly alkaline, or feebly acid liquids it appears red. In testing urine for bilirubine, Ehrlich adds first an equal volume of dilute acetic acid, and then the solution of sulpho-diazobenzol. If the mixture darkens, a further addition of an acid, e.g., glacial acetic acid, brings up the characteristic colour of bilirubine.

Pigments formed on Heating Urine with Acids.—P. Plösz.—The change of colour is due to the production of a number of pigments, one of which named uromelanine, by Plösz, constantly appears, whilst urobiline and indigo occur very frequently. Uromelanine is probably identical with Heller's "urrodine" and Thudicum's "uromelanine."

The Determination of Globuline in the Serum of the Blood.—A. E. Burckhardt.—The "globuline" obtained by Hammarsten's process is a mixture of two albumenoids, paraglobuline, and a body having many properties in common with the albumens.

The Optical Determination of Hæmoglobine.—The error in Vierordt's instrument is overcome if the slit is provided with Kruss's arrangement.

Preparation of Sulphuretted Hydrogen free from Arsenic.—R. Otto.—The author prepares sulphuretted hydrogen for judicial analyses from calcium or barium sulphide with pure non-arsenical hydrochloric acid.

Researches on the smallest Fatal Dose of the Alkaline Chlorides.—C. Richet.—From the *Comptes Rendus*.

On Cantharidine.—E. Dietrich.—Cantharidine dissolves in 30,000 parts of cold and 15,000 parts of hot water. Its solubility is increased by the presence of a small quantity of sulphuric acid or of an ethereal oil.

The Ptomaines.—A compilation from the *Comptes Rendus*, the *Journal für Praktische Chemie*, the *Journal of the Chemical Society*, &c.

The Atomic Weights of Copper, Zinc, and Nickel.—H. Baubigny.—From the *Comptes Rendus*.

The Equivalent Weight of Antimony.—J. Bongartz.—The author finds the equivalent of antimony (referred to $O=79.816$) = 120.193 ; or, taking $O=8$, $Sb=120.470$

Bulletin de la Société d'Encouragement pour l'Industrie Nationale. 3e Série. Tome xi., April, 1884.

Report Presented by M. Bérard on behalf of the Committee of Chemical Arts on an Apparatus for the Production of Hydrogen by M. Egasse.—There is nothing novel in the inventors' principle of producing hydrogen, which is intended for the inflation of balloons.

Origin of the Combined Nitrogen Existing on the Surface of the Earth.—MM. A. Muntz and E. Aubin.—At the origin of the development of organised beings the authors consider there must have been a considerable stock of nitro-compounds. Perhaps we may attribute the luxuriance of vegetable and animal life in the geological epochs to this abundance of combined nitrogen, which in our times is rare and which must be added to the soil at great expense to increase its fertility. On this assumption it seems that we are living upon a stock of combined nitrogen produced at the beginning, and that we are liable to see this quantity decrease under the influence of the causes which restore to a gaseous state the nitrogen which has served in the formation of living beings unless

the supply due to atmospheric electricity restores the balance.

Cosmos les Mondes.

No. 6, June 7, 1884.

Formation-Heat of the Sulphides and the Law of Thermic Constants.—Dr. D. Tommasi.—The author argues that M. Thomsen's determinations of the combining-heats of the neutral and acid sodium sulphites are inaccurate, and that the values more recently obtained by M. de Forcrand agree fairly with those calculated.

No. 7, June 14, 1884.

This issue contains no chemical matter.

No. 8, June 21, 1884.

The Transformation of the Theory of Atoms.—Vidtor Meyer.—A summary of the hypothesis of Prout and of the periodic system of Prof. Mendeleeef and Lothar Meyer, Mr. Newlands being completely ignored.

No. 9, June 28, 1884.

The Existence of Manganese in Plants and its Part in Animal Life.—E. J. Maumené.—Already noticed.

No. 10, July 5, 1884.

This number contains no chemical matter.

No. 11, July 12, 1884.

Copper from a Sanitary Point of View.—Dr. H. George.—Copper possesses no general toxic action upon persons saturated with it; the slight troubles which it may induce are due merely to a local irritation. But on the other hand it does not confer on such persons any special immunity from epidemic diseases, and should not inspire any illusive security.

THE JOURNAL OF SCIENCE,

PATENT OFFICES—5, LORD STREET, LIVERPOOL, and 323, HIGH HOLBORN, LONDON.

Water-Glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S Ardwick Chemical Works Manchester.

Silicates of Soda and Potash in the state of Soluble Glass, or in CONCENTRATED SOLUTION of first quality, suited for the Manufacture of Soap and other purposes, supplied on best terms by W GOSSAGE and Sons, Soap Works Widnes, Lancashire.

London Agents, COSTE and Co., 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

BICHROMATE OF SODA.

Potter and Higgin's Patent

100 parts equal to 101—104 parts
Pure Potassium Bichromate.

PERFECTLY SOLUBLE IN ITS
OWN WEIGHT OF WATER.

Is used in place of the Potash
Salt in all its applications, and
gives perfect satisfaction.

*Is sold in large or small lots
to suit consumers, packed in
strong 5-cwt. barrels.*

Is lower in price than
the Potash Salt.

SOLE MAKERS—

NOTE ON EXAMINATION OF SNOW WATER.

By E. WALLER, Ph.D.

DURING the first snow-storm of the past winter (December 19th, 1883) some of the fresh fallen snow was collected and submitted to examination. As the results may be of some interest I beg to submit them.

The sample was collected in the yard at Columbia College after it had been snowing for some three or four hours, and snow was still falling. The ground was then covered to the depth of about 4 inches.

The snow was taken up without touching it with the hands, and placed in a large stoppered bottle, which was then closed and placed on the shelf in the laboratory until the snow had melted. It may be here noted that the surface beneath the spot from which it was taken was a gravelled walk. The examination of the water was conducted after the larger particles of sand, coal from the engines on the 4th ave, &c. had settled out. The water was slightly turbid. The results were (in parts per 100,000):—

Chlorine	trace
Phosphates	none
Nitrates	none
Nitrogen in nitrates	0.0494
Free ammonia	0.0396
Albumenoid ammonia	0.0318
Hardness	0.91
Total solids	6.3

The sediment from the water was collected. While it was settling a slimy fungoid growth collected at the bottom of the vessel, which caused the sediment to adhere somewhat to the glass. To remove this the material was gently ignited and afterward examined under the microscope. The object aimed at was the identification, if possible, of particles supposed to have come from the Java volcano, Krakatoa, which have been asserted to exist in the snow, &c., which fell in the early part of the winter. A specimen of the volcanic ash known to have come from that volcano was also examined under the microscope at the same time. A one-fifth objective (Beck) was used. To my eye the only forms common to both the specimens were small, vitreous particles looking like broken up microscope covers.

I am, however, not familiar with the characters of volcanic ashes under the microscope, and may have missed what should be looked upon as characteristic. Judging from what was observed, it seems doubtful whether it could be safely asserted that the snow contained any particles which originally came from the volcano.—*Journal of the American Chemical Society.*

METHOD FOR THE ASSAY OF INDIGO.

By CHARLES TENNANT LEE.

THE determination of indigo blue, or indigotin, in indigo presents various difficulties. The processes in use are long, and subject to considerable error. The methods which depend upon the reduction and subsequent measured oxidation of indigo require the elimination, previously, of all other reducible bodies, to ensure accuracy—an operation both long and tedious. The method by formation of sulph-indigotine and its estimation by a standardised perman-

ganate solution, always gives too high results by reason of the presence of other oxidisable bodies.

For several years the author has used a method by sublimation, which has been uniformly satisfactory. Indigo blue sublimes readily, and, by a careful regulation of temperature, can be separated from the other components of indigo, indigo brown, indigo red, mucilaginous matter, &c.

The operation is best effected in a shallow platinum tray. Those in use are 7 c.m. long, 2 c.m. wide, 3 to 4 m.m. deep. Into such a tray is weighed about 0.25 grm. of finely-powdered indigo which has been dried at 100° C. The weighing should be rapid to avoid absorption of moisture, and it is best not to exceed this amount greatly for a tray of the size noted, in order that the layer of indigo may be thin.

Spread the weighed powder evenly over the tray by tapping it with the finger: this can be done easily if the bottom of the tray is quite flat, with no rounding towards the sides. Sublime on an iron plate, at first raising the heat gradually to avoid burning.

When the surface of the indigo is covered over with a shining layer of crystals, turn down upon the plate a piece of Russia iron bent into the form of a flat arch, the highest point of which is about 1 c.m. above the plate, and a little longer than the tray. Lower the heat at the same time that the arch is put on, as the temperature rises rapidly.

The purple vapours of indigotin are now given off, a portion condensing upon the under sides of the arch. Raise the heat slowly, and enough to maintain a constant sublimation of indigotin. By raising the arch the progress of the work is seen. For a 50 per cent indigo the time required is 30 to 40 minutes; but soft, Java indigo must be sublimed with more caution, and sometimes require two hours. The last crystals of indigotin are easily seen upon the dark coloured surface of the residue. When all have disappeared, remove the tray, cool in a desiccator, and weigh. The loss in weight is indigotin. Observe that the heat be no greater than is required to sublime the indigo blue; and that no yellowish vapours appear, which would indicate the destruction of the residue, leaving only ash.

If the bottom of the tray is flat and everywhere touches the plate, the sublimation goes on regularly except in case of very rich indigos, already mentioned, when care must be exercised to prevent burning.

Results by this method are constant within $\frac{1}{4}$ of 1 per cent, but the author has frequently made re-determinations with variations of only half that error.

A little practice enables one to leave the sublimation with only occasional attention, and three or four determinations may be carried on at once under the same arched cover.

For commercial and industrial purposes this method appears to have decided advantages. Its rapidity is in great contrast to the other methods which admit of perhaps two determinations in a day, while in point of accuracy it is not wanting.—*Journal of the American Chemical Society.*

Laboratory, 45, Kilby-street,
Boston, May 5, 1884.

DETERMINATION OF BORIC ACID IN BORO-SILICATES.

By C. BODEWIG.

THE determination of boric acid, as such, or in simple borates, involves, according to usual methods, no especial difficulties provided that pure reagents are employed, and especially hydrofluoric acid free from silica. More difficult is the determination if silica is simultaneously present. For the separation of both acids it is usual to fuse the mineral with four parts of alkaline carbonate, to lixiviate the melt first with pure water and then with water to which a drop of solution of ammonium carbonate has been

added, to wash and to precipitate the silica from the filtrate by means of ammonium sesquicarbonate or chloride.

The addition of ammonium sesquicarbonate is effected in such a proportion ($2\frac{1}{2}$ parts) that all alkaline carbonate is converted into bicarbonate. The ammonium carbonate formed is evaporated almost entirely away on a simmering water-bath, and the silica is washed with water to which a little ammonium carbonate has been added. A considerable proportion of silica remains in solution in the alkaline liquid, which after expulsion of all ammonium carbonate is precipitated by zinc oxide dissolved in ammonia as zinc silicate, all ammonia being expelled by heat. It is rarely practicable to remove all the silica by a single treatment of the alkaline solution. If the experiment is repeated with 10 c.c. solution of zinc oxide, and if the precipitate is dissolved in hydrochloric acid, the silica can be readily detected by the addition of ammonia in excess. It is unimportant whether the solution of zinc oxide is added to a concentrated or a dilute alkaline solution. A concentrated solution of alkaline carbonate (1 : 15) has, however, the disadvantage of dissolving zinc oxide in considerable quantity, whilst a solution of 1 : 50 does not dissolve zinc oxide. It is, therefore, preferable to remove the last traces of silica by diluting the solution to 1 : 50 and adding 10 c.c. solution of zinc oxide, driving off all ammonia, making good the loss of water and repeating the precipitation with zinc oxide a second time. Or the alkaline solution may be concentrated, solution of zinc oxide added until no further precipitate is produced in a filtered portion, diluted to 1 : 50 and then further treated as above. The precipitation is here also incomplete and a repetition is needful.

On repeated treatment with solution of zinc oxide a little zinc borate appears to be thrown down, as the results are too low.

If the alkaline solution is only once treated with zinc oxide, not only silica may remain in solution, but during the long evaporation of the alkaline liquid for the expulsion of ammonia, zinc silicate is dissolved.

From these reasons it is advisable to effect the separation of silica not by means of zinc oxide but with a quantity of ammonium chloride equivalent to the alkali employed. It must, however, be remembered that the separation of the silica is incomplete, and that the portion which remains dissolved must be determined in Marignac's method in the magnesium borate, or in Stromeier's method in the potassium boro-fluoride.

The best process is the following:—To the solution of the alkaline melt, at a dilution of 1 alkali to 30 water, the necessary quantity of alkali is gradually added; the greatest part of the ammonium carbonate formed and the ammonia are evaporated off on a simmering water-bath, making good the escape of water if needful, filtered, and washed with water to which 1 drop ammonia is added per 50 c.c. If the alkaline solution mixed with ammonium chloride is evaporated to neutrality a little boric acid may easily be lost.

On treating sodium borate with ammonium chloride, there are formed sodium chloride and ammonium borate, which latter, on evaporation, is resolved into boric acid and ammonia. The solution containing sodium chloride, ammonium borate, and a little silica, is mixed with ammonium chloride, and so much crystalline magnesium chloride that its weight is fourteen times that of the boric anhydride expected, and the solution is evaporated to dryness, keeping it constantly ammoniacal. All the ammonium chloride is cautiously expelled, and the residue heated to redness, extracted with water, and washed. The filtrate is once more mixed with magnesium and ammonium chlorides and the operation repeated. The residues, consisting of magnesia, boric acid, magnesium chloride, and silica, are dried, carefully mixed in the crucible, moistened with water, dried, and strongly ignited. The moistening, drying, and ignition are again repeated to effect the destruction of the magnesium oxychloride. After weighing, the silica is determined in one-third of the mixture by dis-

solving in strong hydrochloric acid, drying at 120°, and extracting with hydrochloric acid; the magnesia is determined in the hydrochloric solution. In the residue of the magnesium borate the chlorine is determined, letting it stand for 12 to 24 hours in the cold in contact with concentrated nitric acid, when complete solution is effected. The liquid, after filtration, is mixed with an equal volume of water, and the chlorine is precipitated with silver nitrate.

In applying Stromeier's method the excess of ammonium carbonate added to the solution of the melt of potassium carbonate is destroyed by potassa lye, adding such a quantity that 2 mols. potassium hydroxide come to 1 mol. boric anhydride; hydrofluoric acid is added in excess so that litmus paper is reddened, the liquid is evaporated to dryness, and the process is completed as directed by Fresenius ("Quantitative Analysis," 6th edition, vol. i.).

The potassium boro-fluoride obtained contains potassium silico-fluoride. This potassium silico-fluoride cannot, as it is sometimes stated, be removed by evaporation with ammonia. For its determination the method of precipitation with an ammoniacal solution of zinc oxide is used, as recommended by Berzelius.

The author has examined the volumetric method for the determination of boric acid as proposed by E. F. Smith, and is not satisfied with the results.—*Zeitschrift für Analytische Chemie*.

EXTRACTION OF PHOSPHORIC ACID FROM THE SLAGS OF THE THOMAS AND GILCHRIST PROCESS.

By Dr. C. SCHEIBLER.

THE slags obtained in Westphalia by this process contain $4\frac{1}{2}$ to 8½ per cent silica, 9 to 14 iron, chiefly in the ferrous state, 17 to 21 phosphoric acid, and 47 to 52 lime. If it is found practicable to separate the phosphoric acid in the form of calcium phosphate, and to eliminate the silica from the residue of the slag, the remainder, consisting chiefly of oxides of iron and manganese, and of lime and magnesia, will prove an excellent material for the production of manganiferous irons and for other technical purposes. The method used at Schalke and Stolberg aims at this decomposition of the slags into biphosphate and into manganiferous iron oxides. For this purpose it is necessary in the first place to convert the ferrous and manganous oxides into the corresponding ferric and manganic salts by a process of roasting, in a current of air, and thus to make them less liable to the action of acids, at the same time to destroy the iron and calcium sulphides present in the slags by oxidation.

At Schalke the slags are roasted in reverberatories with a sloping double sole 9 metres in length by $\frac{1}{2}$ in breadth, which allow of a complete utilisation of the heat. The consumption of coal is trifling. For roasting 1000 kilos. slag there are required 100 to 130 kilos. of coal, and such a furnace roasts in twenty-four hours 15 to 17,500 kilos. of slag.

The slag is finely pulverised either before or after roasting. The comminution of the greater part of the roasted slags is easily effected by treating them with steam, whereby the quicklime contained in the slags is converted into hydrated lime, which effects the mechanical disintegration of the slags into a fine powder. Portions which resist this process may be pulverised by disintegrators.

The granules of steel are separated by sifting, or by means of magnets. From the finely pulverised slag the earthy silicates and the calcium phosphate are extracted by means of very dilute acids. This dilution is necessary to prevent the coagulation of the silica, so that the solutions may be easily separated from the residues by

filtration or decantation. Hydrochloric acid is to be preferred, as sulphuric acid occasions inconvenience by the formation of gypsum, which envelopes the particles of slag. At Schalke 1180 to 1250 kilos. hydrochloric acid at 30° Tw. are used for working up 1000 kilos. slag. The consumption of acid may be further reduced by previous lixivation with water, which dissolves out free lime.

The process of solution is completed in a few minutes. The operation is conducted in stirring-tanks, and on settling the solution is run off from the solid residue, which is then stirred up and washed with a still weaker acid.

The solutions are neutralised with milk of lime in large stirring-tanks so far that either all the phosphoric and the silicic acid are thrown down as bicalcic phosphate and calcium silicate, or only so far that only the phosphoric acid and a small part of the silica are thrown down, the bulk of the silica remaining in the clear mother-liquor.

To separate the phosphatic mud from the liquid large filter-presses are used, filled by self-acting pumps. The press-cakes contain 65 to 70 per cent of water.

The drying of the cake is effected at Schalke and Stolberg by means of a mechanical apparatus which pulverises it at the same time. The dry product contains 34 to 38 per cent phosphoric acid, 6 to 8 silica, 28 to 32 lime, and 1 to 2 sulphuric acid, along with small quantities of chlorine, ferric and manganic oxides, &c.

On an average 50 per cent of the weight of the slag is obtained as a powder of the above composition. These lime precipitates are well adapted for agricultural processes in virtue of their fine state of division and of their high percentage of phosphoric acid.

The residue amounts to about 30 per cent of the gross weight of the slag, and when dried at 100° contains—silica, 1.5 to 5 per cent; phosphoric acid, 0.3 to 4; ferric oxide, 43 to 69; manganic oxide, 10 to 17; lime, 5 to 16; magnesia, 7 to 13. Hence these residues are especially adapted for producing crude irons rich in manganese. Their value is increased by the presence of the alkaline earths, which admits of their admixture with acid ores without any further addition of lime.—*Berg. und Hutten. Zeitung.*

A RECALCULATION OF THE ATOMIC WEIGHTS.*

By FRANK WIGGLESWORTH CLARKE, S.B.,
Chief Chemist to the U.S. Geological Survey, Washington.

PLATINUM.

For this metal we have to consider only experiments by Berzelius, by Andrews, and by Seubert. In an early paper Berzelius† reduced platinum chloride, and found it to contain 73.3 per cent of platinum. Hence, $Pt = 194.204$, a value very near that obtained most recently by Seubert. In his later investigations, Berzelius‡ studied the potassium chloroplatinate, K_2PtCl_6 . 6.981 parts of this salt, ignited in hydrogen, lost 2.024 of chlorine. The residue consisted of 2.822 platinum, and 2.135 potassium chloride. From these data we may calculate the atomic weight of platinum in four ways:—

1st. From loss of Cl upon ignition		$Pt = 197.722$
2nd. " weight of Pt in residue		" 196.942
3rd. " " KCl		" 196.215
4th. " ratio between KCl and Pt		" 196.652

The last of these values is undoubtedly the most reliable, since it involves no errors due to the possible presence of moisture in the salt analysed. If $O = 16$, the value becomes $Pt = 197.104$.

* Smithsonian Miscellaneous Collections. The Constants of Nature.

† *Poggend. Annal.*, 8, 177. 1826.

‡ *Ibid.*, 13, 468. 1828.

The work done by Andrews* is even less satisfactory than the foregoing, for the reason that its full details seem never to have been published. Andrews dried potassium chloroplatinate at 105°, and then decomposed it by means of zinc and water. The excess of zinc having been dissolved by treatment with acetic and nitric acids, the platinum was collected upon a filter and weighed, while the chlorine in the filtrate was estimated by Pelouze's method. Three determinations gave as follows for the atomic weight of platinum:—

197.86
197.68
198.12

Mean 197.887

If we assume that these values were calculated with $K = 39$ and $Cl = 35.5$, the mean, corrected by our later figures for these elements, becomes $Pt = 197.382$. If $O = 16$, this becomes $Pt = 197.836$. Unfortunately, Andrews does not, in his brief note upon the subject, indicate the manner by which his calculations were made.

Latest of all we have to consider the experiments of Seubert.† This chemist prepared very pure chloroplatinate of ammonium and potassium, and from their composition deduced the atomic weight of the metal under consideration. The ammonium salt, $(NH_4)_2PtCl_6$, was analysed by heating in a stream of hydrogen, expelling the excess of that gas by a current of carbon dioxide, and weighing the residual metal. In three experiments the hydrochloric acid formed during such a reduction was collected in an absorption apparatus, and estimated by precipitation as silver chloride. Three series of results are given for the percentage of platinum in this salt, together with another single result which may be considered alone. Here are the figures:—

Series I.	Series II.	Series III.
43.957	43.871	43.990
43.948	43.876	43.986
43.960	43.872	44.001
43.946	43.881	44.020
43.963	43.875	43.994
43.961	43.879	43.996
		44.004
Mean 43.956 ± 0.002	Mean 43.876 ± 0.001	44.026
		43.998

Mean 44.001 ± 0.003

These series represent three preparations. The additional single experiment above referred to was made with material belonging to series II., but re-crystallised from water. This salt gave 43.955 per cent of platinum, a figure to which we may assign the probable error of one experiment in the first series. Combining, we get the subjoined general mean percentage of Pt in $(NH_4)_2PtCl_6$:—

Series I.		43.956 ± 0.002
" II.		43.876 0.001
" III.		44.001 0.003
Extra experiment		43.955 0.004

General mean .. 43.907 0.009

Hence $Pt = 194.314 ± 0.078$. If $N = 14$, and $Cl = 35.5$, then $Pt = 194.906$. Calculating with Stas's values for N and Cl, Seubert gets from the four results combined above, the following figures for Pt, respectively:—194.685, 194.039, 195.034, 194.665.

For the chlorine estimations in the ammonium salt the subjoined weighings are given:—

Salt.	Pt.	AgCl.
2.7054 grms.	1.1871 grm.	5.2226 grms.
2.2748 "	0.9958 "	4.3758 "
3.0822 "	1.3561 "	5.9496 "

† British Association Report, 1852. *Chem. Gazette*, 10, 380.

* *Ber. der Deutsch. Chem. Gesell.*, 14 865. 1881.

Hence 100 parts of AgCl correspond to the following quantities of salt:—

51·802
51·986
51·805

Mean 51·864 ± 0·041

Hence, calculating directly from the ratio between 6AgCl and (NH₄)₂PtCl₆, Pt = 196·871 ± 0·363.

Seubert himself reckons the percentage of chlorine from the weight of silver chloride, and then calculates the ratio between Cl₂ and Pt. He thus finds, with Stas's value for Cl, Pt = 195·330.

The potassium salt, K₂PtCl₆, was also analysed by ignition in hydrogen, treatment with water, and weighing both the platinum and the potassium chloride. These percentages were found:—

Pt.	KCl.
40·119	30·706
40·120	30·728
40·076	30·698
40·070	30·666
40·107	30·700
40·120	30·627
40·114	30·710
40·130	30·621

Mean 40·107 ± 0·005 Mean 30·682 ± 0·009

From the first column Pt = 194·370 ± 0·068
 „ second „ „ 194·645 0·213

If K = 39, and Cl = 35·5, the first column gives Pt = 194·933. Seubert, from the percentage of platinum, gets Pt = 194·392; and from the ratio 2KCl : Pt he finds Pt = 194·494.

As with the ammonium salt, three experiments were made upon the potassium compound to determine the amount of chlorine lost upon reduction in hydrogen. I cite the weighings, and add in a fourth column the quantity of K₂PtCl₆ proportional to 100 parts of AgCl. This AgCl represents but four atoms of the chlorine:—

Salt.	Pt.	AgCl.	Ratio.
6·7771 grms.	2·7158 grms.	7·9725 grms.	85·006
3·5834 „	1·4372 „	4·2270 „	84·774
4·4139 „	1·7713 „	5·2144 „	84·648

Mean 84·809 ± 0·071

Hence Pt = 195·002 ± 0·415. If K = 39, Ag = 108, and Cl = 35·5, then Pt = 194·955. Seubert, calculating the percentage of chlorine and thence the ratio Cl₂ : Pt, gets Pt = 194·631.

Combining all the values we have the following result for the atomic weight of platinum:—

1. From p. c. Pt in (NH ₄) ₂ PtCl ₆ ..	Pt = 194·314 ± 0·078
2. „ 6AgCl : (NH ₄) ₂ PtCl ₆ ratio ..	„ 196·871 0·363
3. „ per cent Pt in K ₂ PtCl ₆ ..	„ 194·370 0·068
4. „ KCl ..	„ 194·645 0·213
5. „ 4AgCl : K ₂ PtCl ₆ ratio ..	„ 195·002 0·415

General mean „ 194·415 0·049

Or, if O = 16, Pt = 194·867.

Seubert, taking the arithmetical mean of his eight values, gets Pt = 194·620. He regards, however, those results as best which are dependent upon the percentage of platinum in the ammonium salt, and upon the complete analysis of the potassium compound. These give him a mean of Pt = 194·461, which, if corrected by reduction to a vacuum standard, becomes Pt = 194·34.

It will be noticed that three of the ratios, calculated

with K = 39, N = 14, Ag = 108, and Cl = 35·5, give nearly Pt = 195, namely:—

194·906
194·933
194·955

The general mean of all, if O = 16, gives Pt = 194·867. Hence, for all practical calculations, the value 195 may be safely employed.

PROCEEDINGS OF SOCIETIES.

SOCIETY OF CHEMICAL INDUSTRY.

Newcastle-on-Tyne, July 9th, 1884.

Address delivered at the Third Annual General Meeting by the Retiring President, WALTER WELDON, F.R.S., &c.:—

(Concluded from p. 44).

THE two questions which I asked some time ago I have now answered. Clearly, the Leblanc process is not destined to remain our only means of obtaining hydrochloric acid, and for my own part I can have no doubt that the use of hydrochloric acid as the immediate raw-material of the chlorine manufacture is also one of those things in respect of which the old order must,—partially, at any rate,—give place to new.

And I ought to add that the processes for the obtaining of chlorine and hydrochloric acid in connection with the manufacture of ammonia soda which I have mentioned are not the only processes to those ends which are in the field. Within the last few weeks M. Solvay has taken three more patents for such processes, and quite a number of other workers at the problem of obtaining chlorine or hydrochloric acid from calcium chloride now consider that they are on the verge of success.

While, however, it is now quite certain that chlorine will be manufactured at least from magnesium chloride, one can hardly conceive that its manufacture from either magnesium chloride or calcium chloride can ever more than partially displace its manufacture from hydrochloric acid, whatever changes may take place in our mode of obtaining hydrochloric acid. I come now, therefore, to the question of the utilisation of hydrochloric acid in the chlorine manufacture more completely than it is utilised therein at present, a question upon which the continued existence of the Leblanc process certainly now mainly depends.

The present Weldon process, even when performed to the very best advantage, does not yield more than one-third of the total chlorine of the hydrochloric acid treated by it, the other two-thirds of that chlorine being lost as calcium chloride. It is thus unquestionably a barbarous process. It met well enough the wants of the time when hydrochloric acid could be counted as having no value, and when the two problems in respect of the chlorine manufacture which pressed to be dealt with were simply those of how to diminish the then chief item of the cost of chlorine,—that for native manganese,—and how to keep the offensive residual product of the treatment of that native manganese by hydrochloric acid out of the water-courses; but it is no longer equal to the production of cheap bleaching-powder, now that the value of hydrochloric acid has become such that the bleaching-powder produced by it costs more for hydrochloric acid than for all other items of its cost put together. For some years past, therefore, many inventors have been endeavouring to devise a hydrochloric acid chlorine process which should yield in the free state practically the whole of the chlorine of the acid treated by it; and a process which I believe will do this is one of the group of processes to the endeavour to realise which MM. Pechiney et Cie. have for some time past been devoting not only vast material resources,

but a power of overcoming the practical difficulties which are always encountered in attempts to work out new industrial chemical processes, of which I have known no parallel.

The process in question is simply a new form of a very old idea. Its first operation consists in digesting with aqueous hydrochloric acid an oxide of manganese which has been regenerated from manganese chloride in the dry way. There are thus obtained undiluted chlorine and a residual solution of manganese chloride. The latter is then evaporated to dryness, and the solid manganese chloride so obtained is then heated in intimate contact with atmospheric oxygen. The chlorine of the manganese chloride is thereby driven off in the free state,—mixed, of course, with other gases,—and its manganese obtained as an oxide, rich in oxygen, with which to re-commence the round of operations. Per given quantity of hydrochloric acid treated by it, the process yields practically the same quantity of strong chlorine as can be obtained from the same quantity of acid by means of Weldon mud, together with something over twice that quantity of chlorine diluted by other gases.

I shall, certainly, at least not be above the mark if I take the consumption of hydrochloric acid, per ton of bleaching-powder made by the present Weldon process, at the quantity the production of which by the Leblanc process, together with the quantity of soda which must be produced at the same time, costs £5 more than the cost of producing by the ammonia process the equivalent of that quantity of Leblanc soda; or, in other words, at the quantity corresponding to 5 tons of aqueous hydrochloric acid of 27 per cent. I know of no instance in England in which a ton of Weldon bleach is obtained per less than 5·7 tons of such acid; but I propose to assume that a ton of bleaching-powder can be made, by the present Weldon process, per the quantity of acid the present minimum cost of which is £5.

The other items of the cost of a ton of bleaching-powder, made by that process,—apart from lime for the chambers, labour on the chambers, casks, packing, and general charges,—are those for lime for the oxidisers, limestone or chalk for the wells, manganese to make up loss, fuel, labour on the stills, and labour on the regeneration process. I believe that the sum of these items averages about 19s.; bringing up to about £5 19s. that part of the expense of manufacturing a ton of bleaching-powder by the present Weldon process which represents the cost of that ton of bleaching-powder for chlorine only.

The process which is now on the point of being got to work at Salindres, after much experience of it on a semi-industrial scale, requires neither lime nor limestone, nor does one see how there can be any appreciable loss of the manganese employed in it. The loss of manganese incurred in the present Weldon process is mainly due to impurities which are constantly entering that process, and have to be continually eliminated and thrown away, and with which it is impossible to avoid throwing away more or less manganese; but in the new process in question there is nothing to throw away. Its cost is thus simply for acid, fuel, and labour.

That that process is capable of yielding the quantity of chlorine corresponding to a ton of bleaching-powder, per quantity of hydrochloric acid corresponding to less than 30 cwts. of acid of 27 per cent, is already sufficiently demonstrated. The value of that quantity of acid being taken at £1 10s., there remains £5 19s. less £1 10s., or £4 9s., out of which to pay simply the cost of evaporating to dryness a quantity of solution of manganese chloride containing 1½ tons of water, and then treating by heat and air something less than 15 cwts. of manganese chloride mixed with a certain proportion of manganese oxide. The advantage of the new process over the old one, per ton of bleaching-powder manufactured, will be the balance left after deducting from those £4 9s. the cost of these two operations.

The difficulties which have been encountered in the en-

deavour to realise this process have been mainly with respect to the apparatus and mode of working by which to effect the often proposed reaction of atmospheric oxygen upon manganese chloride. Manganese chloride is a somewhat readily fusible salt; oxygen does react upon it below its fusing-point, but only slowly: for the reaction to go on sufficiently rapidly the temperature employed must be above the fusing-point of the manganese chloride, and the latter must present to the air by which it is treated a very considerable surface; while a fused mass of manganese chloride not only presents far too small a surface, but is destructive of all materials of which apparatus for treating it industrially could be formed.

For the treatment of manganese chloride, as of magnesium chloride, the principle adopted at Salindres is that, to which I have already referred, of mixing the chloride to be treated by heat and air with an oxide of the same metal, the main function of the oxide being to mechanically divide the chloride, so as to permit of the chloride being heated to above its fusing-point, without the mass treated becoming fluid or ceasing to be penetrable by air. I will not stay to describe the various ingenious appliances which MM. Pechiney et Cie. have successively devised for the performance of the operation of treating by heat and air mixtures of manganese chloride and manganese oxide; but will only add that I believe that they have now completely overcome all the many difficulties which for a long time seemed to render the industrial realisation of that operation almost hopeless, and that it now seems certain that they will soon be manufacturing chlorine from the hydrochloric acid of the Leblanc process at the rate of the quantity of chlorine corresponding to a ton of bleaching-powder per little more than 14 cwts. of salt.

Given this result—a result diminishing by two-thirds the quantity of Leblanc soda necessary to be manufactured in order to the manufacture of a given quantity of chlorine from Leblanc hydrochloric acid—will it enable the Leblanc process, thus shorn of its proportions, to continue to live, in face of the decomposition by magnesia of the ammonium chloride of the ammonia process, and the direct obtainment from the resulting magnesium chloride of one-half of its chlorine in the free state? I trust that this may be so; but, as yet, the data for a conclusion on the point are insufficient, and of those of them which as yet exist, some tell one way, and some the other. The manufacture of chlorine from magnesium chloride, obtained by decomposing by magnesia the ammonium chloride of the ammonia process, involves much more evaporation than is required for the manufacture of the same quantity of chlorine from hydrochloric acid by the process to which I have just referred; and the whole of the chlorine obtained by the former process is diluted by other gases, whereas one-third of the chlorine obtained by the latter process is undiluted. On the other hand, the degree of dilution of the chlorine obtained from magnesium chloride is somewhat less than that of the chlorine obtained from manganese chloride; and to decompose magnesium chloride, or rather magnesium oxychloride, by heat and air, is somewhat easier than to decompose manganese chloride by the same means. All that is yet clear in the matter therefore is that chlorine will be manufactured in connection with the ammonia process, though perhaps not to any appreciable extent for a few years yet. But the question which, in face of that certainty, it is impossible not to ask: the question of whether it is or is not likely that the greatest chemical invention of the eighteenth century, if not indeed of any century, shall have ceased by the end of the nineteenth to be anything more than a tradition and a name, as yet it is equally impossible to answer.

If, however, unfortunately, that question shall be eventually answered in a sense adverse to those whose capital is invested in the Leblanc process: must the manufacture of soda disappear from Tyneside? It was on Tyneside that "artificial soda," as it used to be called, was first manufactured in England. Must, in such case, this district know that industry no more? I am not of that

opinion. At present, the manufacturer of ammonia soda from brine employs, per ton of soda manufactured, from a ton and a quarter to a ton and a half of coal, and the quantity of brine containing about forty-six hundredweight of salt. His coal consumption is thus light, but the quantity of salt which he consumes is twice the quantity equivalent to the soda he manufactures. Any method, however, of obtaining, either as free chlorine or as hydrochloric acid, the chlorine of the salt decomposed by the ammonia process, must necessarily involve the evaporation of all the water employed in that process,—during which evaporation that portion of the salt employed in which at present escapes utilisation will be recovered,—and must moreover involve a subsequent operation, also requiring an expenditure of fuel. Any such method must thus reduce to absolutely its theoretical amount the quantity of salt consumed in the ammonia process, per unit of soda manufactured thereby, reducing it to one-half the quantity at present required by the manufacturer of ammonia soda from brine, but must at the same time increase his consumption of coal, per unit of soda, by at least between one hundred and two hundred per cent. Under such changed conditions—at any rate when Cleveland salt shall have become obtainable here at a cost not much greater than that of Cheshire salt in Lancashire—I think it ought to be possible to manufacture ammonia soda in this district very nearly if not quite as cheaply as in any other locality whatever.

It is not willingly that I have announced a new—and much more serious than any previous—menace to an industry already sorely tried. How much I should have preferred to have been able to prophesy smooth things with respect to the Leblanc process no words can say. Facts, however, must be looked in the face. Nothing can be less wholesome than the atmosphere of a fool's paradise. And the watch-dog at the gate, who gives timely notice of the approach of unwelcome visitors, at least renders such service as is in his power.

But if such changes as that which I have indicated as now certain to be accomplished at least partially are unwelcome, it is only in so far as they may affect individuals. By such changes individuals may, and alas! do suffer; but the world gains by them. No industrial process is ever superseded, however partially, excepting by a better process. And in so far as the Leblanc process may be doomed to still further restriction, it can only be because some other process can give mankind cheaper soda and cheaper chlorine than it can give.

And the various proposed new processes of which I have spoken all comply with at least one of the ideals towards which all progress in such matters must henceforth tend. They all possess in common one feature which will certainly be held essential to all industrial chemical processes in a not distant future. They are all processes yielding no waste product. They are all processes completely utilising all the constituents of all their raw materials. Excepting coal and water, nothing would be manipulated in any of them which was not finally yielded either as commercial commodity, or as regenerated reagent for use again. That way certainly lies the future.

Amongst the many transcendent merits of the beneficent invention of Nicholas Leblanc, of immortal memory, that of yielding no waste product is not included. There are spots on the sun; and the Leblanc process yields alkali-waste. Countless have been the efforts to utilise at least one of the constituents of that residue; but none of them have fully succeeded. Now, however, ninety-seven years after the invention of the process to which we chiefly owe that soap, and glass, and paper, and countless other commodities only less useful than these, have been placed within the reach of all mankind; seventy-four years after its inventor, "the creator," as Hofmann puts it, "of incalculable wealth for his species," put an end to his existence because he wanted bread, which makes it so pleasant to know that two generations afterwards he at least received a stone-statue, towards the erection of

which, however, I have yet to learn that any English soda maker contributed. Now, when one cannot but fear that the long day of the Leblanc process may be tending towards its close, a means of utilising both the principal constituents of that residue seems almost in sight. To speak now of the recovery of sulphur from Leblanc soda-waste may seem a kind of anti-climax; but the gallant attempt to realise the Schaffner and Helbig process to that end upon which Mr. Alexander Chance recently expended so much enthusiastic effort, and the firm of which he is a member the greater portion of £10,000, has not only resulted in a reduction in the price of pyrites, but also in the suggestion of various other processes for the accomplishment of the same object: to a conceivable combination of certain parts of some of which I would ask permission to devote a very few concluding sentences.

The combined process in question would commence by bringing the calcium sulphide of alkali-waste into solution as calcium sulphhydrate, by treating a mixture of waste and water by sulphuretted hydrogen. The second operation would consist in evaporating the resulting solution of calcium sulphhydrate, and so driving off its sulphur as pure H_2S ; and the third and final operation in burning off the hydrogen only of that sulphuretted hydrogen, setting its sulphur free.

The third of these operations has for some time past been under experiment in the works of Messrs. Chance Brothers, at Oldbury. The apparatus used in it is one invented by Mr. C. F. Claus, of London, and consists of a kiln in which there is a deep bed of fragments of porous material, through which, when the apparatus is at work, there is passed a mixture of sulphuretted hydrogen with a carefully regulated quantity of air. The bed of porous material is maintained at a high temperature by the heat of the reaction which takes place as the mixture of gases passes through it, and from the mixture of gases and vapours passing off from it sulphur condenses as that mixture cools. The operation thus costs nothing for fuel, and its cost for labour is scarcely more than the cost of from time to time removing sulphur from the receptacles in which it has condensed and collected.

The first of the three operations is in industrial operation at Rassuen, in the South of France, in connection with a most ingenious process, invented by M. Lombard, of Marseilles, in which calcium sulphhydrate is used to precipitate dicalcic phosphate from the solution obtained by dissolving native calcium phosphate in hydrochloric acid. It is also in operation, on a semi industrial scale, in the alkali work of Hřřischau, in Moravia. Its cost is simply that of charging waste and water into horizontal cylinders furnished with mechanical agitators, keeping these agitators in motion during the operation, and at the end of the operation discharging the contents of the cylinders.

The second of the three operations is under experiment at Hřřischau, by Dr. Heinrich von Miller and Herr Opl. This second operation is obviously more costly than the first or third; but it yields, in addition to sulphuretted hydrogen, another product, which other product, it is hoped, may pay nearly if not quite the whole cost of the three operations. This other product is chemically pure calcium hydrate—resulting from the reaction—

Unlike the recovered calcium carbonate of the Schaffner and Helbig process, this calcium hydrate can be readily obtained absolutely free from impurities, since no impurities precipitate with it, and its physical condition is such that water or a solution runs from a heap of it almost as readily as from so much sand. It is incapable of causticising solutions of sodium carbonate more than partially; it is too dense for use in Weldon oxidisers; but it seems not unlikely to prove suitable for use in bleaching-powder chambers. If it should prove to be the case, on the one hand, that this dense crystalline calcium hydrate shall have the value of an equivalent quantity of ordinary lime, and, on the other hand, that the hydrogen of sulphuretted

hydrogen can be oxidised, practically completely, without at the same time oxidising any appreciable proportion of its sulphur, then I think that an almost ideally perfect solution of the problem of the utilisation of the residual product of the Leblanc process will at last have been reached. If this should be so, one can only hope that that solution will not have arrived too late.

NOTICES OF BOOKS.

Annual Report of the Chief Engineer of the Philadelphia Water-Department for the Year 1883. Philadelphia: Dunlop and Clarke.

We have often had occasion to remark that in the United States, as population becomes more dense and manufactures increase, the supply of water for domestic purposes must become complicated, as it has been the case in England. Fortunately, most of the large American towns have shown, in this respect, a disposition to be wise in time. The necessity of a pure water supply is fully admitted, not merely in theory, but also in practice.

In the volume before us we meet with much from which the ratepayers of London may draw instruction. The water-supply of Philadelphia, like those of most other large American cities, is in the hands of the municipality. We find it remarked that among the various methods of charging for a water supply, "that of actual measurement is undoubtedly the most equitable, convenient, and direct," whilst the "rateable assessment" and "dimensions" plans are artificial means of averaging charges which are manifestly inequitable.

The Philadelphia water-supply is drawn partly from the Delaware and partly from the Schuylkill. One of the pumping-stations on the Delaware, that at Kensington, gets the full benefit of all the city-sewage, and in addition the Aramingo Canal, an open sewer of large dimensions and choked with filth, discharges in its immediate vicinity. Under these circumstances it is only natural that the water should be pronounced utterly unfit for human consumption.

The Schuylkill is less polluted, but it is still described as the natural sewer for a population of 350,000, largely engaged in manufactures. Here, accordingly, intercepting sewers are proposed. The author is of opinion that "it will be years before the sewage-saturated soil underlying a long-inhabited area and filled with cess-pools, can free itself from poisons." We are by no means sure that where the pollution has been extensive, even a century would suffice, especially in the case—to which the writer refers—of intra-mural graveyards.

Concerning the benefits to be derived from filtration, very judicious views are expressed. It is stated that the river when muddiest from a recent freshet is probably in its most wholesome condition. . . . It is true that the passage of water through a mass of spongy iron has been found to oxidise in part the organic matter, but the cost of inaugurating a plant of this sort is too formidable to contemplate. . . . When all was done the organic (organised?) matters would still remain, and it is these which constitute the real danger.

To our readers the most interesting portions of this volume will doubtless be the preliminary report by Dr. A. R. Leeds into the present and proposed water supplies of Philadelphia, and his final report to the Board of Experts. In his account of the analytical processes adopted he refers to a difference between the two methods of oxidising the organic matters by potassium permanganate and by the so-called "actinic" method, *i.e.*, the reduction of silver nitrate. The amounts of oxygen required, as determined by the latter process, are generally somewhat the lower. The indications of the oxidisable organic matter thus obtained follow along more closely with the relative amounts of putrescible nitrogenous matter than those obtained by the

permanganate. Of course nitrites, oxidisable metallic salts, and sulphides interfere with the actinic method, but they also affect the permanganate process.

Dr. Leeds does not regard nitric acid as an index of previous sewage contamination unless the other analytical data point to the presence of foreign matters of animal origin. Neither can he accept chlorine as indicative of pollution unless either analytical or other testimony prove that it is derived from foreign matters of animal origin or from industrial refuse. He points out that "chlorine and salt are as constant constituents of the atmosphere as of river and ocean waters. . . . A large percentage of the chlorine in river waters must be regarded as coming from the sky and not from the ground."

The progressive absorption of oxygen, he contends with perfect justice, indicates progressive contamination. "It matters not to what extent the oxygen is used up by a direct chemical process of oxidation, and to what extent through the living agency of bacteria and micrococci in presence of decomposing organic matter."

A remarkable circumstance here discussed is that the water of the Schuylkill in January, 1883, became remarkably offensive to taste and smell. The odour was so persistent as to communicate a bad taste to articles of food cooked in the water, and to diffuse itself through houses. At the same time, the albumenoid ammonia found in the water was not greater but smaller than at other times of the year when no offensive smell or taste were complained of. Dr. Leeds considers that the stream being at that time entirely covered with ice, offensive gases accumulated—it was indeed proved that on breaking the ice marsh-gas was found in sufficient quantity to be ignited. The sulphates present in the river underwent reduction, forming hydrogen sulphide and sulphuretted hydrocarbons. During the time when the water was worst, it had an alkaline reaction.

It is well known that the purer a water is from organic pollution, the more its colour, when viewed through a long glass tube with proper precautions, approaches to a blue. We understand—though the fact is not mentioned in the work before us—that the potable waters supplied to most American cities do not exhibit this feature. This is a point which requires further investigation, since, according to European observations, the absence of the blue tint should indicate organic pollution.

We find here an abstract of the observations made by M. Gerardin on the river Vesle, above and below Rheims. In his results there is one point with which we cannot agree. Above Rheims he finds the water clear, wholesome, and containing abundance of fish, charas, *water-cress*, &c. At some distance below the city, we are told, "all traces of pollution had disappeared and fish and *water-cress* flourished. Now *water-cress* grows luxuriantly in polluted waters and even in raw sewage."

We are happy to find that Dr. Leeds takes into due consideration not merely the character of polluting materials entering a river, but their volume, and the proportion which they bear to the volume of water flowing in the river. The non-recognition of this evident principle was the fatal defect in the celebrated "recommendations" of the late Royal Rivers Pollution Commission. Had a law been founded upon those recommendations, any person who wished to run filth into a river could easily have evaded its provisions by diluting the offensive liquid so as to come within the letter of the law, though the river would have been polluted just the same.

Dr. Leeds must be recognised as one of the highest authorities on all chemical and sanitary questions connected with the water-supply of towns.

Platinised Magnesium as a Reducing Agent.—M. Ballo.—Magnesium, which has no action upon pure water, decomposes it instantly in presence of a trace of platinum chloride.—*Zeit. f. Anal. Chem.*

CORRESPONDENCE.

NEW CARBON BATH FOR THE EGGERTZ
COLOUR TEST.

To the Editor of the Chemical News.

SIR,—I was very much interested in Mr. Arnold's description of a new bath for carbon estimation by colour test, but at the same time could not see any improvement upon a properly constructed copper one; in fact, should consider it a great source of danger, being made of glass.

The following is a sketch of a copper one I have had in use for nearly 11 years, without suffering any of the troubles mentioned by Mr. Arnold.

It is $7\frac{1}{2}$ inches in diameter, and contains holes for 32 samples, which numbers I have had regularly every day. It will answer equally as well for one as for 32 samples.

As will be seen, there is a lid with handle, which is removed when the water boils, and the tubes are then placed in the different holes—every tube being labelled, preferring that to having numbers stamped on plate, and taking scarcely any time—resting on a second plate with holes, but not large enough to allow of the tubes passing through; therefore they are perfectly upright, and remain in that position the necessary time, the water boiling.

As regards the objections mentioned by Mr. Arnold.

- (a). It soon gets dirty, &c. Very slightly, and if so, a little oily waste will soon remove it; or have it japped.
- (b). The slanting position of tubes, &c. They are not slanting.
- (c). The water in the bath is out of sight, &c. Certainly not; it never should be allowed to get below the top plate.
- (d). The identity of tubes may be lost by slip of memory, &c. It would be very unwise for anyone to attempt to remember them, and using the small gummed labels dispenses with that.
- (e). The bath frequently leaks, &c. That is entirely due to bad workmanship, I never having been troubled with it.

I notice Mr. Arnold marks two holes, s, for standards, as though every day he made standard solution. I mention this because I have heard that it is done in Sheffield by some chemists, but beg to say it is entirely unnecessary; for a properly-prepared standard solution of burnt sugar and water in a hermetically-sealed tube will keep for years; but of course it must be occasionally checked to see that it is right, my own not having been renewed for several years. In this bath there is no bobbing up of the

tubes, they remaining perfectly steady as placed in the bath.—I am, &c.,

JAMES E. KELSALL.

FREEZING APPARATUS.

To the Editor of the Chemical News.

SIR,—I have read in one of our papers of a new discovery by M. Cailletet in freezing apparatus, which from its description appears to be simple and inexpensive, such an apparatus as could be sent to any of our fishing stations for the freezing up of bait, &c. I shall feel extremely obliged if you will inform me of any apparatus which can be worked without the aid of steam power, or rather by manual labour alone. I need scarcely say the object is to keep bait frozen in any given chamber without the use of ice and similar expensive means, which prevent our fishermen from availing themselves of bait thus secured on account of cost.—I am, &c.,

G. C. FEARNS.

July 16, 1884.

BLOWPIPE ANALYSIS.

To the Editor of the Chemical News.

SIR,—I may perhaps be permitted to criticise a statement quoted by one of your reviewers in the *CHEMICAL NEWS*, vol. 1, p. 30, which I have just received. The quotation to which I take exception is from Lieut.-Col. Ross's new work on "Blowpipe Analysis," and runs:—"It (*i.e.*, blowpipe analysis) is still untaught at the Royal School of Mines." To this extraordinary statement your reviewer adds, with perfect justice:—"Comment is here surely needless."

I happen to have the best possible reasons for knowing that the statement is entirely erroneous, for during the whole time I was a student at the school, viz., from 1880 to 1883, "Blowpipe Analysis" has formed part of our curriculum—though not as a distinct subject with a separate Professor, as Lieut.-Col. Ross would probably wish to see it.

I hope this gentleman will understand that I do not write this letter out of any spirit of discourtesy to him, but simply to ensure that such an inaccurate and injurious statement should not be allowed to spread without a disclaimer from someone who has a right to contradict it. I enclose my card.—I am, &c.,

A.R.S.M.

Minas de Riotinto,
Huelva, Spain, July 25, 1884.

CHEMICAL NOTICES FROM FOREIGN
SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Bulletin de la Société Chimique de Paris.
No. 9, May 5, 1884.

Hydrate Formed by the Combined Carbon in Cast-iron.—M. Zaboudsky.—A re-publication from the *Comptes Rendus*.

Probable Number of Homologous and Isomeric Rosanilines.—MM. Rosenstien and Gerber.—In a former paper the authors have shown among the isomeric or homologous amines fit for the production of rosanilines there may be distinguished three classes. The number

of rosanilines is reduced to 24 arranged in 9 groups, or to 64 arranged in 13 groups.

A New Method of Determining the Carbon in Cast-iron, Steel, and Wrought-iron.—M. Zaboudsky.—For decomposing the specimen the author makes use of a dry mixture of copper chloride and sodium chloride prepared by evaporating the mixed solutions to dryness. The metal finely pulverised is carefully incorporated with this mixture in a mortar; water is added so as to form a pasty mass, and the whole is ground up with the pestle. It is well to place the mortar previously in cold water. For 1 grm. of iron 20 grms. of the mixture suffice. The trituration is kept up for half an hour. The mass is taken from the mortar and placed in a beaker. The mortar is rinsed with 200 c.c. of ferric chloride of mean concentration (1 part Fe_2Cl_6 to 4 parts of water). The beaker may be gently heated without adding hydrochloric acid. This entire operation takes scarcely 45 minutes when the residue may be collected on the filter. The author has determined the quantities of carbon contained in the residue submitted to combustion, and gives the results in a table. He considers that the calorimetric method of Eggertz may serve to determine the carbon rapidly, but it requires great skill, and the results are not mutually comparable with metals of different origin.

On Phosphorus Sulphides.—E. Dervin.—The author has examined the action of light upon a mixture of sulphur and phosphorus sesqui-sulphide dissolved in carbon disulphide; the action of heat upon a mixture of sulphur and phosphorus in solution in carbon disulphide; the action of heat upon mixtures of phosphorus sesqui-sulphide with phosphorus ter-sulphide or penta-sulphide in presence of carbon disulphide, and he has attempted to crystallise PS_3 and PS_2 as obtained by fusing red phosphorus and sulphur, by means of carbon disulphide under pressure.

Sodium Sulphites and Bisulphites.—R. De Forcrand.—The author has determined the formation-heat of these compounds.

Sodium Glyoxal-Bisulphite.—M. De Forcrand.—A thermo-chemical study.

Non-Existence of Ammonium Hydrate.—D. Tommasi.—This paper has been already noticed.

Action of Isobutyl Chloride upon Benzol mixed with Aluminium Chloride.—E. Gossin.—The reaction of MM. Friedel and Crafts with isobutyl-chloride differs from that with propyl- and amyl-chloride.

Reply to MM. Vincent and Delschanal.—F. Sestini.—The author's researches on the preparation of the sulpho-carbonates date back to 1871.

The Synthesis of Diphenylethane derived from Ethylidene Chloride.—R. D. Silva.—The author points out that he has obtained this result as early as 1881, and consequently prior to MM. Angelbis and Anschütz.

The Manufacture of Cyanides and Ferrocyanides by Means of Trimethylamine, according to Ortlieb and Muller's Process.—E. Willm.—Commercial trimethylamine converted into vapour in small boilers fed continuously is decomposed in retorts arranged like gas-retorts and heated to bright redness. It is decomposed into hydrocyanic acid, ammonium hydrocyanate, and carburetted gases. The vapours pass first into dilute sulphuric acid where the ammonia is retained, and thence into a lye of caustic alkali. To obtain ferrocyanides a determined quantity of pure ferrous oxide is added to the alkaline lye.

The Existence of Manganese in Wines.—E. J. Maumené.—Already noticed.

Zeitschrift für Analytische Chemie.
Vol. xxiii., Part 1, 1884.

The Determination of Phenol in Creosote Oil.—Dr. Kleinert.—All distillations give between 150° and 200° the smallest quantity of distillate; such creosote oils, there-

fore, contain extremely little phenol. It cannot be assumed that carbolic acid exists in those portions of the liquid which pass over at temperatures exceeding 200° as its boiling-point is at 184° to 185°. At most there might occur under the existing circumstances a quite unimportant minimum. Yet the fractions which distil over between 200° and 250° are not merely the most abundant, but they exhibit relatively the highest proportion of supposed phenol. The acid oils contain also bodies with boiling-points above 250°, and which behave with bromine similarly to phenol. If, therefore, the supposed phenol is determined in a creosote oil according to the method of Koppeschaar, the larger percentage consists not of phenol but of other bodies contained in the acid oils, soluble in water and having a higher boiling-point than that of phenol.

Remarks on the Applicability of Schlösing's Method of Determining Ammonia to the Extracts of Plants.—E. Schulze.—E. Bosshard, in a memoir contained in the CHEMICAL NEWS (vol. xxii., p. 329), has shown that in presence of glutamine neither Schlösing's method nor distillation with magnesia gives useful results and that the presence of asparagine also interferes with both these methods. The fact that asparagine does not absolutely resist the action of cold milk of lime causes Schlösing's method to appear erroneous in principle. But in the cold the decomposition of this amide by milk of lime proceeds very slowly and does not appear to begin immediately after these substances have been brought into contact. If in an extract containing asparagine the ammonia is determined according to Schlösing's method, and the acid is titrated back after forty-eight hours, the error will be slight even in presence of a considerable quantity of asparagine. The application of the method, however, has its disadvantages. The tests given in the text-books do not show whether, at the end of the experiment, all the ammonia originally present has been expelled. In the examination of amidiferous vegetable matter it will often be doubtful whether asparagine, or glutamine, or a mixture of both these amides, is present.

Determination of Organic Matter in Potable Waters, according to the Methods based upon the Reduction of Potassium Permanganate.—Dr. A. R. Leeds.—Already inserted.

The Separation and Quantitative Determination of Digitaline, Digitaleine, and Digitine.—R. Palm.—After criticising the method of Nativelle and the so-called German process the author proposes to exhaust the plant with water, to filter off animal charcoal until entirely decolorised, and to precipitate the filtrate completely with lead acetate. The filtrate is then treated with solution of basic lead acetate and alcoholic ammonia as long as a precipitate is produced. This last precipitate consists of lead oxide and the glucosides of digitalis. It is washed on the filter, mixed up with water to a thin paste, and completely decomposed by treatment with hydrogen sulphide. The entire mass is then placed upon a filter. The watery liquid contains all the digitaleine whilst digitaline and digitine remain undissolved in admixture with the lead sulphide. If this residue is treated with chloroform the digitaline is dissolved and can be obtained in crystals on evaporating the solvent. The residual lead sulphide is treated with alcohol which dissolves the digitine. This substance remains behind in a state of purity on the escape of the alcohol. The lead-precipitate of digitaline may be distinguished from those of picrotoxine and solanine as follows:—1. The precipitate of picrotoxine is more slimy, and on the addition of strong sulphuric acid becomes saffron yellow. 2. The precipitate of digitaline is gelatinous, and on treatment with sulphuric acid becomes flesh-coloured, or buff. The precipitate of solanine is granular, and on treatment with sulphuric acid turns to a deep buff. If a little sugar is then added to the mixture it takes after some time a violet colour, which ultimately becomes blue.

Conversion of the Hyposulphites into Sulphates by Means of Potassium Permanganate.—G. Brügelmann.—A solution of permanganate, saturated in the cold, is added to the boiling solution of the substance until it has a distinct violet colour. The excess of permanganate is destroyed with alcohol, the precipitate of manganese is filtered off and washed, and the liquid obtained, after the expulsion of the alcohol if necessary, contains the sulphates in solution.

Contributions to Azotimetry.—Carl Mohr.—Already noticed.

Determination of Tartaric Acid in Wines.—R. Kayser.—All the methods in use have the defect of ignoring the tartaric acid which separates out as a neutral calcium salt. A case is given where the error amounted to 0.059 out of a total of 0.022 to 0.120.

Spectroscopic Valuation of Different Kinds of Pure Indigotine.—C. H. Wolff.—Already noticed.

The Hygrometer in the Exsiccator.—Dr. E. Fleischer.—By placing a Lambrecht hygrometer in his exsiccator the author has established that calcium chloride is of questionable value as an absorbent of moisture, and very far inferior to sulphuric acid. It is applicable when gases which are to be dried pass over it in a current (though even in this case a further proportion of moisture may be taken up by sulphuric acid, but in a stagnant stratum of air, as in the exsiccator it is of comparatively little value). By special experiments the author proves that sulphuric acid desiccates four times more rapidly than does calcium chloride.

Lilienfeld's Lamp for Petroleum which Boils at Low Temperatures.—Dr. F. Urech.—This paper cannot be intelligibly reproduced without the five accompanying illustrations.

Spirit-Lamp with a Constant Level.—C. Reinhardt.—This paper also requires the two accompanying illustrations.

Numbering Porcelain Crucibles.—C. Reinhardt.—The author proposes to mark the crucibles with enamel colours as prepared for painting on porcelain. A little of the finely ground colour is ground up in an agate mortar to a thick paste with oil of lavender or aniseed. It is applied to the crucibles with a very fine camel's hair pencil, not too thickly. The crucibles are set on an iron plate, which is gradually heated. When the colour is dry the crucibles are transferred to a muffle and the colour is burnt in.

Determination of Nitrogen.—Dr. Rube.—The author has made at least 3000 determinations of nitrogen, in manures, especially guano, by Ruffe's method. He has always obtained good comparable results by following strictly Ruffe's instructions. He employs always iron tubes, and after use lays them in water. Water is then pumped through them until they are quite clean. A tube serves for many combustions. When other analysts fail to obtain good results with Ruffe's method Rube has occasionally been able to ascertain that they have not followed Ruffe's directions. The determination of nitrogen by Kjeldahl's method is also successful, but it does not economise time.

Analyses of Pure Natural Wines.—R. Fresenius and E. Borgmann.—The results of the authors are given in a series of tables.

The Observation of the Ultra-red Portion of the Spectrum.—H. Becquerel.—From the *Comptes Rendus*.

Solubility of Glass in Various Reagents.—R. Cowper.—From the *Journal of the Chemical Society*.

Determination of the Specific Gravity of Minerals.—P. Gisovius.—The author makes use of a volumometer based on the principle of Phipson and Brügelmann. As a solution he uses cadmium borotungstate.

Determination of Specific Gravity.—W. W. Nicol.—From the *CHEMICAL NEWS*.

A Modified Condenser.—W. A. Shenstone.—From the *Journal of the Chemical Society*.

Apparatus for Gas Analysis.—A. A. Breneman.—From the *CHEMICAL NEWS*.

A Modification of Bunte's Gas Burette.—H. von Jüptner.—This paper requires the accompanying illustration.

A New Form of Gasometer.—L. G. de Saint Martin.—From the *Bulletin de la Société Chimique de Paris*.

A Mercurial Cell as a Substitute for Caoutchouc Connections.—H. Michaelis.—Two forms of this device are figured in the original.

The Acceleration of Evaporation in Capsules.—H. Vogel.—The arrangement cannot be understood without the illustration.

Coating for Retorts.—E. Schaal.—Instead of the common mixture of asbestos and clay the author recommends a soft, moderately thin paste of infusorial earth and soluble sodium silicate; one part of the former being mixed with 4 to 4½ of the latter. It is applied so as to form a coating of ¼ to 1 centimetre in thickness, and allowed to dry slowly.

The Preparation of Carbonic Acid Perfectly Free from Common Air.—S. Hoogewerff and W. A. van Dorp.—The authors grind up chalk, wash it, and dry it in the air. On adding sulphuric acid of full strength pure carbonic anhydride is given off.

Volumetric Determination.—A. Belohoubek had formerly proposed to reduce the acid solution of uranic salts with zinc and to titrate the uranous oxide thus formed with permanganate. According to his experiments the process is equally practicable in sulphuric and in hydrochloric solutions. Follenius subsequently proved that if much hydrochloric acid is present the result is too high on account of the liberation of chlorine. Clemens Zimmermann found that the uranic salts in a sulphuric solution are reduced by zinc to uranous salts and can be very accurately determined by means of permanganate. The determination in hydrochloric solutions is practically only when the air is excluded during titration, and the disturbing influence of the hydrochloric acid is obviated by an addition of manganous sulphate. He operates as follows:—The uranium compound is heated with hydrochloric acid and zinc in a small flask fitted with a Bunsen valve. The yellow colour of the solution passes into green, dirty green, dirty brown, and finally into a splendid red. The reduction is then complete. A quantity of permanganate, more than is required, is poured into a capsule, strongly acidified with sulphuric acid, manganous sulphate is added, and the hot reduced solution is poured rapidly into this mixture. The excess of permanganate is removed by means of a standard solution of ferrous sulphate, and the liquid is finally titrated with permanganate. The same author bases a volumetric process for the determination of uranium compounds upon the following reactions:—If a uranous solution is mixed with an acidified solution of potassium dichromate the uranous salt is rapidly oxidised, whilst iodine is liberated from potassium iodide and determined by means of a solution of sodium hyposulphite. The solution to be titrated is placed in a porcelain capsule, acidified with hydrochloric acid, mixed with an excess of a dichromate solution of known strength, diluted with water to about 150 c.c., and an aqueous solution of potassium iodide is added, stirring constantly. The liberated iodine is determined by means of a standard solution of hyposulphite of known strength in presence of starch paste, and very dilute iodine solution of known strength is added until the blue iodide of starch is formed.

Separation of Nickel from Cobalt.—G. Delraux and G. Vortmann.—Already inserted.

The Occurrence of Pyridine in Commercial Ammonia.—H. Ost.—From the *Journal für Praktische Chemie*.

THE CHEMICAL NEWS.

VOL. L. No. 1289.

A REMINISCENCE OF DR. DALTON.*

By CHARLES CLAY, M.D.

I THINK, but am not quite certain, that it was in the year 1816 or 1817 I was an apprentice to Kinder Wood, Surgeon, 51, King Street, Manchester. About that time the Marsden School of Medicine began its operations, of which my master had the Midwifery Class jointly with Mr. Partington. Jordan and Bluntstone on Anatomy, Dalton on Chemistry, Fawdington on Surgery, Davies on Botany, and some others. I mention this as it has often been stated that the Pine Street School of Medicine was the first in Manchester, *which is not correct.*

Among other lectures I was advised by my master to attend the Lectures on Chemistry, by Dalton, which I did. The course consisted of ten lectures, which were to be extended afterwards. I thus became a pupil to Dalton. At that time he was busy experimenting on gases; and he asked my master if he could suggest any plan by which he could obtain some of the gases of the coal-pits, more especially what was usually called fire-damp. Mr. Wood replied, he had a friend in Oldham whose pits were unusually troubled with fire-damp and had had many serious explosions; and if Dr. Dalton was very anxious he would try, *but how?* The Dr. then suggested some bottles filled with water, then taken into the mine and emptied, and when emptied well corked. Mr. Wood said he thought he would send his apprentice to his friend with bottles and instructions, and he felt sure it would be attended to correctly. *I was then asked, and willingly volunteered to go.*

Four wine-bottles, which the Dr. thought sufficient, were got, and a wine basket that just held them, with a piece of sealing-wax in my pocket and four tightly-fitting corks greased at the ends, to be inserted. I started for Oldham with the note. Mr. Wood drove me as far as Hollinwood; from thence I walked to Oldham, and with some difficulty found the gentleman, who was just starting on a journey. After reading the note he smiled, and asked me to get into his gig. He drove right to the pits, explained the matter fully to his manager, and left me in his care. The underlooker was then signalled from the pit, and soon after made his appearance, black enough from head to foot. Careful instructions were given to him on taking the basket. I interfered, and said I had come to see the matter myself, and therefore wished to go into the pit. The manager smiled, and asked me if I had ever been in a coal-pit; I said no, but I was ready to go. So in the end we prepared to start; I was placed in the tub with the underlooker, who went with me one leg in the tub and the other outside, to guard the descent, as there were no conducting-rods. On progressing downwards I felt a curious sensation as though I should be sick, and I sensibly felt I was descending rapidly on looking at the sides of the pit; but when the light failed the motion appeared reversed, as though I was going upwards. In a few seconds more I felt the elasticity of the rope, which felt as though it elongated and contracted alternately, and which produced something like sea-sickness: on the tub reaching the floor of the mine I got out, and was surrounded by about half a dozen black-faced mortals, full of curiosity as to what I could want there. What had the bottles in them? Was it gin? My conductor replied, "*Nobbut water*"; loud laughter followed. "*Neaw, lads,*"

says the conductor, "look handy; two of you go with me and this lad as far as we can with candles, and then stop for orders."

The conductor took the basket preceded by one of the men. I followed, and a man followed me; in this order we marched along the mine. I felt the iron rails beneath my feet. After proceeding for a considerable distance I heard a noise like thunder, and enquired what it was. The conductor said only the waggons. "Now," said he, "stand close to the wall." I had no sooner done so when four waggons of coal were pushed past by lads. We then proceeded as before; at last we got to a point that the conductor called out *Halt*, and put out all candles but one that was put into a lump of clay and fastened on the wall of the passage.

"Now go on carefully." Soon after we came to a turn and entered another drift, where we had to creep in a bent position. My breathing at this time became difficult, I felt great oppression about my chest, and the perspiration was profuse all over my body. The conductor called out to me, "Heaw dost feel, lad?" I said, "Not very well!" "Con theaw manage a bit further?" I replied, "I think I can." We then proceeded, but in a short time we stopped. The conductor declared it was not safe to go further. "Neaw, lad," said he, "get done what theaw has to do." He gave me the basket; I felt for the bottles, took one and gave a cork to one of the party, and having emptied the water out gave the bottle to be corked well, instructing him to force it in well, and so on with the other three bottles, which when finished I said I was ready to return, the bottles being put mouths downwards into the basket.

We then began to retrace our steps, and every few seconds I felt a sensible relief in my breathing. Turning from the narrow drift into the main track, we progressed more rapidly, until I could see a glimmer of light at a distance. It was the candle we had left, and by the time we arrived at it I felt no difficulty at all in my breathing. I now asked the men to stay a few minutes. One held the candle, and I took the piece of sealing-wax out of my pocket, melted it at the candle,—having first cut the cork off level,—smeared it over with the wax. We then proceeded, and soon arrived at the bottom of the shaft. Five or six miners, now full of curiosity, crowded round. One said "That's a queer go, bringing water and taking nowt back." "Aye," said another, "and corking *nowt* down, as if it would jump out." These remarks were cut short by my conductor telling me to get into the tub, basket and all. The signal given we mounted, and left our curiosity mongers no wiser.

The same sensations accompanied me up as on the way down, and when we emerged from the pit's mouth the sun was shining brilliantly, and the more so it appeared from being in the dark regions for some hour and a half; the daylight was to me a pleasurable surprise and delight. I experienced a similar sight in after years on emerging from the Peak Cavern in Derbyshire, after a long visit in its interior, on rounding the angle of a rock and coming suddenly to where the light came streaming in. But to my narrative: the underlooker gave an account to the banksman, who remarked that I should make a collier in time; then sent a lad with me to carry the basket and show me the way to Manchester Street, in Oldham. Having arrived there, I looked about me to see if there was any way of riding to Manchester; seeing none, I trudged along homewards. After I had gone a mile or so I saw a stand coach, with the horse's head towards Manchester, standing at a public-house door. I went in and asked the driver if he would give me a lift to Manchester. He asked me in return "If I saw any green in his eye?" After he had perpetrated his joke he told me he would take me for five shillings. I said I had no five shillings to spend, but if he would take me and the basket to 51, King St., Manchester, I would give him half a crown. After some demur he said "Well, get in"; and off we set, and a weary ride I got. He stopped at almost every

* A Paper read before the Manchester Literary and Philosophical Society, April 15, 1884.

public-house either to drink or let his horse drink. In two hours I landed safely in King Street. Mr. Wood was delighted and laughed heartily at my account, paid the man his two shillings and sixpence, and sent me to wash and refresh myself. When that was done I was sent to George Street with my bottles. The Doctor received me very kindly, and the quiet twinkle of his eye showed his satisfaction, which was greatly increased when he learned the particulars of my travels. He eyed the bottles with great satisfaction; he looked at the corks closely sealed, and seemed puzzled. I asked him what he was going to do with them? "Well," he said, "I am thinking how I am to get the corks out without mixing it, more or less, with the atmosphere. I want to put the air into that receiver on the shelf of that pneumatic trough." I said, "I think I could do it." He looked at me and said, "How?" I said, "File the bottle-neck round, and then a smart tap under the water I think will do it." He said "Capital, thou shalt try." He gave me some coppers to fetch a file, and I soon filed a bottle-neck round, then held it under the shelf of the pneumatic trough, a gentle tap with the handle of a knife, and the air-bubbles very speedily rose into the receiver. The other bottles were beheaded, and very soon I took leave of the Doctor, who was apparently well pleased, and on parting said, if there was anything in his lectures which I did not understand, he wished me not to hesitate, but ask him, and he would always willingly assist me, and he was as good as his word; in fact, he showed me many little kindnesses afterwards, and so ends my small reminiscence of Dr. Dalton.

DETECTION AND DETERMINATION OF PICRIC ACID.

By G. CHRISTEL.

THIS compound forms yellowish white leaflets which take up ammonia on exposure to the air and assume a deep yellow colour. The solutions of tri-nitrophenol in dilute acids, in chloroform, and carbon disulphide are colourless. If the solution in chloroform is evaporated to dryness there remains a colourless residue which is coloured deep yellow by a drop of water. If a yellow (ammoniacal) picric acid is dissolved in a little water, mixed with two or three volumes of ether, and shaken up, a part only of the acid is taken up by the ether, and further additions of ether dissolve scarcely any colouring matter. The addition of acetic acid does not alter this behaviour, but after adding a little sulphuric acid the entire picric acid may be extracted with ether. Ammonia withdraws the dissolved picric acid from ether; and the golden-yellow ammonium picrate is insoluble in ether. Chloroform removes only a part of picric acid from its pure watery solution or from one which has been acidulated with sulphuric acid. In searching for picric acid it is therefore best to acidulate with sulphuric acid and exhaust by shaking up with ether.

If to a solution of picric acid or ammonium picrate in water we add neutral lead acetate or copper sulphate there is no precipitate, but on further adding a little alkali (ammonia) there is formed with lead acetate a reddish yellow precipitate, and with copper sulphate a greenish precipitate. On the other hand, 1-20th milligram picric acid dissolved in 5 c.c. water with a few drops of basic lead acetate becomes strongly opalescent, and gives subsequently a slight but distinct yellow precipitate. This precipitate is decomposed by dilute sulphuric acid. If the same precipitate is submitted to prolonged treatment with water, a part of the picric acid is dissolved, whilst there remains an apparently more basic compound of a deep orange-yellow.

The yellow colouring-matters of *Quercus tinctoria* (quercitron bark) and of *Broussonetia tinctoria* (fustic) behave in a similar manner with the salts of lead. These

and analogous colouring matters are distinguished from picric acid thus: they are neither changed by potassium cyanide nor reduced by potassium stannite. Their precipitates are never so pale yellow as that of picric acid. The soluble aniline yellow of commerce dissolves to a reddish yellow liquid, which if much diluted appears of a pure yellow. It is very imperfectly precipitated by basic lead acetate, not changed by potassium cyanide, but turned at once to a purple by hydrochloric acid.

If a solution of tri-nitrophenol, not too dilute, is mixed with an aqueous solution of methyl green, there appears a green precipitate which in excess of water dissolves to a bluish green liquid. It is soluble also in acetic acid and in other acids. With organic bases (alkaloids) picric acid gives precipitates, as is well known, but they are not suitable for its separation. On boiling solutions of picric acid with permanganate considerable quantities of the latter are reduced. If to an aqueous solution of picric acid there is added stannous chloride, a yellowish brown precipitate falls down, but if a little ammonia is added, or if potassium stannite is used, the liquid becomes red from the formation of picramic acid. If to a solution of barium chloride there are added a few crystals of caustic baryta and a solution of picric acid, not too dilute, there is formed a red precipitate. Sulphuretted hydrogen reddens an alcoholic solution of picric acid. The same effect is rapidly produced by ammonium sulphide. By the addition of zinc and dilute sulphuric acid upon picric acid there is formed a yellowish red turbid liquid. If this is decanted off from the zinc, mixed with an excess of alcohol (ethyl), allowed to stand for some time and filtered, the liquid becomes greenish, and changes first to a violet-blue and then to a reddish violet. If even a very small quantity of picric acid (much less than 1 milligram) or of an alkaline picrate is heated with hydrochloric acid and stannous chloride, allowed to cool, a trace of potassium chlorate added to the mixture slightly heated, the liquid becomes first greenish yellow and then a fine blue, but an exceedingly trifling excess of potassium chlorate destroys the colour. In presence of organic matter this reaction is not distinct. One of the most sensitive and trustworthy reactions is the well-known transformation of picric acid into red phenyl-purpuric acid on heating with potassium cyanide. Tri-nitroresol, in like manner, forms cresyl-purpuric acid on treatment with potassium cyanide. If an aqueous solution of picric acid, not quite saturated, is mixed with potassium sulphocyanide and the mixture heated, there appear in the liquid (which at first remained clear) numerous yellow crystalline needles, which reflect incident light with splendid green and red colours. If the crystals are separated from the liquid, dried, and touched with an incandescent body they explode with extreme violence. Nitrogenous tissues (wool, silk) take a permanent yellow in an aqueous solution of picric acid; absolute alcohol, hydrochloric acid, dilute caustic alkalis, and aqueous ammonia withdraw the picric acid, partially or entirely, from such tissues. The residue from the evaporation of the ammoniacal solution thus obtained is particularly fitted for the basic acetate of lead reaction and for that with potassium cyanide. Animal charcoal, if added in small quantities to a solution of picric acid, does not decolourise it, but larger quantities entirely withdraw picric acid from its solutions.

To detect picric acid in beer Christel evaporates 200 c.c. to the consistency of a syrup; introduces the residue into a small flask, adds 50 c.c. of alcohol at 90 per cent, lets it stand for twenty-four hours, during which the whole is repeatedly well shaken up, filters, extracts again with 30 c.c. alcohol, evaporates the mixed filtrates to the consistency of a syrup, adds to the residue 4 to 5 drops of dilute sulphuric acid (1:3), and then mixes it with 5 to 6 volumes of ether in a test-tube closed with a cork. After the mixture has undergone strong and prolonged shaking the ether is decanted, 2 or 3 drops of sulphuric acid are added to the residue, which is again shaken out with ether. The mixed ethereal solutions are evaporated in a porcelain capsule

at common temperatures, the residue is diluted with water to 5 to 10 c.c., filtered, and neutralised with ammonia. The solution thus obtained can be further tested as above. Christel determines picric acid colorimetrically, comparing the intensity of the colour of a solution of phenyl-purpuric acid obtained from the substance under examination with the intensity of solutions prepared simultaneously and under the same conditions from different but known quantities of picric acid. This procedure admits of determinations as close as .1 milligram. picric acid in 100 c.c.—*Zeitschrift f. Analytische Chemie und Archiv. der Pharmacie*.

ON THE

FORMATION OF DIBENZYL BY THE ACTION OF ETHYLENE CHLORIDE ON BENZOL IN THE PRESENCE OF ALUMINIUM CHLORIDE.*

By WILLIAM H. GREENE.

By a series of the most remarkable chemical investigations of late years MM. Friedel and Crafts have shown that the radicles of the saturated hydrocarbons can be grafted upon the benzol nucleus by the action of aluminium chloride upon a mixture of benzol and the monatomic chlorides, bromides, &c. Thus, on passing methyl chloride into benzol in which aluminium chloride is suspended, all of the methyl derivatives of benzol, from toluol to hexamethyl benzol, may be formed, according to the proportions of benzol and methyl chloride which are brought into contact. In the same manner the ethyl, propyl, and other derivatives of benzol may be obtained abundantly.

In these reactions hydrochloric acid is disengaged, and the explanation proposed by Friedel and Crafts supposes the reaction to take place in two phases:—In the first a compound of benzol and aluminium chloride is formed, with elimination of hydrochloric acid:—

In the second the aluminium-benzol compound reacts upon the monatomic chloride present, the organic radicle entering the benzol nucleus, and aluminium chloride being re-formed:—

A small quantity of aluminium chloride serves for the preparation of an indefinite quantity of the new hydrocarbon.

By the action of aluminium chloride on the monatomic chlorides alone, hydrochloric acid is also eliminated, and the radicle is condensed. Hence the reaction which would take place between benzol and a polyatomic chloride under the same circumstances cannot be entirely foreseen. It seems possible that in the case of ethylene chloride, for example, both atoms of chlorine might be replaced by phenyl groups; but it would seem more probable that, after the first substitution, one molecule of hydrochloric acid would be removed from the ethylene chloride, and that a more condensed hydrocarbon, styrol, would be formed. However, the first reaction is that which actually occurs.

When aluminium chloride is introduced into a mixture of benzol and ethylene chloride the reaction begins in the cold, and becomes energetic on the application of heat. Hydrochloric acid is disengaged abundantly: when the reaction has ceased the mixture is thrown into water to separate the aluminium chloride, and the oily liquor which separates is heated with alcoholic potassium hydrate, in order to decompose any remaining ethylene chloride.

After washing and drying the product it yields, on fractional distillation, very nearly the theoretical quantity of dibenzyl; after which a thick oily mixture remains, which

does not completely distil at 200° in a vacuum. This mixture consists of condensation products, and yields no satisfactory results, as it cannot well be fractionated, and does not solidify in a freezing mixture.

Pure dibenzyl melts at 52.5° to 53°, and boils at 279°, under a pressure of 767 millimetres, the thermometer being entirely immersed in the vapour. This boiling-point is lower than that given by Cannizzaro and Rossi (284°), and higher than that indicated by Fittig (272°).

ON THE

ACTION OF HYDROCHLORIC ACID AND OF CHLORINE ON ACETO-BENZOIC ANHYDRIDE.

By WILLIAM H. GREENE.

In a note published in the *Bulletin de la Société Chimique* (32, 164), M. Loir states that aceto-benzoic anhydride prepared by the action of benzoyl chloride on sodium acetate is decomposed by hydrochloric acid at 130°, into acetyl chloride and benzoic acid, while at 140° chlorine converts it into acetyl-chloride and chloro-benzoic acid; under the same circumstances the anhydride made by the reaction of acetyl-chloride with sodium benzoate yields nothing, but at 160° hydrochloric acid converts it into benzoyl chloride and acetic acid—with chlorine at 170° it yields benzoyl chloride and chlor-acetic acid.

These reactions appeared extremely improbable. Aceto-benzoic anhydride begins to decompose at a temperature below 150° into acetic anhydride and benzoic anhydride; at temperatures near this point it should act with reagents as would a mixture of the two anhydrides. Besides this, M. Loir determined the nature of his decomposition products by putting them in water, and did not, it appears, attempt to fractionate his distillates in any manner. Acetic anhydride is decomposed by hydrochloric acid at ordinary temperatures, and aceto-benzoic anhydride, a less stable compound, would hardly withstand the action of the same reagent at temperatures near 100°.

I have repeated the experiments of M. Loir with the following results:—

If dry hydrochloric acid be passed into aceto-benzoic anhydride at ordinary temperatures, the reaction is the same, by whichever process the anhydride may have been prepared; benzoic acid is deposited, and the tube conveying the hydrochloric acid becomes obstructed. On raising the temperature, acetyl-chloride begins to distil at 55° to 60°, and the product obtained up to 130° is a mixture of acetyl-chloride and acetic acid. If the heat be raised much above 130°, and the current of hydrochloric acid rapid, a small quantity of benzoyl-chloride is carried over and will be found in the distillate. The residue in the apparatus consists of benzoyl-chloride and benzoic acid. If the anhydride be heated to 130°, or any other temperature, before passing the hydrochloric acid, the reaction is the same with the anhydride prepared by each process. However, it seems that the lower the temperature the greater the proportions of acetyl-chloride and benzoic acid which are formed, while at higher temperatures (130 to 150°) the reaction yields acetyl-chloride, acetic acid, benzoyl-chloride, and benzoic acid in about equivalent proportions.

Chlorine acts in an analogous manner; the products are the same in whichever manner the anhydride may have been prepared; but with the exception of the acetyl-chloride, these products are more difficult to separate than those formed in the reaction with hydrochloric acid. Indeed, chloracetic acid boils at about 186°, and benzoyl-chloride at 198°; yet, in the experiments of M. Loir, the latter compound seems to have distilled over first, leaving the chloracetic acid in the retort. At temperatures near 150° the products of this reaction are acetyl-chloride, chloracetic acid, benzoyl-chloride, and o-chloro-benzoic

* Read before the American Philosophical Society.

acid; at lower temperatures the principal products are acetyl-chloride and chloro-benzoic acid.

From his experiments M. Loir concludes that the constitution of benzoyl acetate differs from that of acetylbenzoate; but the results of these experiments being erroneous, such a conclusion is unsustainable. The bodies thus named are identical, all of their reactions under the same conditions are the same, and they must be represented by the same rational formula.—*American Chemical Journal*.

A RECALCULATION OF THE ATOMIC WEIGHTS.*

By FRANK WIGGLESWORTH CLARKE, S.B.,
Chief Chemist to the U.S. Geological Survey, Washington.

OSMIUM.

THE atomic weight of this metal has been determined by Berzelius and by Fremy.

Berzelius† analysed potassium osmichloride, igniting it in hydrogen like the corresponding platinum salt. 1.3165 grms. lost 0.3805 of chlorine, and the residue consisted of 0.401 grm. of potassium chloride, with 0.535 grm. of osmium. Calculating only from the ratio between the Os and the KCl, we have, $Os = 198.494$; or, if $O = 16$, $Os = 198.951$.

Fremy's determination,‡ is based upon the composition of osmium tetroxide. No details as to weighings or methods are given; barely the final result is stated. This, if $O = 15.9633$, is $Os = 199.190$. If $O = 16$, $Os = 199.648$.

Berzelius's work is evidently entitled to preference, although neither determination is in any sense equal to the present requirements of chemical science. The values given are doubtless several units too high.

IRIDIUM.

The only early determination of the atomic weight of iridium was made by Berzelius,|| who analysed potassium iridichloride by the same method employed with the platinum and the osmium salts. The result found from a single analysis was not far from $Ir = 196.7$. This is now known to be too high. I have not, therefore, thought it worth while to recalculate Berzelius's figures, but give his estimation as it is stated in Roscoe and Schorlemmer's "Treatise on Chemistry."

In 1878 the matter was taken up by Seubert,§ who had at his disposal 150 grms. of pure iridium. From this he prepared the iridichlorides of ammonium and potassium, $(NH_4)_2IrCl_6$ and K_2IrCl_6 , which salts were made the basis of his determinations. The potassium salt was dried by gentle heating in a stream of dry chlorine.

Upon ignition of the ammonium salt in hydrogen, metallic iridium was left behind in white coherent laminae. The percentages of metal found in seven estimations were as follows:—

43.742
43.725
43.745
43.739
43.726
43.739
43.705

Mean 43.732 ± 0.0035

The potassium salt was also analysed by decomposition

in hydrogen with special precautions. In the residue the iridium and the potassium chloride were separated after the usual method, and both were estimated. Eight analyses gave the following results, expressed in percentages:—

Ir.	2KCl.	Cl ₂ .
39.881	30.829	29.290
39.890	30.842	29.277
39.868	30.813	29.300
39.876	30.835	29.289
39.877	30.825	29.287
39.879	30.811	29.310
39.882	30.814	29.285
39.883	30.792	29.288

Mean 39.880 ± 0.0015 30.820 ± 0.0037 29.291 ± 0.0024

From these data several values for the atomic weight of iridium may be calculated:—

From per cent Ir in $(NH_4)_2IrCl_6$..	Ir = 192.951 ± 0.064
" " K_2IrCl_6 ..	" 192.536 ± 0.060
" " KCl in " ..	" 192.474 ± 0.111
" " Cl ₂ in " ..	" 192.757 ± 0.148
General mean ..	" 192.702 ± 0.039

If $O = 16$, this becomes $Ir = 193.145$.

In the potassium salt, instead of calculating from the percentages directly, we may reckon upon the ratios between Ir and Cl₂, and between Ir and 2KCl:—

From Ir : Cl ₂ ratio ..	Ir = 192.626 ± 0.081
" Ir : 2KCl ratio ..	" 192.514 ± 0.044
General mean ..	" 192.539 ± 0.039

Or, if $O = 16$, $Ir = 192.982$.

Again we may combine this mean with the value derived from the ammonium iridichloride, and so estimate the relative importance of the latter:—

From K_2IrCl_6 ..	Ir = 192.539 ± 0.039
" $(NH_4)_2IrCl_6$..	" 192.951 ± 0.064
General mean ..	" 192.651 ± 0.033

If $O = 16$, this becomes $Ir = 193.094$.

We may assume, then, from all the facts before us, that if $O = 16$, the atomic weight of iridium varies from the even number 193 only within the limits of experimental error.

PALLADIUM.

The atomic weight of palladium has been studied by Berzelius and by Quintus Icilius. In an early paper Berzelius* found that 100 parts of the metal united with 28.15 of sulphur. Hence $Pd = 113.63$, a result which is unquestionably far too high.

In a later paper† Berzelius published two analyses of potassium palladiodichloride, K_2PdCl_4 . The salt was decomposed by ignition in hydrogen, as was the case with the double chlorides of potassium with platinum, osmium, and iridium. Reducing his results to percentages, we get the following composition for the substance in question:—

Pd.	2KCl.	Cl ₂ .
32.726	46.044	21.229
32.655	45.741	21.604
Mean 32.690	45.892	21.416

From these percentages, calculating directly, very discordant results are obtained:—

* *Poggend. Annal.*, 8, 177. 1826.

† *Ibid.*, 13, 454. 1828.

From percentage of metal	Pd=106.612
" " KCl	104.674
" " Cl ₂ (loss)	110.796

Obviously, the only way to get satisfactory figures is to calculate from the ratio between the Pd and 2KCl. Doing this, we get, Pd=105.737; or, if O=16, Pd=105.981.

This last value varies so slightly from the even number 106 that the latter may be safely used for all purposes of chemical calculation.

The determination made by Quintus Icilius* need be given only for the sake of completeness. He ignited potassium palladiochloride in hydrogen, and found the following amounts of residue. His weights are here recalculated into percentages:—

64.708
64.965
64.781

Mean 64.818

From this mean, Pd=111.879. Upon looking at the values deduced from Berzelius's figures, it will be seen that the highest, 110.796, is calculated from the chlorine lost upon igniting the palladiochloride. The same kind of error which vitiates that result probably affects also these data drawn from the palladiochloride.

ON CERTAIN SUBSTANCES OBTAINED FROM TURMERIC.

By C. LORING JACKSON AND A. E. MENKE.

(Continued from vol. xlviii., p. 100.)

OWING to the difficulty of preparing curcumin, and the very unmanageable nature of the products obtained from it and from turmerol, we have not made as much progress in the study of these substances as we had hoped. In fact, we should not publish our results at the present time were it not that we cannot continue the work together at all, and neither of us will be able to return to it for at least a year; we have therefore decided to collect in the following papers all the results we have obtained up to this time, although many of them are very fragmentary, and others consist only in indications which may prove useful in future work.

IV. CURCUMIN.

Action of Acetic Anhydride upon Curcumin.

Monaceturcumin, C₁₄H₁₃(C₂H₃O)₂O₄.—This substance is formed by the action of acetic anhydride and fused sodic acetate on curcumin: probably also by the action of acetyl chloride. As has been stated in a previous paper,† it forms an uninviting brown resin, which we have not as yet succeeded in bringing into a crystalline condition; but, nevertheless, it can be obtained in a state of purity by the following method:—Curcumin is heated on the water-bath with a slight excess of acetic anhydride and a little fused sodic acetate for about sixteen hours in a flask with a return cooler; the dark brown viscous product is then dissolved in a little glacial acetic acid and precipitated with water. After repeating the solution in acetic acid, and precipitation with water, the yellowish brown precipitate is washed until free from acetic acid, and dried *in vacuo*.

0.1710 grm. of substance gave 0.4178 grm. of carbonic dioxide and 0.0922 grm. of water.

	Calc. for C ₁₄ H ₁₃ O ₈ .	Found.
Carbon	66.67	66.62
Hydrogen	5.55	5.99

* Die Atomgewichte vom Pd, K, Cl, Ag, C, und H, nach der Methode der kleinsten Quadrate berechnet.† Inaug. Diss. Göttingen, 1847. Contains no other original analyses.

† American Chemical Journal, iv., 19; and Proc. Amer. Acad., xvii., 123.

Properties.—A viscous brown mass without definite melting-point, although it shrinks together at 58° to 60°, but it does not become fully liquid below 100°. It is soluble in alcohol and glacial acetic acid, essentially insoluble in ligroine and carbonic disulphide, slightly soluble in ether and in benzene; but its solubility in the latter is greater than that of curcumin. It dissolves in strong sulphuric acid with a blood-red colour like that produced by curcumin. Aqueous sodic hydrate dissolves it, forming a red solution, which becomes decomposed, with the formation of ill-defined black products, when allowed to stand exposed to the air. A mixture of alcohol and sodic carbonate was reddened instantly by the substance, showing that the acetyl group had replaced the hydrogen of the phenol hydroxyl, as was to be expected; that is, its formula would be—

As has been stated already,* the substance gave unsatisfactory results when submitted to oxidation with potassic permanganate.

Diacteturcumin, C₁₄H₁₂(C₂H₃O)₂O₄.—On one occasion the process described above yielded a yellow crystalline product instead of the brown viscous monaceturcumin. The coming of the vacation interrupted our work before we had succeeded in determining the conditions on which the formation of this substance depends, the few experiments which we had time to try giving invariably monaceturcumin; we must, therefore, for the present, confine ourselves to describing the properties and analysis of the substance. After the removal of the acetic anhydride and sodic acetate by treatment with water, it was purified by washing with alcohol and crystallisation from glacial acetic acid, dried at 100°, and analysed.

0.2230 grm. of substance gave 0.5348 grm. of carbonic dioxide and 0.1090 grm. of water.

	Calc. for C ₁₄ H ₁₂ O ₈ .	Found.
Carbon	64.45	65.39
Hydrogen	5.45	5.43

Properties.—It crystallises from glacial acetic acid in rosettes of a vivid yellow colour without the orange shade of curcumin, which are made up of very characteristic rhombic plates; melting-point 154°. It is more soluble in glacial acetic acid than in any other solvent, especially when the acid is hot; less soluble in alcohol than curcumin; slightly soluble in ether and benzene; essentially insoluble in ligroine and carbonic disulphide. Strong sulphuric acid dissolves it, becoming blood-red in transmitted light, green like rosaniline in reflected light; the red colour is somewhat more purple than that produced by curcumin. Sodic hydrate in aqueous solution acts upon it very slowly, and not rapidly, even if dissolved in dilute alcohol. The red solution thus obtained gives with hydrochloric acid a viscous brown mass with a low melting-point, which seems to be impure monaceturcumin. Sodic carbonate and alcohol give an orange solution looking like that of potassic dichromate. According to the formula given by us to curcumin in our first paper this substance should be a mixed anhydride of curcumin and acetic acid, with the other acetyl group attached to the phenol oxygen, as in the monacet compound—a constitution which would be expressed by the following formula:—

That the carboxyl group is affected by the introduction of the second acetyl is shown by the fact that alkaline reagents act upon it only after some time, and then evidently decompose it; whereas the monacet compound is attacked by them instantly, and the action consists only in the formation of a salt; but, on the other hand, the substance is more stable than acid anhydrides are usually, as is shown

by this very action with alkalis, and by the fact that it can be boiled with water for many hours without undergoing any change in melting-point or the formation of any soluble acid.

Action of Phosphoric Oxychloride on Curcumin.

Of all the reactions of curcumin which we have observed this is by far the most striking, and we have decided therefore to describe it at some length, although we have not succeeded in determining the nature of the substance formed. If a few drops of phosphoric oxychloride are added to some curcumin suspended in ligroïne, its orange-yellow colour is converted instantly into a rich reddish purple, which in reflected light appears bronze-green with a metallic lustre, between the colours of rosaniline and Hofmann's violet. To prepare the substance in quantity the curcumin was rubbed in a mortar with phosphoric oxychloride diluted with ligroïne and afterward washed repeatedly with ligroïne; the dark purple viscous mass thus obtained was dried in a desiccator over sulphuric acid, lime, and paraffin. This treatment, the best which we could devise, was usually far from effectual, as in every case but one the substance contained phosphorus, and was invariably converted during drying into a black mass having very different properties from the purple viscous substance at first obtained. The analysis of the substance free from phosphorus gave results less than one per cent higher than those required by curcumin, and this was confirmed by the analysis of one of the preparations containing phosphorus, after the phosphorus present had been calculated as phosphoric acid, and subtracted from the weight of the substance.

The properties of the purple product are quite as striking as its formation from curcumin, for the addition of water converts it again into curcumin, and the change from purple to orange-yellow is instantaneous. That curcumin was formed in this case was shown by the melting-point, 178°. Alcohol also changes the colour instantly from purple to yellow, but the product is much more soluble in alcohol than curcumin, and is possibly its ethyl-ether. Ether acts in the same way, leaving on evaporation a viscous red mass; in ligroïne and benzene it is essentially insoluble. By standing even in a desiccator it is gradually decomposed—more rapidly at 100°—into a black mass, which is unaffected by water, but soluble in alcohol or sodic hydrate, forming dark solutions. Owing to the uninviting properties of this decomposition product it was not studied further.

It is highly probable that the blood-red colour imparted to strong sulphuric acid by curcumin is due to this substance, as curcumin is deposited when this solution is diluted. As to the nature of the purple substance our analyses show nothing; but its easy conversion into curcumin by the addition of water indicates that it is an anhydride, and we are inclined to believe that the carboxyl of the curcumin alone is involved in the reaction, because we obtained a similar but somewhat redder colour when monacetcurcumin was treated with phosphoric oxychloride.

In our first paper on curcumin we assigned to it the formula $C_6H_3(OH)(OCH_3)(C_6H_5COOH)$. Our work since then has been directed toward the determination of the structure of the side-chain C_6H_5COOH , and, although we have not succeeded in proving anything about it definitely, we may be allowed to state that our results can be explained by the assumptions that the carboxyl is attached to the carbon atom next but one to the benzene ring, and that in the remainder of the side-chain some of the carbon atoms are united to form a ring.

TURMEROL.

In our first paper on this subject we mentioned that, although turmerol is converted into terephthalic acid by treatment with an excess of a hot solution of potassium permanganate, the same reagent produces, when cold and not in excess, one or more apparently new acids. In the

following paper we describe our study of the product of this reaction, a complex mixture of acids, from which we have succeeded in isolating two new acids—one having the formula $C_{11}H_{14}O_2$, which we propose to call turmeric acid; the other either $C_{10}H_{12}O_4$, or $C_{10}H_{10}O_4$, to which we would give the name apoturmeric acid.

In order to obtain this product a little turmerol was allowed to stand at ordinary temperatures with a moderately strong solution of potassium permanganate until the latter was reduced. The operation was carried on in large beakers, and the yield seemed to be better when not more than 500 c.c. of permanganate solution were used in each oxidation than when larger quantities were employed; with this amount the action came to an end in about three days. After the liquid had become colourless, the oxide of manganese and unaltered oil were removed by filtration and again treated with permanganate solution; this treatment being repeated until the permanganate ceased to act, when it was found that the oxide of manganese was essentially free from organic matter, and therefore that the entire product was contained in the aqueous filtrate. The mixed filtrates from a number of operations were then concentrated on the water-bath, acidified with sulphuric acid, extracted several times with ether, and the extract, a black tarry liquid, distilled with steam, when a yellow oil (A) passed over with some difficulty; this was mostly turmeric acid. The residue in the flask (B) contained a tarry substance and apoturmeric acid, which not infrequently separated in white crystals as the solution cooled.

Upon distilling with steam the solution left after extraction with ether it yielded a strongly acid distillate containing a little of the yellow oily acid, from which it was freed in great part by extracting it five times with ether. It was then boiled with baric carbonate to convert it into a barium salt, which crystallised, after it had evaporated spontaneously nearly to dryness. The crystals, freed from mother-liquor by pressure between filter-paper, were nearly pure baric acetate, as shown by the following analysis:—

1. 1745 grms. of the air-dried salt lost 0.0661 grm. when dried at 100°.

	Calculated for $Ba(C_6H_5O_2)_2H_2O$.	Found.
Water . . .	6.59	5.63

1. 1038 grms. of the dried salt gave 0.9974 grm. of baric sulphate.

	Calculated for $Ba(C_6H_5O_2)_2$.	Found.
Barium . . .	53.73	53.13

As, however, a solution of the silver salt blackened much more easily than argentic acetate should, and crystallised at first in balls made up of radiating needles, although after one or two re-crystallisations attended by blackening it gave the flattened needles characteristic of argentic acetate, we suspected that there might be some other acid present, the barium salt of which had been removed in the mother-liquors, and resorted to fractional acidification with sulphuric acid to settle this point. For this purpose a quantity of the acid distillate, after treatment with ether, was converted into the calcium salt and treated with one-third of the amount of sulphuric acid necessary to set free all the acid it contained. It was then distilled with steam as long as the distillate showed an acid reaction. The residue in the flask was treated twice successively with the same amounts of sulphuric acid, and the first and third fractional distillates converted into calcium salts.

I. 0.3582 grm. of salt from the first fraction gave 0.2894 grm. of calcic sulphate.

II. 0.2281 grm. of salt from the third fraction gave 0.1980 grm. of calcic sulphate.

	Calculated for $Ca(C_6H_5O_2)_2$.	Found.	Calculated for $Ca(C_6H_5O_2)_2$.
		I.	II.
Calcium . .	25.32	23.76	25.54
			21.50

From these numbers it appears that there is no large amount of any acid except acetic present, and the blackening and different crystalline forms of the silver salt were probably due to a trace of turmeric acid which could not be removed by ether.

As it was possible that a neutral lactone might have been formed, a portion of the acid liquid was boiled with baric carbonate, distilled with steam, and the neutral distillate boiled with baric hydrate for some time; as after removing the baric hydrate with carbonic dioxide there was no residue on evaporation, no lactone was formed.

The formation of carbonic dioxide was determined by a special experiment, in which a portion of turmerol was oxidised out of contact with the air; upon acidifying with sulphuric acid a gas was given off, which gave a copious white precipitate with lime-water.

A. Study of the Distillate obtained from the Ether Extract with Steam.

This consisted principally of water, with a few yellow or brown oil-drops floating in it. It was extracted with ether, and the extract, which had acid properties, boiled with water and calcic carbonate. The solution of a calcium salt thus obtained, when allowed to evaporate spontaneously, deposited spherical collections of white needles and a yellow viscous substance somewhat more soluble than the crystals.

The crystalline body proved to be the calcium salt of the new acid, which we have called turmeric acid, after it had been purified by repeated crystallisation from water, which is tedious in the highest degree, as all the solutions and evaporations have to be carried on at ordinary temperatures; in fact, it took us more than a year and a half to prepare and purify the 4 or 5 grms. of this substance which have served for the present research.

In regard to the nature of the viscous non-crystalline salt we cannot speak with certainty, as we were unable to obtain it free from calcic turmerate; but we are of the opinion that it is a salt of an isomeric acid, as an analysis of the salt, which had not been purified by crystallisation, gave 8.12 per cent of calcium instead of 8.93 calculated for calcic turmerate, and the acid set free from the amorphous salt remained liquid even at -5° , while turmeric acid solidifies at ordinary temperatures.

The total yield of mixed calcium salts cannot be more than 1 or 2 per cent of the turmerol oxidised, and the proportion of amorphous salt in this product is comparatively small.

Turmeric Acid, $C_{11}H_{14}O_8$.—The calcium salt prepared and purified as just described was treated with hydrochloric acid, and then extracted with ether. On evaporating off the ether a yellowish oil was left, which crystallised on standing, and gave the following analytical results after being dried *in vacuo*:—

I. 0.2198 gm. of substance gave 0.5954 gm. of carbonic dioxide and 0.1586 gm. of water.

II. 0.1320 gm. gave 0.3584 gm. of carbonic dioxide and 0.0960 gm. of water.

	Calculated for $C_{11}H_{14}O_8$.	Found.	
		I.	II.
Carbon	74.16	73.87	74.04
Hydrogen	7.86	8.02	8.08

Properties.—The turmeric acid, as at first precipitated, is an oil which gradually solidifies in long white branching needles, or crystalline masses, with a faint smell like cocconut; freed from oil by pressing between the filter-paper it melts at 34° to 35° ; it is slightly soluble in water, very freely in all the other common solvents except methyl alcohol, in which, however, it is readily soluble, so that it was found impossible to crystallise it from this or any other solvent; it distils slowly with steam, and is a monobasic acid. When oxidised with a hot solution of potassium permanganate, not in too great excess, it gives the apoturmeric acid, which will be described later in this paper.

Calcic Turmerate, $Ca(C_{11}H_{13}O_8)_2 \cdot 3H_2O$.—The preparation and purification of this salt have been described in connection with the manufacture of turmeric acid. For analysis it was dried, at first *in vacuo*, and afterward at 100° or 110° , when several agreeing analyses gave the percentage of calcium 10.78 to 11.13, whereas calcic turmerate contains only 10.15 per cent of calcium. This led us to suspect that the salt had undergone a constant decomposition at this temperature, which we were the more inclined to do because at first it lost weight very rapidly, but later the loss dropped to a few milligrammes a day, and more than a week of continuous heating was necessary to obtain a constant weight, while at the same time the salt gradually became brown and viscous. We have therefore calculated our results upon the salt dried *in vacuo*, and these agree very well with the amount of calcium in calcic turmerate containing three molecules of water of crystallisation.

I. 0.3131 gm. of substance dried *in vacuo* gave 0.0970 gm. of calcic sulphate.

II. 0.2993 gm. gave 0.0912 gm. of calcic sulphate.

	Calculated for $Ca(C_{11}H_{13}O_8)_2 \cdot 3H_2O$.	Found.	
		I.	II.
Calcium	8.93	9.11	8.96

Properties.—It forms spherical collections of white radiating needles looking like chestnut-burrs; the purer the salt the more distinct are the separate needles. When boiled with water it melts to a viscous mass, which is then acted on by the water only very slowly; it is therefore advisable to dissolve it in the cold.

7.861 grms. of the solution saturated at 16° gave 0.0344 gm. of calcic sulphate. Therefore a saturated solution at 16° contains 1.27 per cent of $Ca(C_{11}H_{13}O_8)_2$.

The salt is also soluble in alcohol, and is decomposed by a heat of 100° to 110° , as already stated.

The behaviour of a solution of the calcium salt with various reagents was also studied, and it was found to give a white flocculent precipitate with aluminic chloride; a similar reddish brown precipitate with ferric chloride; heavy white precipitates with mercurous or plumbic salts, the plumbic salt melting under boiling water, and forming, when prepared in quantity, an uninviting yellowish viscous mass; cupric nitrate produced pale blue flocks, and argentic nitrate a heavy white precipitate somewhat soluble in water; the other common reagents gave no characteristic precipitates.

An attempt was made to prepare and analyse the *silver salt*, but we did not succeed in purifying it, since its solubility in water is so great that the impurities could not be removed by washing without using a larger amount of substance than was at our disposal; and it was impossible to re-crystallise it from water, as its solutions decomposed with great ease. An imperfectly washed specimen gave a result which approaches that required by theory.

0.1932 gm. of the salt dried *in vacuo* gave 0.0750 gm. of silver.

	Calculated for $AgC_{11}H_{13}O_8$.	Found.	
		I.	II.
Silver	37.89	38.82	

The *barium salt* resembled the calcium salt in that it formed little balls of radiating needles, but showed a much greater tendency to separate in a viscous state, so that it was hard to obtain it crystallised.

The behaviour of the *zinc salt* is very characteristic. When a solution of it is prepared by boiling the acid with water and zinc oxide, allowing the liquid to cool, and filtering, the clear solution thus obtained becomes turbid, when warmed even to temperatures far below the boiling-point, but clears up again as the liquid cools. The salt could be obtained only as a viscous mass.

B. Study of the Residue from Distillation with Steam.

The flask-residue, after the turmeric acid had been distilled off with steam, contained a black tarry substance,

and not infrequently a white crystalline acid, which can be separated from the tar by treatment with boiling water. On extracting with ether the aqueous mother-liquor, from which the white acid had crystallised, a third substance, yellow and buttery, was obtained. All these substances are acids, but we have been unable to bring the black tarry acid or the yellow buttery one into a state fit for analysis, and can only say that the very ill-defined calcium salt of the former contained 1.69 per cent of calcium, while the latter gave on oxidation an acid melting near 180°, which was not phthalic acid, and was formed in such small quantity that we were unable to determine whether it was a pure substance or only a mixture of apoturmeric acid with some impurity.

Apoturmeric Acid.—The white crystalline acid was separated from its impurities by crystallisation from boiling water, till it showed a constant melting-point. The same acid is obtained by oxidising calcium turmerate with a hot solution of potassic permanganate, and a good part of the substance used for analysis was prepared in this way. The yield, however, was so small, not over 10 per cent of the turmeric acid used, that we have been unable to determine even its formula with certainty, as will be seen from the following analyses.

0.1138 grm. of substance gave 0.2582 grm. of carbonic dioxide and 0.0590 grm. of water.

	Calculated for $C_{10}H_{10}O_4$.	Found.	Calculated for $C_{10}H_{12}O_4$.
Carbon ..	61.86	61.87	61.22
Hydrogen .	5.15	5.76	6.12

The calcium salt made by boiling the acid with calcic carbonate and water gave the following results:—

I. 0.2274 grm. of salt dried *in vacuo* lost 0.0304 grm. when heated to 100°.

II. 0.1390 grm. lost 0.0186 grm. when heated to 100°.

	Calculated for $CaC_{10}H_8O_4 \cdot 2H_2O$.	Found.	Calculated for $CaC_{10}H_{10}O_4 \cdot 2H_2O$.
	I.	II.	
Water .	13.43	13.36 13.39	13.33

0.1826 grm. gave 0.3370 grm. of carbonic dioxide, 0.0758 grm. of water, and 0.1016 grm. of calcic sulphate.

	Calculated for $CaC_{10}H_8O_4$.	Found.	Calculated for $CaC_{10}H_{10}O_4$.
Carbon ..	51.72	50.32	51.29
Hydrogen .	3.40	4.61	4.27
Calcium ..	17.24	16.36	17.10

The barium salt prepared like the calcium salt gave a result which is not in harmony with the preceding.

0.2704 grm. of salt dried at 100° gave 0.1742 grm. of baric sulphate.

	Calculated for $BaC_{10}H_8O_4$.	Found.	Calculated for $BaC_{10}H_{10}O_4$.
Barium ..	41.64	37.87	41.39

If, however, we suppose that the salt retained two molecules of water at 100° the result agrees very well with the calculated per cents.

	Calculated for $BaC_{10}H_8O_4 \cdot 2H_2O$.	Found.	Calculated for $BaC_{10}H_{10}O_4 \cdot 2H_2O$.
Barium ..	37.53	37.87	37.32

But this supposition is, to say the least, improbable, as the calcium salt loses its water easily at 100°; unfortunately, we did not have enough of the acid to repeat the analysis of the barium salt.

Properties.—The apoturmeric acid separates from its solution in boiling water as a white, rather stiff, woolly mass, which renders the whole solid if the solution was a strong one. It melts at 221°, and is easily soluble in alcohol, ether, and boiling water; nearly insoluble in cold water.

Ammonic apoturmerate is not very freely soluble, and gives the following characteristic precipitates:—With

plumbic acetate, white flocculent; with cupric sulphate, whitish green,—both soluble in an excess of the precipitant; with mercurous nitrate, white flocks; with ferric chloride yellowish white; with argentic nitrate, a heavy white precipitate, slightly soluble in boiling water. With the other common reagents it gives no precipitates at all, or very slight white ones.

Several attempts were made to oxidise the apoturmeric acid, but they gave no satisfactory result. The acid was attacked only with difficulty either by potassic permanganate or chromic anhydride, and the only insoluble substance left after the oxidation was simply undecomposed apoturmeric acid. In no case have we observed the formation of terephthalic acid from apoturmeric, or from carefully purified turmeric acid; but this acid has appeared when a calcic turmerate containing the non-crystalline impurity was oxidised. We should therefore ascribe the formation of terephthalic acid from turmerol by violent oxidation rather to this substance than to the turmeric acid formed; but our experiments must be repeated on a larger scale before we can consider this point finally settled.

It is to be regretted that we were unable to settle definitely the composition of the apoturmeric acid, as this would have thrown much light on the constitution of turmeric acid; as it is, it is not worth while to advance any hypotheses on this subject.

We may add one more observation in reference to turmerol, viz., isobutyl-turmerol does not give an addition-product with bromine, but there is formed with evolution of hydrobromic acid a most uninviting unstable viscous oil.—*American Chemical Journal*.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcvi., No. 26, June 30, 1884.

The Use of Formene for Obtaining very Low Temperatures.—L. Cailletet.—Formene or marsh-gas if slightly compressed and cooled in boiling ethylene under atmospheric pressure becomes a colourless and extremely mobile liquid, which, on returning to the gaseous state, gives a cold sufficient to liquefy oxygen immediately.

On Chemical Compounds obtained by means of a Gas Battery and of Effluve Apparatus.—A. Figuier.—From carbon monoxide and dioxine the author has obtained oxalic and formic acids. The same two acids have been obtained from carbon monoxide and sodium carbonate, from ethylene and oxygen, and from hydrogen and carbonic acid.

Conversion of Liquid Batteries into Dry Batteries.—M. Onimus.—The author mixes the exciting liquid with gypsum, which is then allowed to solidify, and which may then be either used alone or mixed with manganese peroxide or ferric oxide.

The Coagulation of Colloidal Bodies.—E. Grimaux.—The coagulation of the colloids is not an obscure or unexplained phenomenon. It depends on chemical equilibria such as are observed in etherification and dissociation.

Preparation of Hydrated Chromic Acid, and certain New Properties of Chromic Anhydride.—H. Moissan.—Chromic anhydride absorbs hydrochloric acid at ordinary temperatures, producing abundant red fumes, which condense into chloro-chromic acid. Hydrobromic and hydriodic acids under the same circumstances do not furnish analogous chrome compounds. Chlorine when absolutely dry does not attack chromic anhydride.

Production of Neutral Crystalline Aluminium Orthophosphate.—A. de Schulten.—To a concentrated solution of sodium aluminate the author adds phosphoric acid until the mixture is strongly acid, and heats the whole for some hours to 250° in a sealed tube. There is formed an abundant deposit of small hexagonal prisms, which are absolutely pure if a sufficiency of phosphoric acid has been used.

A New Alcohol Extracted from Bird-lime.—M. J. Personne, jun.—The composition of the compound in question is $C_{50}H_{44}O_2$. It is an alcohol, and if treated with acetic anhydride it yields an acetic ether, the melting-point of which is between 204° to 206°.

On Colchicine.—M. S. Zeisel.—Dilute mineral acids split up colchicine into *colchicine* and methylic alcohol. Colchicine, if treated with strong mineral acids at 110° to 120°, yields a new base, apocolchicine, along with methylic alcohol and acetic acid.

Detection and Determination of Small Quantities of Carbon Disulphide in Air, Gases, the Sulpho-carbonates, &c.—M. Gastine.—The reaction proposed consists in passing air containing vapours of carbon disulphide into an alcoholic solution of potassa. Potassium xanthate is formed. The alcoholic solution of potassa should be prepared with absolute alcohol and potassa recently fused, for even a trace of water much reduces the sensitiveness of the reagent. For the same reason the gas or air in question is dried. The alcoholic liquid is neutralised with acetic acid, and the presence of xanthic acid is shown by adding a drop of copper sulphate. There is formed copper xanthate, insoluble in water and of a fine yellow colour.

Processes used in Determining Phosphoric Acid in Superphosphates.—E. Aubin.—In presence of mixtures like the superphosphates it is rational to extract the soluble matter completely with water before employing ammonium citrate. Another error is often committed by not determining the quantity of ammonium-magnesium phosphate which remains in solution in liquids containing large proportions of ammonium citrate.

Power of Cultivated Wine Yeast.—Alph. Rommier.—The author proposes to add to the juice of the pressed grapes the ferment of wine purified by systematic cultivation.

Zeitschrift für Analytische Chemie.
Vol. xxiii., Part 1, 1884.

Determination of Specific Gravity by means of the Pycnometer.—S. Pagliani.—If the instrument consists of very thin glass even a slight pressure on the bottom of the instrument affects its shape and consequently its level.

An Increase of the Proportion of Oxygen in Air.—According to the *Laterna Magica* this may be effected by aspirating a current of air through several layers of taffeta which have been plunged in alcohol or carbon disulphide, and then coated with a thin layer of caoutchouc. After passing through four such layers the proportion of nitrogen in the air is said to be reduced to 5 per cent.

A Reagent for the Potassium Compounds.—Giacomo Campari.—The author uses bismuth-sodium hyposulphite, which, in contact with potassium salts, forms the corresponding potassium double salt, perfectly insoluble in strong alcohol and of a bright lemon-yellow colour. The reagent is prepared by dissolving 1 part of basic bismuth oxide in a minimum of hydrochloric acid at common temperatures. In the meantime two parts of crystalline sodium hyposulphite are dissolved in a minimum of water, and each is brought to a volume equal and as small as possible. When wanted for use two or three drops of each are mixed and diluted with 5 c.c. of alcohol, thus forming the reagent in question.

Reactions of Uranous Salts.—C. Zimmermann.—These reactions are inaccurately stated in many text-books

owing to experiments made upon uranous salts containing uranic oxide. Potassa or soda gives a bulky, pale green precipitate, insoluble in excess. It quickly changes if exposed to the air, first to black-brown urano-uranic hydroxide, and then to yellow potassium- (or sodium-) uranic oxide. Ammonia acts in a similar manner. Alkaline carbonates give a greenish white precipitate which becomes dark if heated. Bicarbonates give the same precipitate, but soluble in excess. If heated, it is partially oxidised and re-precipitated. Ammonium carbonate gives a greenish white precipitate, readily soluble in excess and not re-precipitated on heating. Potassium ferrocyanide gives a yellowish green precipitate, which gradually turns to a reddish brown. The ferrocyanide gives at once a reddish brown precipitate. In presence of tartaric acid, ammonia, ammonium sulphide, and the fixed alkalis give no precipitate, and the liquid does not take a dark colour. Ammonium sulphide gives a light green precipitate, which quickly becomes dark brown and turns black if boiled. Barium carbonate completely precipitates uranous salts even in the cold.

Method for Determining Manganese Peroxide in Commercial Pyrolusite.—J. W. Chalmers Harvey.—From the *CHEMICAL NEWS*.

Solubility of Lead Sulphate in Basic Lead Acetate.—K. Stammer.—If in a moderately strong solution of a sulphate a precipitate of lead sulphate is produced by adding basic lead acetate, it re-dissolves completely on adding an excess of the latter salt. If acetic acid is then added the lead sulphate is re-precipitated.

A Reaction of Mercuric Chloride.—H. Debray.—If to an aqueous solution of mercuric chloride there is added a large excess of sodium chloride, the mixture, after treatment with sulphurous acid, may be heated to boiling without the precipitation of mercurous chloride.

The Electrolytic Determination of Copper.—J. B. Mackintosh criticises in the *American Chemical Journal* Luckow's well known process. Luckow replies that he adds tartaric acid only in the specific case of the Mansfield cupriferos shales to obviate the disturbing action of the manganese, and maintains that the electrolytic precipitation of copper from solutions containing nitric acid is quite practicable if any lower oxides of nitrogen are previously expelled and a moderate constant current is kept up.

Determination of Phosphoric Acid.—H. Pemberton, Jr.—From the *CHEMICAL NEWS*.

Determination of Phosphoric and Molybdic Acids in the Phospho-Molybdates.—Wolcott Gibbs.—From the *American Chemical Journal*.

Detection of the Hydracids of Chlorine, Bromine, Iodide, Cyanogen, Ferro- and Ferri-cyanogen, and of the Chloric, Bromic, and Iodic Acids.—A Longi.—From the *CHEMICAL NEWS*.

Determination of Small Quantities of Nitrous Acid in a Free or Combined State.—E. J. Davy.—From the *CHEMICAL NEWS*.

Detection of Urea in Aqueous Solutions.—C. L. Bloxam.—From the *CHEMICAL NEWS*.

Detection of Aldehyds and Ketones.—E. Nageli.—Already inserted from the *Berichte der Deutsch. Chem. Gesell.*

New Reaction for Aldehyds.—F. Petzoldt and E. Fischer.—From the *Berichte der Deutsch. Chem. Gesell.*

Qualitative Reaction of Acetal.—M. Grodzki.—From the *Berichte der Deutsch. Chem. Gesell.*

Reaction of Eugenol.—Klunge.—If eugenol, or any ethereal oil in which it is present, is heated with double its volume of sulphuric acid (undiluted) for a short time in the water-bath, diluted, digested with barium carbonate until neutral, filtered, and mixed with ferric chloride, there is formed a deep blue solution. To avoid confusion with salicylic acid Klunge recommends to add to a few drops of the oil suspended in water a few drops of ammonium car-

bonate and a small fragment of ferrous sulphate. If eugenol is present the drops of oil turn violet.

The Presence of Caffeine in Cacao.—E. Schmidt.

On Gelsemine.—A. W. Gerrard.—From the *Pharmaceutical Journal*.

The Quinine Reaction with Potassium Ferrocyanide.—A. Vogel.—The author recommends to use the reagents always in the following order:—Bromine water (in place of chlorine water), ferrocyanide, and then borax, in place of ammonium carbonate.

Solubility of the Strychnine Salts in Acids.—Hanriot and Blarey.—From the *Comptes Rendus*.

Determination of the Halogens in Organic Compounds.—E. Mulder and A. S. Hamburger.—In determining the halogens by ignition with caustic lime the authors make use of a lime obtained by igniting precipitated calcium carbonate in a current of pure hydrogen. This process is continued until baryta water is no longer rendered turbid by the escaping gas. They heat the substance mixed with such lime in a tube 0.6 centimetre in width and 30 c.m. in length, and attach, in order to observe the progress of the analysis, a small U-tube with silver nitrate.

Determination of Halogens in Volatile Organic Compounds.—R. T. Plimpton and E. E. Graves.—From the *Journal of the Chemical Society*.

The Quantitative Determination of Methyl-Aldehyd.—L. Legler.—From the *Berichte der Deutsch. Chem. Gesell.*

Behaviour of Dextrose with Ammoniacal Solution of Silver containing Caustic Soda.—B. Tollens.—From the *Berichte der Deutsch. Chem. Gesell.*

Preparation of Glucose by the Schwarz-Neubauer Process, and its Determination with Knapp's Solution.—Worm Müller.—From the *Journal f. Prakt. Chemie*.

Determination of Starch in Grain.—G. Francke.—The author heats in sealed tubes with water in presence of a trace of lactic acid.

Determination of Chloride of Lime in Water.—Anthony A. Nesbit.—This paper appeared originally in the *CHEMICAL NEWS*, but is by mistake credited to the *Pharm. Central. Halle*.

Examination of Milk.—A. Jørgensen.

Determination of the Fat in Milk.—C. H. Wolff.—To 50 c.c. milk the author uses 3 c.c. of potassa lye (sp. gr. 1.145) and 54 c.c. of aqueous ether. The mixture is well shaken up at 17° to 18°; 20 c.c. of the ethereal solution are drawn off with a pipette, evaporated in a tared flask, and weighed.

Examination of Butter.—J. Zanni.—The author shows that certain butters are mixed with butyric acid in order to increase the relative proportion of the soluble acids and decrease that of the insoluble. Such butter is sold in Constantinople as Siberian butter.

A New Adulterant for Lard and Butter.—J. Muter.—From the *Analyst*.

Caffeine in Cacao.—E. Schmidt.—The author proposes to separate caffeine from theobromine by making use of their different solubility in cold benzol.

Examination of Rum.—E. List.—The author finds formic acid constantly present.

Detection of Free Mineral Acids in Vinegar.—Wharton.—The author evaporates down to a syrup, lets cool to a hand heat, and stirs in a few centigrammes of potassium chlorate. If there is more than 1 per cent of sulphuric acid the mass ignites violently. Smaller quantities are detected by the odour of chlorine.

Vermicelli Coloured with Aniline Yellow.—Mercier and Bertherand.—The colour is almost instantly destroyed by dilute sulphuric acid, whilst the colour of saffron is attacked.

Distinction between Rice-Meal and the Meal of Buckwheat.—A. Lehn.—The sample is made into a paste with strong potash-lye, heated on the water-bath, and treated with hydrochloric acid. In case of rice the paste is yellow, and after treatment with acid, white. Buckwheat gives a dark-green paste which is turned red by hydrochloric acid.

Is a Colour fixed in the Fibre or Printed on with Albumen?—R. Meyer.—Already inserted.

Detection and Determination of Picric Acid.—G. Christel.—This paper will be inserted in full if possible.

Detection of Solar Oil in Petroleum.—Solar oil raises the specific gravity and the boiling-point of the mixture. Copper butyrate dissolves in both with a bluish green colour. But if the solution is heated to 210° it remains, in case of pure petroleum, green and clear. Solar oil becomes yellow at 120°, and deposits yellow flocks.

Determination of Ammonia in Gas-Liquor.—Knublauch.—The author puts 100 c.c. in a half litre flask, fills up to the mark with water, and shakes well. He puts some of this water into a stoppered bottle, so as to occupy two-thirds of its capacity, adds a few fragments of quicklime, and lets stand for an hour, shaking frequently; 50 c.c. of the filtrate are titrated with an acid, using rosolic acid as an indicator.

Value of Isinglass.—F. Prollius.—The author determines ash, moisture, matter insoluble in water, viscosity of solution, and examines microscopically.

Distinction between Oils of Cinnamon and Cassia.—Woodland.—From the *Pharm. Journal*.

Detection of Cotton Oil in Olive Oil.—E. Becchi.—Five c.c. of the sample are mixed in a glass flask with 25 c.c. of alcohol at 98 per cent, and 5 c.c. of a reagent made by dissolving 1 gm. silver nitrate in 100 c.c. alcohol at 98 per cent. The flask is then heated to 84°. If even a trace of cotton oil is present it takes a dark colour.

Apparatus for Determining the Air in Carbonic Acid.—J. Sohnke.—The apparatus is not here described.

Determination of Chromium in Iron and Steel.—J. O. Arnold.—From the *CHEMICAL NEWS*.

Detection of Suint in Tallow.—L. Meyer.—This paper will be given in full if possible.

Rapid Determination of Fatty Acids and Alkali in Soaps.—M. Pinchon.—The author effects this process by means of a small burette, capable of being closed above, and fitted with a tap below. He introduces 5 c.c. normal hydrochloric acid, introduces 1 gm. of the soap in thin shavings, and 8 to 10 c.c. ether. He then closes the burette above and shakes well from time to time. When the decomposition is complete the lower watery stratum is run off, drop by drop into a beaker, the ethereal solution is washed with water until the latter has no longer an acid reaction, and rinsed with ether into a flat-bottomed porcelain capsule. The ether is evaporated at common temperatures under a funnel, the residue dried and weighed. The alkali is determined by titrating back the acid solution.

Determination of Sugar in Beets.—P. Degener.—This paper does not admit of useful abstraction.

Occurrence of a Oxyglutanic Acid in Molasses.—E. v. Lippmann.—From the *Berichte der Deutschen Chem. Gesell.*

Examination of Basic Bismuth Nitrate for Arsenic.—Th. Salzer.—A critique on the method recommended in the *Pharmacopœia Germanica*.

Determination of Iodine in Urine.—F. Pecirka.—The author has examined Hilger's method and finds that the results are invariably too low.

Detection of Mercury in Urine.—V. Lehmann.—The author gives the preference to Mayer's method.

New Process for the Determination of Urea.—L. Hugounenq.—From the *Comptes Rendus*.

Presence of Acetacetic Acid in Urine.—R. v. Iaksch.—The author fully proves the occurrence of this acid in urine.

Determination of Uric Acid.—E. A. Cook.—From the *British Medical Journal*.

Detection and Approximate Determination of Sugar in Urine.—G. Johnson.—From the *British Medical Journal*.

On Hemi-albumose in Urine.—This compound is obtained by the action of digestive ferments or boiling acid upon various albumenoids, and seems to occupy in its position and properties a medium place between the two albumenoids and the peptones.

Detection and Determination of Albumen in Urine. A. B. Haslam.—From the *CHEMICAL NEWS*.

Chemico-Legal Detection of Hydrocyanic Acid.—R. Otto.—For the detection of hydrocyanic acid or potassium cyanide in presence of the non-poisonous double cyanides Beckurts and Schoenfeldt recommend a modification of the methods of Jacquemin and Barfoed.

Luminescence of Phosphorus in Mitscherlich's Apparatus.—According to Schwanert this luminescence is prevented by the presence of salts of lead.

Formation of Arsenic Hydride of Fungi.—C. Bischoff.—The author suggests that this reaction may be the cause of the peculiar kakodyle-like odour experienced on exhaling old arseniferous dead bodies, and not met with under any other circumstances.

Permanence of the Spectroscopic Reaction of Carbon Monoxide.—C. H. Wolff.—Blood saturated with carbon monoxide in well-filled stoppered bottles retains its properties for years.

The Equivalent Weights of Bismuth, Manganese, Zinc, and Magnesium.—C. Marignac.—The author's purpose was to ascertain whether the oxides of these metals, which have hitherto been regarded as homogeneous, might, like the oxides from cerite, prove on fractionated precipitation to be mixtures. He finds that this is not the case. For bismuth he finds as a mean result the weight 208.16; for manganese, 55.07; zinc, 65.43, and magnesium, 24.38.

The Equivalent Weights of Lanthanum, Didymium, Decipium, and Samarium.—If $O = 16$ and didymium oxide Di_2O_3 , the determination of Cleve are 147 and 142.12; those of Brauner 146.38 and 145.42. For lanthanum, assuming its oxide to be La_2O_3 , Marignac gives the value 138.81, Cleve 139.15 and 138.22, and Brauner 138.88 and 138.28. For decipium, supposed to form a sesquioxide, Delafontaine gives 171. For samarium we have, according to Marignac, 149.4; according to Delafontaine, 151.5; and Cleve, 150.021.

Journal für Praktische Chemie.
New Series, Vol. xxix., Part 1.

Products of the Action of Phosphorus Pentachloride upon Komenaminic Acid.—Dr. Theodor Bellmann.—On allowing 5 mols. of the pentachloride to act upon 1 mol. of komenaminic acid at temperatures of 220°, 250°, and 275° the author obtains a mono-chloroxy-acid which he designates as mono-chlor- γ -oxy-picolic acid. An account of its derivatives follows. From the mother-liquor the author obtains mono-chlor-kyamic acid. He next examines the action of 3 mols. phosphorus pentachloride upon 1 mol. komenaminic acid at 200°. Among the products is methyl-oxy-pyridone, $C_6H_7NO_2$. The behaviour of this compound with bromine, with hydriodic acid, and with phosphorus pentachloride is further investigated.

Chemico-Critical Passages.—Herman Kolbe.—These papers are incapable of useful abstraction, but are well worthy of thoughtful perusal.

On Fractionated Distillation in a Current of Steam as a New Method for Examining the Components of Mineral Oil.—Faustin Rasinski.—A preliminary notice. The raw material which the author employs is the so-called astraline (sp. gr. 0.831) obtained from the petroleum of Baku.

A Reply.—F. Salomon.—The author defends himself against certain criticisms of *Musculus*. (See *Journal für Praktische Chemie*, vol. xxviii., pp. 84 and 496).

Action of Epichlorhydrine upon Diethylamine.—M. Reboul.—From the *Comptes Rendus*.

Vol. xxix., Part 2.

Determinations of Chemical Affinity.—Dr. W. Ostwald.—The author examines the solubility of potassium bitartrate and of barium, strontium, and calcium sulphates. The values of the affinities appear as constants, which determine the chemical action quantitatively. This result unites in a peculiar manner the two opposite theories of affinity of the last century.

The Nitrogenous Derivatives of Meconic Acid.—H. Ost.—The author describes a number of oxy-pyridines and oxy-pyridine-carbonic acids.

Studies on Milk.—H. Struve.—We have here an account of α - and β -caseine, and of the albumen and peptone of milk.

The Use of Boiling Oxygen as Refrigerating Agent, the Temperature thus obtained, and the Solidification of Nitrogen.—S. v. Wroblewski.—The author is in doubt whether the crystalline precipitate which remains when liquid oxygen evaporates consists of pure crystals of oxygen, or is derived partly, or entirely, from possible impurities of the gas. Another circumstance which makes the use of liquid oxygen difficult as a refrigerating agent is the necessity of experimenting in closed, very strong vessels. The temperature of boiling oxygen is approximately -186° . Nitrogen compressed in a glass tube, refrigerated in a current of boiling oxygen, and then re-expanded, falls down in snow-like flakes, consisting of crystals of remarkable size.

Moniteur Scientifique, Queneville.
Vol. xiv., July, 1884.

Chemical Products at the Swiss National Exhibition of 1883.—Dr. G. Lunge.—The only Swiss establishment which produces the mineral acids and the alkalies is that of Schnorf Brothers, at Uetikon, on the Lake of Zurich. Most of the chemical works in the cantons are occupied with the production of colours, mordants, and other preparations used in connection with textile manufactures.

On the Chemistry and the Analytical Examination of the fixed Oils.—A. H. Allen.—From the *Journal of the Society of Chemical Industry*.

Contribution to the Study of the Artificial Blue Colours, with Reference to Wool-dyeing.—W. Rospendowski.—A very important paper, which we hope to reproduce in full.

The Industrial Society of Mulhouse; Meetings of the Chemical Section.

April 19th.—M. Procharoff and M. Schmid gave an account of the preparation and use of canarine (cyanogen persulphide).

M. Camille Kœchlin submitted specimens of two new yellows, flavaniline, a dye for silks and woollens and which works best with an equal weight of tartaric acid and magnesium acetate, and auramine, which is applicable on wool and on cotton, and which to be fixed on the latter requires an equal weight of tartaric acid, six parts of tannin, and a passage in tartar-emetic, after steaming.

May 14.—M. A. Scheurer presented a note on discharges on indigo by means of gaseous chlorine. Chlorine,

even when moist, destroys indigo only slowly; but if caustic alkali, thickened, is printed on the indigo, the discharge by gaseous chlorine is immediate. It is the same with Turkey-reds. Coloured discharges may be produced in the same manner on blue or red grounds. If there is printed a mixture of lead oxide and chrome oxide dissolved in soda the synthesis of lead chromate is effected, the blue is destroyed, and a yellow discharge is produced. For red discharges on indigo a very alkaline sodium aluminate is printed on, the pieces are taken through chlorine, then dunged and dyed in alizarin.

The Transformation of the Theory of Atoms.—M. Victor Meyer.—Already noticed.

Remarks on a Recent Memoir by M. Hesse.—M. Grimaux.—A reclamation of priority with reference to a memoir on morphine published in Liebig's *Annalen*, Dec. 22, 1883.

Bulletin de la Société Chimique de Paris.
No. 10, May 20, 1884.

On Anthemene. Researches on Roman Camomile.—M. Laurent Naudin.—The author has succeeded in separating and purifying the two bodies which he described at the meeting of the *Société Chimique*, July 13th, 1883, and has completed the examination of the one which melts at 63° to 64°. It boils at 440° in the vapour of sulphur without apparent decomposition, and has the sp. gr. 0.942 at 15°. It is insoluble in water, soluble in ether, petroleum, carbon disulphide, and chloroform. It dissolves in absolute boiling alcohol, but it is almost entirely re-deposited on cooling.

Quantities of Heat Liberated during the Compression of Solid Bodies.—W. Spring.—The author's experiments show that the compression of a solid body does not liberate such quantities of heat as it has been thought. He considers, therefore, the chemical combinations produced under pressure are due not to the heat developed during compression, but simply to the intimate contact which pressure occasions between the solid particles of the elements mixed.

Quantities of Sulphides formed by the Successive Compressions of their Elements.—W. Spring.—The experiments described show that pressure occasions under certain conditions the mutual combination of solid bodies. The quantity of the compound produced depends at once on the magnitude of the surfaces of contact of the elements and on the duration of the contact. The phenomena of combination under pressure approximate in their nature to the slow combinations produced under certain conditions. Thus a piece of sodium exposed to the action of dry air is slowly oxidised, although its temperature is below the point of ignition properly so-called. In like manner silver brought forcibly into contact with sulphur passes slowly into the state of sulphide without a sensible rise of temperature. Hence, if a mixture of solid bodies in powder is submitted to a single and brief compression the result will be very imperfect. Accordingly pressure is not a chemical agent of the same kind as heat or electricity.

Researches from the Laboratory of the Chemical School of Mulhouse.—These consist of a memoir by MM. E. Noetting and G. de Bèchi on the constitution of phthalyl chloride; a memoir by Noetting on phenols of a high boiling-point contained in coal-tar; and another paper by the same author on nitro-benzyl chloride.

Silicates of Soda and Potash in the state of Soluble Glass, or in CONCENTRATED SOLUTION of first quality, suited for the Manufacture of Soap and other purposes, supplied on best terms by W GOSSAGE and Sons, Soap Works Widnes, Lancashire.

London Agents, COSTE and Co., 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

ESTABLISHED 1798.

ROBERT DAGLISH & CO.,
ENGINEERS, BOILER AND BRIDGE
MAKERS, MILLWRIGHTS,
BRASS AND IRON FOUNDERS.

Manufacturers of every description of Condensing, or High-pressure Blowing, Pumping, Rolling, Winding, and Patent Steam-engines of any required power, for Irrigating, Draining, Mining, Rolling Mills or Water Works purposes, and Manufacturers of every description of Chemical, Colliery, Copper Ore, Gold Mining, Glass, and Rock-salt Machinery.

Black-ash Revolving Furnaces of the Most Approved Type.
Bessemer Steel-Rail Plant.
Compressing-Engines for Collieries, Iron Works, and Weldon's Patent Bleaching-Powder Process.
Caustic, Chlorate, Decomposing, Nitre Nitro-Glycerine, Iodine Potash, Sulphur, Acid, and Oxalic Pans.
Gas Producers Patent for Heating and other Purposes.
Pyrites Burners for Irish, Norwegian, and Spanish Ores of Improved Construction.
Patent Rousing Machinery for Brewers.
Retorts, Acid, Gas, Iodine, Nitric, Nitre Nitro-Glycerine and Vitriol Refining.
Steam Superheaters improved or Oil Tar and Resin Refining.
Steam Sulphur Melter.
Stillers for Oil, Resin, and Tar.
Wheels, Bevel Mitre, and Spur Moulded on the Shortest Notice by Patent Machinery.

Makers of Alizarine Plant, Jones and Walsh's Patent Sulphate of Soda Furnace, Kynaston's Patent Alum Plant, Macdon's Patent Carbonating Furnace, and Parnell and Simpson's Patent Causticiser.

Lists sent on Application.

BAILEY'S HYDRAULIC MOTORS.

BAILEY'S WATER MOTORS.

Silver Medal, Manchester, 1879; Blackburn, 1881.

WHAT THEY ARE DOING:—

The Water Motor blows Blacksmiths' Fires at Penmaenmawr.
The 2-horse Water Motor daily works Waggon's up an incline at Edge Hill Collieries, Bolton, with success.
The *Brighton Guardian* is regularly printed by these Motors, giving the highest satisfaction.
The Lifts are in Hotels and Warehouses of Manchester, Dublin, Liverpool, Lancaster, &c.
The "Thirlmere" drives a Grindstone at Bristol.
The 4-horse Water-Motor is at work Cutting Timber, by circular saw, 5 inches thick.
A 20-horse Water Motor, pumping for H. Vivian, Esq., M.P.
A 12-horse Water Motor, pumping at the Mine of G. N. Newdegate, Esq., M.P.

TESTIMONIALS.

June 22, 1881.—From H. H. Vivian, Esq., M.P.—"I have just heard that the Water Motor sent out last year is doing well."
Lord Salisbury's Clerk of Works writes:—"I am much pleased with the Water Motor, for it is most compact and useful."
From Messrs. Seed Brothers, Leather Merchants, Halifax:—"The Water Motor is doing its work well and quietly, and bids fair to answer our highest expectations."
From Lever Edge Coal Company, Bolton:—"The Water Engine you have supplied does its work well."

Prices and full particulars on application to—
W. H. BAILEY & Co., Albion Works, Salford, Manchester.
Hydraulic Engineers, Pump Makers, Gauge Makers, also Makers of all kinds of High-class Steam Fittings; Brass Founders to Her Majesty's Government Departments, Woolwich Arsenal, Indian State Railways, Trinity Board, &c.

Water-Glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S Ardwick Chemical Works Manchester.

THE CHEMICAL NEWS.

VOL. L. No. 1290.

PASTEUR AND THE GERM THEORY.*

By FREDERICK J. FARADAY, F.L.S.

1. I HAVE been encouraged by Dr. Angus Smith to present to you a *résumé* of some of the most remarkable results of the experimental development of what is known as the germ theory. In carrying into effect this idea it will not be expected that I should restrict my attention to Pasteur's work. There have been many able workers besides Pasteur in this field of biological investigation. But the work done by Pasteur is so original and important that he may well be regarded as the great leader of the school; and such other work as it may be desirable to refer to can be most conveniently dealt with as bearing upon his researches. I have no new microbe to show you, nor have I succeeded in demonstrating the mutual convertibility of any known species. I have, however, given considerable attention to the literature of the subject, and it has appeared to my kind sponsor, as a member of this Society, that a special presentation of such of the facts as have grouped themselves together in my mind, and of some of the thoughts which have been spontaneously evolved from these groupings, might not be without utility. It may provoke what may be considered at the present juncture as a timely discussion, which may bring into clear outline the frontier points of one of the most profound and practical series of enquiries which have ever fascinated scientific men or exercised the human intellect. It is very probable that the paper may take a more philosophical turn than will be in keeping with the exact scientific character of the papers which the Society is in the habit of receiving. In extenuation I must plead that the Society is known as the Literary and Philosophical Society, and that according to the interesting centenary volume lately published by it, it has from time to time received even purely speculative communications. To follow the example of men like Percival and White may appear not entirely reprehensible.

2. It is now a couple of centuries since Leeuwenhoek communicated to the Royal Society an account of what was apparently the first discovery of bacteria. In a letter to *Nature*, Professor Cohn, a few months ago, called the attention of the scientific world to the fact that towards the close of 1683 Leeuwenhoek announced the discovery of active microscopic organisms, including bacilli, bacteria, and vibrios. The Dutch microscopist discovered them in the white substance adhering to his teeth, and bearing in mind the important part which thermal conditions have played, or have been supposed to play, in recent experiments on the sterilisation of "culture" infusions and the "attenuation" of microbes, it is worth while to note that, failing on a subsequent occasion to perceive the movements of bacteria in the same substance, he assumed that they had been killed by the hot coffee which he had taken at breakfast. The discovery not only gave a new vitality to the discussions on spontaneous generation, both sides finding therein arguments in favour of their special opinions, but also suggested ideas as to the propagation of contagious diseases and the nature of infection. In the papers communicated to the Royal Society during the last quarter of the 17th and the 1st quarter of the 18th centuries we find most of the ideas which are still the leading ideas of micro-biologists. With reference to generation in general it is argued that the animalcule is

the germ furnished only by the male, and that the female merely supplies the nidus requisite for its development. Springing from this hypothesis we have the suggestion that the nidus affects or modifies the germ, which I take to imply that, given the germ, the nidus in which it is implanted determines the species evolved therefrom. Experiments were made with rain water, mineral water, infusions of pepper-corns, bay-berries, oats, barley, and wheat, and the scum collected from these infusions was discovered to be masses of organisms. Round and elongated pulsating bodies with transparent ends and opaque centres were observed. The possibility of disease being carried from person to person by sheets, towels, handkerchiefs, gloves, &c., in consequence of minute organisms having obtained a lodgement thereon, is referred to as an inference from the fact that the minute organism of itch can live outside the body for two or three days. The existence of globular and elliptical micro-organisms in water, wine, brandy, vinegar, beer, spitte, and urine is mentioned, with the occasional though rare appearance of spots therein and central constriction; and the tendency of certain species to seek the top of the liquor apparently "for the sake of the air" is also mentioned. Small-pox is compared to fermentation, and it is suggested that it may be propagated through the air, "a bad disposition of the air" being favourable to its reappearance. It is suggested that the "variolous pus" when inoculated finds in the body "the native congenial variolous seeds" and ferments with them. This appears to be an inversion of the common modern doctrine which regards the inoculated matter as containing the germ and the animal body as producing the special fluid or *milieu* for its development; but it is perhaps in accordance with the ideas of Béchamp, the "native congenial variolous seeds" being possibly the micro-zymes of that inquirer.

3. These earliest speculative results of Leeuwenhoek's important discoveries cover the whole range of the latest investigations into the nature, life-history, and action of microbes. The problems then started still occupy the minds of scientific men, and it may even be said that no absolute answer has yet been given to any of them. Though Dr. Tyndall has said that the doctrine of spontaneous generation is dead, the advocates of that doctrine are prepared to maintain that the question has only been moved a stage further back. It is quite certain that the extreme members of the evolutionary school would not admit that it has been finally demonstrated that inorganic matter does not contain "the promise and potency of all terrestrial life"; indeed this is the doctrine enunciated by Tyndall himself at Belfast; and it is equally certain that even many of those who do deny that organisms capable of reproducing their species are ever evolved from absolutely unorganised matter, nevertheless do not consider the presence of any specific atmospheric or other germ as necessary for the reproduction of any given species. There is a domain which still invites the experimentalist, who may succeed in harmonising apparently antagonistic ideas. A very large and important amount of work has been done in showing the analogies between fermentation and disease, and in discovering apparently specific pathogenic microbes or ferments. Indeed, in recent years the multiplication of specific microbes has become almost embarrassing. But though strong evidence has unquestionably been adduced that, at least in certain cases, the characteristic microbe is the originator of the disease, or is capable of conveying it, the very multiplication of microbes is reviving the question as to whether these organisms are the causes or merely the accompaniments (in the sense in which the culture is the accompaniment of carrion), or even the products of disease. The recognition of these facts does not imply any depreciation of the practical value or the significance of the work which has been done during the last thirty years, but helps us to a clearer view of its bearing and scope.

4. In considering the development of the germ theory we may pass almost directly from Leeuwenhoek and his

* A paper read before the Manchester Literary and Philosophical Society, April 15, 1884.

contemporaries to Pasteur. As a matter of history we must not of course overlook the observations of Cagniard la Tour and Schwann, based upon an observation of Leeuwenhoek, and really establishing the vegetable nature of yeast. But it is to Pasteur that we are indebted for definite progress in establishing or refuting the ideas which sprang immediately from Leeuwenhoek's discovery. The work of the Germans, and even of the French, apart from Pasteur, has been mainly in the filling up of details. Extremely important have been many of those details. The discovery of the micro-organism of anthrax by Rayer and Davaine; the subsequent discovery by Koch of the spores into which the anthrax filaments break up; Koch's discovery of the bacillus of tuberculosis; and, lastly, the same ardent investigator's latest discoveries bearing upon the nature and etiology of cholera, are all alike, not only important confirmations of previously-existing ideas, but in themselves elucidatory and suggestive. The Germans, too, have been most important critics, a natural consequence of their close attention to details; and Koch's criticisms of Pasteur's work may be perused with the greatest advantage by all who are interested in the subject, or are practically engaged in medical or surgical work. Some regret may be felt at a certain want of respect for the great Frenchman which seems to pervade the illustrious German's remarks. The true lover of science is little impressed, however, by the temporary acrimony of rival investigators, but is thankful for their mutual watchfulness. Pasteur remains the central figure in connection with the modern development of the germ theory; the discoveries and criticisms of the greatest of his contemporaries in the same sphere of investigation are, after all, of the nature of side-lights upon his work.

5. This is not the place in which to offer any opinion on theistic questions. But it is strictly within the scope of a scientific paper to recognise facts having a direct bearing upon the subject under consideration. It is a fact that Pasteur must be added to the list of "spiritualist" *grands initiateurs* enumerated by Naville. We may take cognisance of Pasteur's religious beliefs as resulting in an attitude of mind and a selective influence which have undoubtedly been the primary conditions of his peculiar success. Perhaps the most general expression of the scientific consequence of his beliefs will be to say that they have made of him in even an unusually strict sense an inductive rather than a deductive inquirer. He has approached natural phenomena, in the most absolute sense of the words, with the simplicity and teachableness of a pupil. When the French Ministry of Agriculture commissioned him in 1865 to study the diseases of the silk-worm, Pasteur, as he declares in the preface to his "*Etudes sur la Maladie des Vers à Soie*," had never even seen a silkworm. He mentioned this fact as a reason for declining the commission. "It is all the better" said Dumas, "that you know nothing about the subject; you will have no ideas upon it except those which result from your own observations." The determining mental conditions in Pasteur's work have been, firstly, a profound sense of the gulf between organic and inorganic matter, and, secondly, what may be most accurately described as a Christian sense of duty to his neighbours. The first was expressed in discovery of what he calls molecular dissymmetry, resulting in his formulation of the law that while all inorganic compounds can be superposed, all organic compounds are characterised by what he has graphically symbolised as right and left-handedness. Starting from this basis, the same fundamental principle guided him into a strong opposition of the doctrine of spontaneous generation, and into the famous researches on fermentation which have afforded the sure foundation of the modern developments of the germ theory, of the study of the etiology and rational treatment of zymotic diseases, of antiseptic surgery, and of sanitary science in general. Nor is the second principle less deserving of recognition as a cause of Pasteur's science. Dumas's description of the misery resulting to the rural population of France from the silk-worm disease induced him to undertake

those researches on *pébrine* and *flacherie* which resulted in further important confirmations and elucidations of the germ theory; his researches on the "maladies" of beer were undertaken with the avowed hope that the impoverishment of France, consequent on the war of 1870, might be alleviated by the establishment of a great national brewing industry, rivalling that of Germany; in the interests of the ruined stock farmers of France, and with the same patriotic motive, he turned his attention to fowl cholera and anthrax; and not less have his later researches on every zymotic disease on which he has been able to lay his hands, and on hydrophobia, been inspired by a philanthropic desire to minister to the happiness of mankind.

6. In studying the work of one of the greatest and most successful investigators of this century, it is of scientific importance to recognise all the conditions which have contributed to the attainment of such remarkable results; and the facts noted in the last paragraph really force themselves upon the attention of the student of Pasteur's writings. It is the more desirable that attention should be given to these facts because erroneous impressions concerning Pasteur may retard the progress of science by weakening the influence of his utterances, and the confidence which they merit. There is a danger that the animated scenes in the French Académie des Sciences which have occasionally been reported, the tone of some of Koch's criticisms, the charges of dogmatism which have been levelled against Pasteur, and still more the misleading statements of those whose judgments are weakened by a more or less morbid and ignorant sentimentality respecting the lower animals, may give rise to misconceptions of the character of Pasteur. It is worth while, therefore, to say that no reader of Pasteur's own works can rise from their perusal without a strong consciousness that Pasteur is, in an exceptional degree, a single-minded and earnest man.

7. The foregoing brief *résumé* of the course of Pasteur's investigations indicates the inquiries into which the accumulated mass of work done in connection with the development of the germ theory now resolves itself. Starting with Leeuwenhoek's discovery of micro-organisms, Cagniard la Tour and Schwann's discovery that the globules of yeast are living plants capable of indefinite multiplication in suitable media, and Pasteur's demonstration that fermentation in general is necessarily associated with the presence of living organisms, we have opened up a series of most profound inquiries into the relations between chemical force and affinities in general and that undefined something which may be provisionally called vital force. From speculations as to the influence of vital force on the chemistry of nature in general, concerning which vastly wider views are now presented than were dreamt of in the pre-Pasteurian period, we naturally pass to inquiries as to the influence of chemical conditions upon the special forms and the special attributes of particular forms of organised life. From such inquiries we proceed to inquiries as to the origin and nature of microbes themselves, and the phenomena of their pathological relations.

8. With the overthrow of Liebig's motion or contact theory of fermentation, and the substitution of Pasteur's demonstrations that fermentation is a vital process, our view of the influence of the unknown force, vitality, in the chemistry of nature, has become so vastly extended that it may almost be said that chemical changes are dependent upon life. Death itself is life. The tendency is to the conclusion that no other forms of force could exert a sustained influence in rearranging the elements of matter. The changes possible in consequence of mere thermal or electrical conditions are so strictly limited that it may be said that without vitality certain forms and combinations of matter must have been eternal. Chemical affinity alone must have resulted in absolute stability. We may conceive the possibility of heat from an external source breaking up any matter, even living

matter; but it is the tendency of Pasteur's work to show that without such external action and without life a few given forms must have remained for ever unchanged. We have long been familiar with the notion that life alone can build up organic combinations. The vegetable takes up the inorganic element and elaborates it into food for the more complex tissues of the animal; Pasteur's teaching brings us to the conclusion that for the reverse process life is still necessary. Without the action of micro-organisms, dead organic matter would accumulate and be at least as permanent as the rocks. Pasteur's researches tend to banish from the universe such a process as purely chemical decay. It is the function of anaerobes to split up organic tissues into simpler combinations, and we are indebted to the aerobes for the resolution of these simpler combinations into inorganic forms. It seems almost as though chemical affinity acted under the direction and control of life, and the fact that man in the laboratory is able to produce artificial compounds can scarcely be regarded as an exception to this rule. The opinions based on Pasteur's suggestion in 1862, that the production of nitrates in the soil is the work of a living organism, have been much strengthened and extended by such papers as that by Mr. R. Warrington, on the value of microbes to the agriculturist, read at the meeting of the British Association at Southport, last year. Not less remarkable is Dr. Angus Smith's discovery of the giving off hydrogen from water as a consequence of the presence of microbes, and as constituting even a test of their activity. A brief résumé of Dr. Smith's observations on this point appeared in the *Manchester Guardian* of January 28th. Dr. Smith's own account, which will form part of his forthcoming Report as Inspector under the Rivers Pollution Commission, will be looked forward to with the greatest interest, and all will anticipate with keen expectation Dr. Smith's further researches based on a discovery which seems so full of suggestiveness. Dr. Smith found that from very pure spring water up to the most foul sewage hydrogen is given off, and that in each case its quantity is strictly proportionate to the activity of the microbe life present. Nitrates are found in rain-water, but have been attributed by Obin and Muntz to electrical action, and to the presence of minute crystals in the atmosphere.* Considered from Pasteur's standpoint it will be seen that such phenomena may vastly extend our idea of the part played by life throughout the universe. The philosophical result of Pasteur's teaching may be perhaps best expressed by his answer to the famous question of Liebig, repeated by M. Bouillaud in the Academy of Sciences, as to what are the ferments of ferments? "If," says Liebig, "the fungus or mushroom be the cause of the destruction of the oak—if the animalcule be the cause of the putrefaction of a dead elephant,—what, then, is the cause of the putrefaction after death of the fungus? what is the cause of the putrefaction and decay of the dead animalcule? They also ferment, decay, and putrefy, and finally disappear entirely, just as do the mighty tree and the gigantic animal; and the final products are the same in all." "Dead aerobes," replies M. Pasteur, "become the prey of new aerobes of different species or of their own species. Though a mass of germs becomes in its turn a mass of organic matter susceptible to putrefaction and combustion, those germs, nevertheless, represent life in its eternal form; for life is the germ, and the germ is life."

9. A consideration of the new views as to the influence of the microbe in the chemistry of the universe naturally leads to a consideration of the possible influence of chemical conditions upon the microbe. This is the old question of the influence of the environment upon the form of the organism, or, as we may say, in perhaps a deeper philosophical sense, upon its life. This branch of the enquiry has an important bearing upon the patholo-

gical problems involved. One of the things which most strike the student of Pasteur's work and that of his followers is the remarkable variety of conditions under which microbe life is apparently carried on. Here, again, it seems as though life was the dominant force in the universe which moulded almost any conceivable conditions to its use. "You have discovered," said Dumas to Pasteur, "a third order of beings in animated nature—creatures who can live either with or without free oxygen." Following up the experiments of Pasteur demonstrating the existence of life outside the conditions which mankind had come to regard as essential to life, and resulting in his classification of germs as anaerobes and aerobes, we have had a most astonishing series of observations. Semper has called attention to the fact that far higher forms of life than we assume the micro-organisms to be actually do live under gaseous conditions which would be fatal to the higher Vertebrata, and that the capability of breathing assumed poisonous gases varies greatly in different animals. The mere inference by Pasteur that each form of fermentation has its peculiar ferment implies the existence of life under a most extraordinary variety of chemical conditions. Dr. Miquel has cultivated a bacterium which has the singular power of transforming sulphur into sulphuretted hydrogen, and which apparently lives and prospers in a *milieu* charged with sulphuretted hydrogen gas. The same experimentalist is sure of at least one bacillus which lives and multiplies in solutions heated to a temperature of from 70° to 72° C., or 15° above the temperature assigned by Cohn as the limit beyond which, though spores may retain latent the power of germinating, no actual growth or multiplication by scissiparity or spore production can take place. Van Tieghem professes to have carried the limit within which vegetation is possible up to 74° C. We have further the experiments of the lamented Frank Hutton on the cultivation of bacteria in the presence of various gases supposed to be inimical to life, showing that bacteria can live and thrive in the presence of carbonic oxide, cyanogen, sulphurous anhydride, nitrogen, nitrous oxide, carbonic anhydride, and coal gas. Bacteria were also cultivated by the same inquirer in solutions containing large quantities of salicylic acid, strychnine, morphine, narcotine, and brucine. In all these cases the presence of the bacteria affected in a greater or less degree the chemical results; the decomposition of cyanogen, for instance, was "assisted" by the bacteria.

10. In all these cases it is far from unreasonable to assume that the particular media acted upon may have, in their turns, an influence upon the germs themselves. And although with that strong tendency to see things simply as they are and to avoid generalising, which is, in a peculiar degree, the quality of Pasteur, the author of the modern theory of fermentation has refused to recognise the hypothesis of Von Nägeli, Buchner, and of Dr. William Roberts, as to the convertibility of the different species of micro-organisms, he does not expressly deny its possibility, and has, indeed, together with his immediate disciples, demonstrated by many suggestive and remarkable experiments the existence of a certain amount of variability, or adaptability, in microbes. But provisionally, at least, Pasteur rests upon the recognition of a special ferment for each particular kind of fermentation, and what is, in his view, another way of saying the same thing, a special microbe for each zymotic disease; and the variability which he admits is simply a variability of vigour. With him, moreover, vigour and youth appear to be convertible terms, and it is important in following the course of his researches to retain this idea. "Do I deny absolutely the polymorphism of *Mycoderma aceti*?" says Pasteur in his "Etudes sur la Bière"; "on the contrary, I have endeavoured many times to establish it. I have sought chiefly for physiological polymorphism; that is, whether *Mycoderma aceti* was not, for instance, the aerobic mutor of a ferment differing from it physiologically, say of the lactic ferment, whose analogies of form with the *Mycoderma aceti* are sometimes striking. I have not

* If any reliance can be placed on spectrum analysis, alcohol is present in the tails of comets.

found anything hitherto. What I deny, with reference to this *Mycoderma*, are the polymorphisms admitted by M. Béchamp and other authors, which, in my judgment, rest upon erroneous and incomplete observations." Dr. Miquel, whose remarkable book on "Les Organismes Vivants de l'Atmosphère," containing the record of his experiments at the Montsouris Observatory, is full of interest, gives his testimony on the same side. "The theory of the evolution of species," he says, "can derive little profit from this class of experiments if they are conducted with the necessary rigour." After an enormous number of experiments he has found that the different species of microbes maintain their habits and their individuality unchanged for months and years. "Of 50,000 experiments," adds Dr. Miquel elsewhere, "not one has contradicted the affirmations of M. Pasteur, while many are in complete opposition to the statements published by some of his too zealous or inexperienced followers." Klein, as well as Koch, has also been forced to the conclusion that no satisfactory proof of the truth of Non Nægeli's fascinating hypothesis of the "sporting" of saprophytes, or, in other words, of the conversion of pathogenic bacteria into harmless saprophytes, and the reduction of the latter into the former, has yet been adduced, and he has published a series of experiments tending to show that Buchner was mistaken in supposing that he had established the convertibility of *Bacillus subtilis* and *Bacillus anthracis*, and offering an explanation of the phenomena on which Buchner's conclusion was based.

II. Nevertheless it must be admitted that the successive outbreaks and disappearances of epidemics, and the observations of Pasteur and others on the adaptability of microbes to different environments, and on the attenuation and cultivation of their vigour as ferments, cause Von Nægeli's hypothesis to have an inherent probability. Not that the idea that there is a struggle for existence between rival microbes, enunciated by Pasteur in his "Etudes sur la Bière," assumed by Klein to be the explanation of Buchner's supposed evolution of the anthrax bacillus from the hay bacillus (both forms being supposed to have inadvertently obtained admission to Buchner's culture solutions), and referred to by Miquel as the explanation of the varying proportions of germs in his cultures, may not also explain the occurrence of epidemics. If we assume the absolute inconvertibility of all species of microbes, epidemics might still be explained as the consequence of the occurrence of temporary conditions more favourable to the development of noxious than of harmless species. But this would really force us logically to the conclusion that all zymotic diseases have specifically existed as long as life itself. On the other hand we must be careful to distinguish between variability of species and what Pasteur means by variability of vigour. Pasteur's idea is perhaps most clearly conveyed by the use of the terms young and old germs, or we may perhaps better grasp the idea by using the terms tame and savage germs. Thus, let us take the remarkable observation of Pasteur concerning the difference in the proportion of fermentation accomplished in brewing, to weight of organism, in the presence or absence of free oxygen. In shallow vessels in which the ferment easily obtains free oxygen, 1 kilogram. of ferment will correspond to 5 or 6 kilogramms. only of decomposed sugar; while in deep vats, in which the free oxygen is speedily exhausted, and the access of fresh supplies is prevented by the layer of carbonic acid formed above the vats, a kilogram. of ferment corresponds to 70, 80, 100, and even 150 kilogramms. of sugar decomposed. It is as though the ferment in the presence of free oxygen lived the quiet and easy life of civilization, brought up a large family, and destroyed or consumed no more than was necessary for the support of the community; while the ferment thrust into the recesses of the vat and forced to tear oxygen from the material around him, figuratively speaking, cuts down a tree in order to cook a dinner, and destroys a forest in order to obtain a little breathing space. As the savage may acquire strength and ferocity by his

mode of life, so it may be inferred that the germ actually acquires virulence by exercise in its anaerobic mode of life. The question is, does this virulence become fixed by heredity, in any case, in such away as to amount to the establishment of a new species, with peculiar attributes which will enable it, not only to tear oxygen as a saprophyte from dead organic matter, but as a parasite from living tissues. For it must be borne in mind that, so far as reliable experiment has yet gone, the process absolutely stops at this point. The transformation of the harmless saprophyte into the deadly animal disease has not yet been conclusively shown.

(To be continued.)

A RECALCULATION OF THE ATOMIC WEIGHTS.*

By FRANK WIGGLESWORTH CLARKE, S.B.,
Chief Chemist to the U.S. Geological Survey, Washington.

RHODIUM.

BERZELIUS† determined the atomic weight of this metal by the analysis of sodium and potassium rhodichlorides, Na_3RhCl_6 , and K_2RhCl_5 . The latter salt was dried by heating in chlorine. The compounds were analysed by reduction in hydrogen, after the usual manner. Reduced to percentages the analyses come out as follows:—

In Na_3RhCl_6 .		
Rh.	3NaCl.	Cl ₃ .
26.959	45.853	27.189
27.229	45.301	27.470
		27.616
Mean 27.094	45.577	27.425
In K_2RhCl_5 .		
Rh.	2KCl.	Cl ₂ .
28.989	41.450	29.561

From the analyses of the sodium salt we get the following values for Rh:—

From per cent of metal..	Rh = 104.507
" " NaCl..	" 102.980
" " Cl ₃ ..	" 105.696
" ratio between Cl ₃ and Rh..	" 104.829
" " NaCl " "	" 104.093

These are discordant figures, and indicate some doubt as to purity of material. The last value is fairly good, however, and is confirmed by results from the potassium compound:—

From per cent of metal..	Rh = 104.054
" " KCl ..	" 104.046
" " Cl ₂ ..	" 104.065
" Rh : Cl ₂ ratio ..	" 104.057
" Rh : KCl ratio ..	" 104.051
Mean ..	" 104.055

If O = 16, this becomes Rh = 104.285.

RUTHENIUM.

The atomic weight of this metal has been determined only by Claus.‡ Although he employed several methods, the only results worthy of present notice come from the analysis of potassium rutheniochloride, K_2RuCl_5 . The

* Smithsonian Miscellaneous Collections, "The Constants of Nature."

† Poggend. Annal., 13, 435. 1828.

‡ Journ. f. Prakt. Chem., 34, 435. 1845

salt was dried by heating to 200° in chlorine gas, but even then retained a trace of water. The percentage results of analysis are as follows:—

Ru.	2KCl.	Cl ₂ .
28·96	40·80	30·24
28·48	41·39	30·22
28·91	41·08	30·04
Mean 28·78	41·09	30·17

Reckoning directly from the percentages we get the following discordant values for Ru:—

From percentage of metal	Ru = 103·016
" " KCl	" 107·190
" " Cl ₂	" 96·854

Obviously, the best result is to be obtained from the ratio between Ru and 2KCl. This gives Ru = 104·217; or, if O = 16, Ru = 104·457. But little weight can be attached to this determination.

THE INFLUENCE OF ORGANIC MATTER AND IRON ON THE VOLUMETRIC DETERMINATION OF MANGANESE.*

By J. B. MACKINTOSH, New York City.

THE present note is intended as an addition to my previous communication on the volumetric determination of manganese, read at the Roanoke meeting,† it having been suggested‡ that the circumstances under which my experiments had been conducted were essentially different from those met with in the analysis of irons. The method used in these experiments is the same in all its details as that described in the paper referred to.

I have made seven experiments in all: two of these were in duplicate on half a gramme of a sample of spiegel dissolved in hydrochloric acid; one was on the same amount of spiegel with the addition of 25 c.c. of a standard solution of potassium permanganate; one was on the same amount of spiegel with the addition of 35 c.c. permanganate and much organic matter, viz., one drop of castor oil, two or three drops of coal-tar benzol and of gasoline (petroleum), about ten of alcohol, portions of starch and of sugar about the size of a small pea, and about half an inch of a common match cut into shavings. This organic matter was added to the manganese solution after the hydrochloric acid had been replaced by nitric, and the solution was heated until the wood shavings had disappeared. The fifth experiment was made by dissolving

and the seventh experiment by dissolving half a gram. of spiegel in hydrochloric acid, and adding 35 c.c. permanganate, without, however, taking the precaution to evaporate off all the excess of hydrochloric acid.

Under these circumstances one would expect that if organic matter exercises any influence on the determination it would be plainly evident in the results obtained. But the accompanying table of results shows that there is no such evidence, the slight differences obtained being easily accounted for as errors of manipulation.

Experiment 3 shows that iron and the carbonaceous matter present in spiegel have no practical effect; experiments 4 and 6 show that extraneous organic matter has no effect; while experiment 7 shows that hydrochloric acid tends to make the results decidedly low. This is what we should expect, for the energetic oxidising action of the nitric acid and potassium chlorate employed, is very apt to destroy all organic matter present, while we know that MnO₂ is decomposed by hydrochloric acid. Another cause of the slight lowness of the results is the formation of permanganate. Frequently the wash-water is tinted slightly pink.

It may be well to call attention to the fact that the differences between the observed and calculated values in Nos. 3, 4, and 6 correspond to errors of 0·43, 0·92, and 0·22 per cent of the total amount of manganese present, including that in the spiegel, or to errors of 0·05, 0·12, and 0·025 per cent, if working on 1 gram. of spiegel or ferromanganese, on the total amount of all the constituents present.

The low results obtained by some chemists may perhaps be explained on the supposition that the potassium chlorate used may be contaminated with potassium chloride, thus giving rise to the formation of free hydrochloric acid, which we see interferes with the accuracy of the process.

ON DIOXYETHYL-METHYLEN, AND THE PREPARATION OF METHYLEN CHLORIDE.*

By WILLIAM H. GREENE.

WITH the exception of the diethyl-ether of methylen glycol, all of the oxy-ethyl substitution compounds of methan have already been described. Ortho-formic ether, CH(OC₂H₅)₃, was studied by Kay and Williamson, and is generally known as Kay's ether; ortho-carbonic ether, C(OC₂H₅)₄, was discovered and described by H. Bassett; methylen-ethyl oxide has long been known.

By a reaction similar to that by which these ethers are formed I have isolated dioxy-ethyl-methylen, the reaction

half a gram. of spiegel alone in nitric acid; the sixth by dissolving half a gram. of spiegel in nitric acid with the addition of 25 c.c. potassium permanganate, some oxalic acid, half an inch of a match, one filter-paper 7 c.m. in diameter, and two drops each of castor oil and turpentine;

between sodium ethylate and methylen chloride taking place as indicated by theory.

The chief difficulty lies in the preparation of pure methylen chloride. The process described by Perkin, and depending upon the reduction of chloroform by zinc and ammonia, yields only small quantities of methylen chloride, and the direct chlorination of methylen chloride yields equally unsatisfactory results. The method which, after

* A Paper read at the Chicago Meeting of the American Institute of Mining Engineers, May, 1884.

† Transactions of the American Institute of Mining Engineers, vol. xii., p. 79; and CHEMICAL NEWS, vol. xxxviii., p. 176.

‡ CHEMICAL NEWS, vol. xxxviii., p. 273.

* Read before the American Philosophical Society.

numerous experiments, I have found to answer best consists in the reduction of an alcoholic solution of chloroform by zinc and hydrochloric acid.

The zinc and chloroform, mixed with several times its volume of alcohol, are placed in a flask connected with a suitable condensing apparatus, and hydrochloric acid is added in small portions. The reaction develops considerable heat, and methylen chloride and chloroform distil over. When the reaction has somewhat subsided, and no more liquid distils, more hydrochloric acid is added, and a moderate heat is applied if necessary. In any case the mixture is heated towards the close of the operation, until alcohol begins to distil in quantity. The operation is then arrested, and the product in the receiver is washed, dried, and rectified, that portion which passes below about 53° being retained. The residue is returned to the flask, and again submitted to the action of the zinc and hydrochloric acid. By several careful rectifications of the product passing below 53° pure methylen chloride boiling at 40° to 41° is obtained.

By several operations in this manner the yield of methylen chloride may be brought up to about 20 per cent of the chloroform employed.

Little or no advantage is gained by attempting to fractionate the product as it distils from the flask, so that the chloroform may flow back into the reducing mixture, for such distillation necessarily takes place in a stream of hydrogen, which carries with it about as much chloroform as methylen chloride.

Dioxy-ethyl-methylen.—This compound was prepared by gradually introducing one molecule of sodium into a mixture of one molecule of methylen chloride and about four times the theoretical quantity of absolute alcohol, contained in a flask connected with a reflux condenser. After all of the sodium has been introduced the mixture is heated on a water-bath for about an hour, and is then distilled. The distillate is fractionated, and the portion which passes below 78° contains all the diethyl ether. It is agitated with a tolerably concentrated solution of calcium chloride, and the light ethereal layer is separated, dried over calcium chloride, and carefully rectified, until a liquid is obtained which boils at 86° to 89°.

Dioxy-ethyl-methylen so obtained is an ethereal liquid, having a penetrating pleasant odour, somewhat recalling that of mint. Its specific gravity at 0° is 0.851, and it boils at 89°, under a pressure of 769 millimetres. It is slightly soluble in water, from which it may be separated by the addition of calcium chloride: it mixes in all proportions with ether and alcohol, and it cannot readily be separated from its alcoholic solution if much alcohol be present. In such a case, fractional distillation and treatment of the portion which passes below 78° with solution of calcium chloride effect the separation.

ON A NEW SYNTHESIS OF SALIGENIN.*

By WILLIAM H. GREENE.

THE method by which I have obtained saligenin synthetically is an application of a general method for the preparation of phenolic derivatives, made known by Reimer and Tiemann. Indeed, since by the reaction of chloroform or of carbon tetrachloride on an alkaline solution of sodium phenate salicyl c aldehyd or salicylic acid may be obtained, it may naturally be expected that, under the same circumstances, methylen chloride would yield saligenin, the latter being an oxy-benzylic alcohol.

A mixture of 30 grms. of methylen chloride, 30 grms. of phenol, and 40 grms. of sodium hydrate dissolved in 50 grms. of water, was heated in a sealed matrass in a water-bath. The reaction is complete in about six hours, after which the contents of the matrass is neutralised with hydrochloric acid, and agitated with ether, which takes up

the saligenin and the excess of phenol. The ethereal solution is decanted, and the ether distilled off; the residue is repeatedly exhausted with boiling water, which takes up the saligenin and leaves the greater part of the phenol undissolved. The aqueous solution is concentrated to a small volume, and the drops of phenol which separate on cooling are removed. After exposing the residue for some time over sulphuric acid, a crystalline mass is obtained, which is pressed, and re-crystallised from boiling water or from alcohol. Pure saligenin is thus obtained.

The quantity of saligenin is by no means in proportion to the quantity of phenol employed, and an alcoholic solution of sodium hydrate was found to yield no better results than an aqueous solution, although the reaction took place more promptly.

Isomeric oxy-benzylic alcohols may be, and probably are, formed at the same time, but I have not yet been able to isolate such compounds.

THE QUALITATIVE DETECTION AND THE QUANTITATIVE DETERMINATION OF ARSENIC, SULPHUR, AND PHOSPHORUS, AND OF CERTAIN METALS PRESENT IN MINUTE QUANTITIES IN COMMERCIAL COPPER.

By O. KUHN.

THERE was published in the *Zeitschrift für Analytische Chemie* (vol. xxi., p. 516) a memoir under the above title by Dr. Jul. Löwe, upon which I submit certain remarks.

The author states:—"In presence of sulphur (or of one of its oxides) along with lead in copper a part of the precipitate insoluble in nitric acid will consist of lead sulphate." This, however, can happen only when a considerable quantity both of lead and sulphur occurs in the copper in question. Even then only a part of the lead sulphate formed is precipitated, whilst the rest remains in solution, and is only thrown down on the addition of alcohol. Most of the refined coppers of commerce, which really contain lead, give no precipitate on the direct addition of sulphuric acid until alcohol is also added.

The same remark applies to the method laid down for precipitating the main quantity of the lead, in which likewise an addition of alcohol, and the washing of the precipitate with water containing alcohol and sulphuric acid, is necessary.

The separation of the arsenic by precipitating the solution of the copper (first rendered ammoniacal) with magnesia mixture gives too low results, and if the quantity of arsenic is trifling no precipitation at all takes place, so that the presence of arsenic may be entirely overlooked. In order to retain 15 to 18 grms. copper in ammoniacal solution a considerable quantity of water must be added, and in the volume of liquid thus formed (at least 1½ litre) a notable quantity of ammonium-magnesium arseniate remains in solution. An addition of alcohol lessens this evil, but does not remove it entirely.

The separation of the phosphorus from the ammoniacal solution of copper suffers from the same defect, though to a far less extent, since ammonium-magnesium phosphate is far less soluble in ammoniacal water than is the corresponding arsenical compound.

The separation of copper from zinc, nickel, and cobalt suffers from the same evil, which the author himself points out as regards the separation of arsenic with potassium sulphide. When 15 to 18 grms. copper are used—and this is scarcely to be avoided in view of the minute proportion of the foreign metals in question—the precipitate of copper sulphide produced by the introduction of sulphuretted hydrogen is very bulky, and cannot easily be thoroughly washed, remembering how readily copper sulphide becomes oxidised.

* Read before the American Philosophical Society.

With reference to the above-mentioned sources of error I venture to propose a method which I have used for some time, and which on several grounds seems to me preferable to the method of Dr. Löwe.

For the determination of the proportion of copper a small quantity of the sample (0.5 to 0.8 grm.) is dissolved in nitric acid, and titrated with potassium sulphocyanide, according to Volhard's well-known method. The determination of silver, lead, and bismuth (iron and manganese) is effected in a separate portion of the sample, and that of arsenic, phosphorus, sulphur, zinc, nickel, cobalt, iron, and manganese in a third portion, both the two latter of from 15 to 18 grms.

The two latter portions are dissolved, each separately, in nitric acid, evaporated to dryness, to render tin oxide insoluble if present, and the residue is dissolved in water, with the addition of a quantity of nitric acid just sufficient. If a residue is left it is filtered off, washed with hot water, and tested by known methods for antimony, tin, silicon, phosphorus, arsenic, and lead sulphate, the last only, as above mentioned, when considerable quantities of lead and sulphur are present. It must be remembered that when the copper contains iron along with tin the tin oxide always appears coloured yellow by iron oxide, from which it cannot be separated by boiling with acids. It is therefore necessary to separate them by fusion with sodium carbonate and sulphur.

The solution of one portion of 15 to 18 grms. copper is mixed with hydrochloric acid for the separation of silver. To the filtrate are added sulphuric acid and alcohol to throw down lead sulphate, which is filtered off and washed with water containing sulphuric acid and alcohol. Up to this stage of the process care must be taken that a sufficiency of acid is always present in the solution to prevent a separation of bismuth, if present, by the washing-water.

The filtrate from the lead sulphate is supersaturated with ammonia according to Löwe's method, when bismuth and iron oxides are eliminated and separated by known methods. If, however, the copper contains along with iron relatively considerable quantities of phosphorus or arsenic the precipitation of iron oxide is always imperfect. Both precipitate and solution contain ferric oxide and phosphoric or arsenic acid. This is at once perceived on adding to the filtrate magnesia mixture. The precipitate of ammonium-magnesium phosphate (or arseniate) is coloured more or less deeply yellow by a simultaneously deposited ferric oxide. If iron and phosphorus are both present we obtain them in two separate precipitates, on which account it is preferable to determine the iron in the second portion of 15 to 18 grms. copper.

In the solution of this second portion the sulphuric acid is first precipitated by means of barium nitrate; the filtrate is evaporated to dryness with such a quantity of sulphuric acid that all the metallic oxides may be combined with this acid.

The residue from evaporation is dissolved in water, mixed with just enough sodium carbonate to cause a permanent precipitate, heated almost to boiling along with sulphurous acid, and all the copper is thrown down as a sulphocyanide by means of the smallest possible excess of potassium sulphocyanide. When quite cold the liquid and the entire precipitate are rinsed into a 500 c.c. flask, filled up to the mark with water, and well shaken after so much more water has been added as corresponds to the volume of the precipitated copper sulphocyanide. This compound, when recently precipitated, has the sp. gr. 3.16, whence the volume of the precipitate may be readily calculated (10 grms. copper give 19.16 copper sulphocyanide,

$$= \frac{19.16}{3.16} = 6.06 \text{ c.c.})$$

From the contents of the flask 400 c.c. are filtered through a dry folded filter, and concentrated to a small volume. It is then heated with nitric acid added drop by drop till all excess of potassium sulphocyanide is decomposed, and the resulting hydrocyanic acid is expelled. The

liquid thus concentrated is boiled with sulphurous acid, the latter driven off, and sulphuretted hydrogen is passed into the hot liquid until the arsenic present is entirely thrown down. The arsenic in the iron arsenide thus obtained is determined by one of the known methods.

From the liquid thus freed from arsenic, the iron, nickel, cobalt, zinc, and manganese are precipitated as sulphides by the addition of ammonia and ammonium sulphide, and are separated and determined by the ordinary methods. The ammonium sulphide in the filtrate is decomposed by hydrochloric acid, and phosphorus is precipitated by ammonia and magnesia mixture as ammonium-magnesium phosphate. On account of the large quantity of potassium salts in the solution the precipitate always retains potassa and must be redissolved in a little hydrochloric acid and again thrown down by ammonia and a few drops of magnesia-mixture.—*Zeitschrift für Analyt. Chemie.*

VERMILLION—ITS MANUFACTURE IN CHINA.

THE Chinaman has no knowledge whatever of chemistry, and of the principles of natural philosophy and statics generally his notions are of the most rudimentary and primitive description. How, then, in the face of these obvious disadvantages have the Chinese contrived to place themselves in the front rank amongst nations in the matter of certain chemical manufactures, one of the most important of which is the subject of this article,—Vermillion? In our last article we have seen with what ingenuity and pertinacity in carrying out his ends the Chinaman has succeeded in making perhaps the most delicate and perfect iron castings in the world. He has succeeded in that instance not by any deep researches into the hidden mysteries of Nature, by no process of thought involving an inquiry into the 'reason why;' to this the Chinaman is averse, the whole tendency of his education, such as it is, tends to make him satisfied with observing effects; it is sufficient to him to know that things are so, without going into troublesome or elaborate investigations into those changeless laws of Nature into which his philosophy teaches him that, as he cannot alter or control research, is fruitless; but that he has in his own small, ingenious, patient way observed effects to very good purpose the unrivalled excellence of some of his manufactures testifies. We will now enter a vermilion manufactory and watch the process from the first stage of mixing its two ingredients—mercury and sulphur—to the final process of weighing and packing this costly and beautiful pigment for the market.

The first objects to attract the visitor's attention on entering the yard attached to the works will probably be large piles or stacks of charcoal, crates, or baskets of broken crockery ware, and numerous rusty old iron pans of somewhat similar shape to the rice pans previously described, but considerably thicker and heavier. There will also probably be a few broken and disused cast-iron mortars. All these articles are the cast off or worn out implements of the manufacture, and will be described in their proper order. On entering the factory proper, scores of little stone mills, each being turned by one man, and other long rows of workmen weighing out and wrapping up the vermilion will be seen. The furnaces are then arrived at: these may be a score or more in number and may be ten or twelve in each furnace room, five or six on each side. After passing these the stores of quicksilver, sulphur, alum, glue, new spare iron pans, serviceable crockery ware, and sieves and other utensils used in the factory are arrived at, and this completes the view of the works. The iron pans in which the vermilion is sublimed are those referred to above; they are circular and semi-spherical in shape; all are of the same size and weight; they are cast upside down, and in the casting, a runner or lump of iron, two and three-eighths inches in diameter by from six-eighths to one inch in depth, is purposely left on

every pan in order to enable the workman the more readily to handle the pan when stirring up its contents. The size of the pans proved by actual measurement to be 29½ inches in diameter, by eight and seven-eighths inches deep, and the weight 40 catties, or say about 53 pounds. These pans are set in rows of 5 or 6 on each side of a small rectangular room, in size some 12 ft. by 15 ft.; the door of this room is of wood and contains an aperture a few inches square in order to enable the workman to watch the progress of his operation, from time to time, without the necessity of lowering the temperature of the apartment by opening the door. The pans are set in brickwork, each pan having beneath it a grate to hold the charcoal used as fuel. There is no communication between the grates or furnaces under each pan, and no chimney, the flames and products of combustion finding exit from the front of the grate which is left wholly open at all stages of the operation.

The process of manufacture is as follows:—Taking an iron pan, which is of four inches smaller diameter than those described, and also in all other respects proportionally less, except the runner, which is of the same size, a skilled workman proceeds to weigh out 17½ lbs. of sulphur. This he places in the pan, and adds about half the contents of a bottle of quicksilver. The pan with its contents is then put upon a small earthen brazier or portable furnace, the fuel used in which is charcoal. When the sulphur is sufficiently melted, the workman, taking an iron spatula or stirrer, rapidly stirs up the quicksilver with the sulphur, and gradually adds the remaining contents of the bottle of quicksilver, stirring the two ingredients together meanwhile until the mercury has wholly disappeared, or "been killed," as the Chinese put it. When this takes place the pan is removed from the fire, a small quantity of water is added, and rapidly stirred up with the contents of the pan, which have now assumed a dark blood-red appearance and semi-crystalline structure. This mass is then turned out of the pan into an iron mortar, and then broken up into a coarse powder. This forms a charge for one of the large pans previously described, and when sufficient material has been prepared to charge all the pans in one furnace chamber the sublimation is proceeded with as follows:—All the pans having received their quantum of crude vermilion, this is covered with a number of crockery- or porcelain-ware plates of tough, strong manufacture, each about 8 inches in diameter; some of these plates, however, are broken up, and are in a more or less fragmentary condition. When these plates have been piled up into a dome-shaped heap of the same shape as the bottom of the upper pan, to which they should extend, the whole is covered with one of the smaller pans previously described. Now, it will be remembered that the smaller pan was of 4 inches less diameter than the larger one; there will consequently be a circular space of two inches all round between the circumference of each pan. Consequently the rim of the upper or covering pan will be about 2 inches lower than the rim of the lower pan; there will also be some 4 inches space horizontally between the rim of the large lower pan and that portion of the smaller pan which is at the same height as the rim of the larger one. This space is carefully filled with a clay luting into which some holes, generally about four in number, are pierced, extending down to the rim of the smaller pan or cover; this is done in order to allow the heated air and other matters to escape. All the pans in one furnace chamber being thus charged and covered the fires are lighted. The flames from the charcoal should occasionally play several feet above the mouths of the furnaces. The door of the chamber is kept closed, except when it is open for a moment in order to enable the workmen to replenish the fires, which must be kept up at a fierce heat for eighteen hours. During this process a blue lambent flame is seen to play above each of the four holes which are pierced through the clay luting of the pans, so it is evident that a considerable quantity of either one or probably both the ingredients is wasted. After eighteen hours the fires are

allowed to go out, and the contents of the pan cool down. When this is accomplished the greater portion of the vermilion will be found adhering to the lower surface of the broken-up porcelain plates with which the crude product is covered. The vermilion is then carefully removed from the porcelain by means of chisels, and is now ready for the elutriating mills. Another portion of vermilion of not so good quality is found adhering to the upper iron pan and that obtained by washing the clay luting in a cradle, as diggers wash dirt for gold. This together with the wipings and scrapings generally is mixed up with alum and glue-water into cakes, and, after drying on a brick surface heated beneath by means of wood or charcoal, is powdered up on a mortar, and re-sublimed when a sufficient quantity has accumulated.

The vermilion which was removed from the porcelain plates is of a blood-red colour and crystalline structure. This is then powdered up in a mortar and removed to the levigating mills; these are the ordinary little horizontal stone mills used by Chinese and other natives of the East to grind rice and other grain into flour or pulp, as the case may be. Each stone is about 2½ feet in diameter; the lower stone is stationary, the upper is turned by a direct-acting piece of wood having a hole in it which works a wooden peg affixed to the upper stone, which is made to revolve by a backward and forward movement of the piece of wood, or handle, some 3 or 4 feet long, previously mentioned. One man turns each mill. The upper stone has a small hole in it near its centre, down which the workman from time to time pours a little spoonful of the powdered vermilion, which he washes down into the mill with water: as he turns the mill the workman keeps continually ladling little spoonfuls of water down the aperture or hole in the upper stone; the ground and thus elutriated vermilion, as it escapes from between the stones, is washed down by the water into a vessel placed beneath to receive it. When work is suspended for the evening the ground vermilion is carefully stirred up with a solution of glue and alum in water, in the proportion of about an ounce of each to the gallon. The glue has been made to mix with the water by previously heating it with a small quantity of water; the earthen pots in which this process is effected each hold about 6 gallons. The mixture is then left to settle. In the following morning the mixture of glue and alum is poured off the vermilion, and the upper portion of the cake of vermilion at the bottom of the vessel—that is, the portion which remained longest suspended in the liquid—will be found to be in a much finer state of subdivision than the lower portion, which requires to be again elutriated as on the previous day: this separation of the more finely divided vermilion from that which was coarser, by suspension in a dense medium, is a really most ingenious process, for which we should give the Chinaman every credit. The process of grinding, elutriation, and separation of the coarsely ground from the fine vermilion, sometimes requires to be several times repeated, in order to fully bring out the colour. As a final process the damp cake of finely ground vermilion is stirred up with clean water, and allowed to settle down until the next morning, when the water is carefully poured off into large wooden vats to still further deposit a small quantity of vermilion still remaining in suspension, and the vermilion dried in the open air on the roof of the premises. When quite dried the cakes of now full-coloured pigment are carefully powdered and sifted by means of square muslin-bottomed sieves, contained in a covered box some 2 feet high by 2½ wide, in which the sieves, which slide on a framework inside the box, are jerked backwards and forwards by means of a handle on the outside of the box or case containing them.

The now fully-prepared vermilion is removed to the packing house, where may be seen rows of workmen, men and boys, seated before a series of tables. Between every two workmen is a third, with a small pair of scales, which he holds in his left hand; and as the workmen on either side place before him the little pieces of paper in which

the vermilion is to be wrapped up, he weighs into each paper one tael (about an ounce and a third avoirdupois) weight of vermilion: the papers are two in number, the inner a black or prepared paper, and the outer a piece of ordinary white paper. After being wrapped up the packets are placed in rows before another workman, who stamps them with a seal containing in Chinese characters the name and address of the manufactory in which the article has been made, and the quantity and quality of vermilion contained in the packet.

The rapidity and deftness of the Chinese workmen at this employment is really surprising, the stamping, for instance, is effected at the average rate of sixty impressions per minute, and the wrapping up is carried on with proportionate rapidity. The mixture of alum, which is the ordinary aluminium potassium sulphate, with the vermilion, in one of its stages of manufacture as described above, is not added, as at first sight we thought it might be, merely to assist in clarifying or purifying the water by causing it to deposit its sediment, but seems to have some peculiar effect upon the colour. Although what may be the rationale of the process, or how it acts we cannot quite clearly see; the glue is added as described above merely to favour separation of the finely elutriated vermilion by holding it longer in suspension than the coarser particles, which sink first, and may therefore be separated in their order of stratification. The actual composition of vermilion is one hundred parts of mercury to sixteen of sulphur, when both these ingredients are in a perfectly pure state; the excess of five and one-third pounds of sulphur added by the Chinese is probably volatilised and lost in the process of sublimation, or as the sulphur used is generally not quite pure, a part may go for foreign matter contained in the sulphur; the balance being probably the *raison d'être* of the blue lambent flame seen playing over the apertures in the luting during the sublimation process. For a people having like the Chinese no acquaintance with even the first rudiments of chemistry, the proportion of ingredients taken—56½ catties to 13 catties, or say 75 pounds to 17 and one-third pounds—shows wonderfully accurate powers of observation and a knowledge of combining proportions only to be gained by much experience and a long extended series of careful observations highly creditable to the manufacturers. The entire process is one of the most ingenious and interesting to be seen in any part of the world.

T. I. B.

Hongkong, March 29, 1884.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 1, July 7, 1884.

The Absorption of Chlorine by Carbon, and its Combination with Hydrogen.—MM. Berthelot and Guntz.—When purified wood-charcoal is saturated with gaseous chlorine, and then treated with hydrogen gas, hydrochloric acid is formed, with a fall of temperature. The authors explain this anomaly by the consideration that the absorption of heat results not from the chemical action, properly speaking, but from the simultaneous evaporation of the chlorine condensed upon the charcoal.

The Chemical Composition and the Alimentary Value of the various parts of the Grain of Wheat.—Aimé Girard.—The author regards the grain of wheat as consisting of three parts, the shell (which forms 14.36 per cent), the germ (1.43 per cent), and the farinaceous layer (84.21 per cent). The author considers that the introduc-

tion of the shell and the germ into flour is only of an insignificant utility, and is attended with serious inconvenience.

Electric Conductivity of Very Dilute Aqueous Solutions.—E. Bouty.—All the organic substances which the author has examined conduct very badly. Anhydrous alkalis and acids are not conductors; hydrated alkalis and acids conduct in the same manner as salts.

On Phosphoric Anhydride.—P. Hautefeuille and A. Perrey.—In this memoir the authors establish the existence of three phosphoric anhydrides, the first crystalline, the second amorphous and pulverulent, the third amorphous and vitreous, the two latter being polymers of the former. The phosphoric anhydride obtained by the ordinary method is not a homogeneous substance, but a mixture of the crystalline and of the amorphous pulverulent anhydrides. The crystalline anhydride is obtained by distilling the products of the complete combustion of phosphorus. The amorphous pulverulent anhydride is prepared by heating the crystalline form to 440°. The vitreous amorphous form is produced on heating either of the foregoing to incipient redness under a strong vapour-tension.

Certain New Borotungstates.—D. Klein.—The author has obtained disodium-tungsto-borate, and a corresponding barium salt, which, however, contains six more molecules of water.

Dehydrating Action of certain Salts.—D. Tommasi.—From the researches of M. Grimaux on the coagulation of colloidal bodies it would appear that salts promote the coagulation of colloidal bodies by acting as dehydrating agents. The author mentions that there are cases where certain salts produce an effect exactly opposite, and entirely hinder bodies from becoming dehydrated. Thus cupric hydrate, if heated in presence of water, is rapidly transformed into the black oxide at about 77°, but in presence of a trace of manganese sulphate it does not become dehydrated even on boiling.

Perseite, a Saccharine Matter analogous to Mannite.—A. Muntz and V. Marciano.—This compound, until recently confounded with mannite, occurs in the fruit of *Laurus perseæ*.

On Certain Derivatives of Meta-xylene.—A. Colson.—The compounds investigated by the author are meta-xylene bibromide, meta-xylene glycol, and meta-xylene bichloride.

Polarimetric Researches on Cellulose Regenerated from the Pyroxylys, and on Cellulose submitted to the Action of Sulphuric Acid.—A. Lavallois.—The author's results show, contrary to the theory of M. Blondeau, that the substance recovered from the nitro-cellulose is identical with cellulose, or rather with hydro-cellulose. Cellulose poured into an excess of alcohol after prolonged treatment with sulphuric acid gives a deviation of only 5.5°, that of the cellulose of paper being 10.5°.

Preparation of Farm-yard Manure.—P. P. Deherain.—The author finds that straw is oxidised in contact with the air only under the influence of a "figured" ferment. There may be distinguished in dung a neutral fermentation producing carbonic acid and formene, and an acid fermentation in which there are produced butyric acid, hydrogen, and formene.

No. 2, July 15, 1884.

Second Memoir on Flour.—M. Balland.—Among the author's conclusions are that the proportion of moisture contained in the various products of grinding is sensibly the same. There is a constant relation between the hygrometric state of the air and the degree of moisture of a flour. Flours generally contain from 1 to 2 per cent more moisture in winter than in summer. The mean of moisture in the flours of commerce is 14 per cent.

Electro-Conductivity of Distilled Water and of Ice.—The resistance of distilled water becomes 15,000 times

greater at the moment of congelation. The resistance of ice, however, undergoes variations corresponding to those of the water from which it is formed.

Purification of Methylic Alcohol.—MM. J. Regnault and Villejean.—In the alcohol regenerated from methyloxalic ether the authors dissolve about 1-10th of its weight of iodine. To this liquid they add by degrees an aqueous solution of sodium hydroxide in sufficient quantity to produce complete decoloration and a decidedly alkaline reaction. If submitted to careful distillation this mixture gives methylic alcohol, not convertible into iodoform, and which, on rectification over quicklime, has the spec. gr. 0.8110 at 15°.

Deposit of Saltpetre near Cochabamba in Bolivia.—M. Sacc.—To the east of Cochabamba is an immense saline deposit consisting of potassium nitrate, 60.70; borax, and traces of salt and water, 30.70; organic matter, 8.60. If this mixture is dissolved in boiling water there is, on cooling, an abundant crystallisation of pure saltpetre.

No. 3, July 21, 1884.

Comparison between the Hypothesis of Currents around the Axis of a Magnet with that of Currents around each Molecule.—Augustin Fresnel.

Second Note on the Hypothesis of Particular Currents.—Augustin Fresnel.—These two memoirs have been discovered amongst the papers of Ampère. They do not admit of useful abridgment.

Electro-capillary Relations.—P. Garbe.—The electric capacity at the constant surface of an electrode plunged into a liquid is a function alone of the electric difference, independent of the sign of this difference, and it is at a minimum when this difference is null.

Direct Measurement of the Two Static Components and of the Dynamic Component of the Magnetic Field of Collector-Machines.—G. Cabanellas.—This paper does not admit of useful abridgment.

Researches on Magnetism.—M. Duter.—The author proves experimentally that the magnetism of flat steel magnets whose surfaces are their poles does not disappear when they are removed from the magnetic field.

New Battery with Electrodes of Coke.—MM. D. Tommasi and Radiguet.—Both electrodes consist of plates of coke; the one surrounded by a paste of lead peroxide, and the other covered on its horizontal upper surface with fragments of platinised coke. The two are separated by means of parchment paper. The exciting fluid is a saturated solution of sodium chloride.

Critical Temperature and Pressure of Nitrogen. **Boiling-points of Nitrogen and Ethylen under Low Pressures.**—K. Olszewski.—At a pressure of 9.8 m.m. the temperature of ethylen is -153.4° . At a pressure of 33.6 atmospheres and a temperature of -146° nitrogen boils and its meniscus is observed. The author maintains that his experiments do not confirm the solidification of nitrogen under the conditions indicated by M. Wroblewski.

Properties of Liquefied Marsh-Gas, and its Use as a Refrigerant.—S. Wroblewski.—By making use of the vapours of ethylen the author has reduced their pressure to 0.015 metre, and lowered the boiling-point to -144° . The boiling-point of liquefied marsh-gas is between -155° and -160° . Oxygen, air, nitrogen, and carbon monoxide may be liquefied at low pressures if cooled with this gas.

Action of the Induction-Spark upon Benzol, Toluol, and Aniline.—A. Destrem.—Benzol yields a mixture of 42 to 43 per cent acetylen, the residue being hydrogen. Toluol gives hydrogen, with 23 to 24 per cent of acetylen. Aniline yields 21 per cent of acetylen, 65 of hydrogen, hydrocyanic acid 9, and nitrogen 5.

Production of a Crystalline Barium Manganite.—G. Rousseau and A. Saglier.—The authors, by obtaining this compound, confirm the view of Gorgeu and Risler

that manganese peroxide may be regarded as manganous acid. Artificial barium manganite forms small acicular crystals of a bluish black. It dissolves readily in hydrochloric acid, with liberation of chlorine. Its specific gravity is 5.85, whilst that of the native manganite (psilomelane) is only 3.7 to 4.4.

Compounds formed by Chromium Sesquichloride with other Metallic Chlorides.—L. Godefroy.—Chromium sesquichloride forms definite crystalline compounds with the other metallic chlorides. They are all formed when the two chlorides are mixed in presence of an excess of strong hydrochloric acid. An increase of temperature promotes their formation, but the presence of water prevents it. They are all decomposed by water. Double chromium bromides and iodides may be obtained in a similar manner.

On a General Reaction of the Polyatomic Alcohols in presence of Borax and the Para-tungstates.—D. Klein.—A solution containing less than 0.5 mol. of borax to 1 mol. of dulcite is strongly acid. A solution containing 0.5 mol. borax to 1 mol. dulcite is neutral, and a liquid containing more than 0.5 mol. of dulcite per mol. of borax is alkaline. A mixture of solutions of dulcite and sodium para-tungstate presents the same reactions as those of mannite with the same salt.

Origin and Distribution of Phosphorus in Coal and Cannel.—A. Carnot.—The author finds ponderable quantities of phosphorus in the fossil plants imbedded in coal.

Variation, with Pressure, of the Temperature at which the Transformation of Silver Iodide is produced.—MM. Mallard and Le Chatelier.—Silver iodide at 146° passes from a hexagonal to the cubic symmetry, but an increase of pressure lowers the temperature at which this change takes place.

Bulletin de la Société Chimique de Paris.

No. 11, June 5, 1884.

Isomeric Benzene Hexachloride.—Jean Meunier.—The ordinary hexachloride melts at 157° and crystallises in tables belonging to the clinorhombic system. The isomer melts at 310° , subliming at once and crystallising in cubic octahedra.

Formation-Heat of Certain Soluble Compounds, and on the Law of Thermic Constants.—D. Tommasi.—The author gives the combination-heat of potassium and ammonium chromates as determined experimentally, and as calculated according to his law. He appends a table of the calculated combination-heats of the remaining soluble chromates and bichromates, the glycolates, sulphites, and fluoïdes. He shows, in opposition to M. Berthelot, that his law is applicable to the soluble salts of lead and mercury.

Pretended Association by Crystallisation of Bodies having no Analogy in their Atomic Constitution.—C. Marignac.—The author refutes the objections raised by Brügelmann to the doctrine of isomorphism as generally accepted. When a salt crystallises in a solution containing foreign salts in a notable proportion, the crystals formed cannot be perfectly pure; they always entangle a small quantity of these foreign salts whatever their nature. This mechanical occlusion of some traces of mother-liquor saturated with such salts has no connection with the regular association in proportions far larger, which takes place between salts of the same atomic constitution.

Russian Correspondence.—M. Lwoff announces that iso-butylen chloride cannot be obtained even when the action of chlorine upon iso-butylen takes place in direct sunlight.

M. Mihailoff communicated a new method of obtaining pure albumen. He filters white of egg through a cloth and adds a volume three times as large of a saturated

solution of ammonium sulphate, adding to the liquid obtained further quantities of the same salts until it no longer dissolves. All the albumenoid substances are then found in the precipitate. This precipitate is washed with a saturated solution of ammonium sulphate, and the concentrated solution of this precipitate (previously neutralised with ammonia until the reaction is slightly alkaline) is dialysed. The water precipitates all the globulins and globulins, whilst pure albumen remains in solution. This solution does not coagulate if heated to boiling, has a reaction almost neutral (feebly acid), and does not precipitate salts of barium. The precipitation by ammonium sulphate is one of the most sensitive reactions of all the albumenoid matters and their derivatives.

M. Mihailoff discussed the application of Mohr's method to the determination of chlorine in urine.

M. Sokoloff gave the results of the analysis of the water of the Neva during November.

M. Alexeeff expounded his researches on the solutions of substances containing carbon in sulphur. The solubility of the homologues diminishes with the increase of the molecular weight.

M. Mendeleeff presented a paper on solutions. On calculating the pressure corresponding to the solution of the salt according to the contraction which accompanies the formation of the given solution, the author finds that to each mol. of sodium chloride dissolving in 100 parts of water there corresponds for all concentrations one and the same pressure = 120 atmospheres. For calcium chloride, the pressure is also constant and three times greater.

M. Lawroff announces that in the action of metallic glucinum upon mercury dimethyl at 130° in sealed tubes, we obtain a white, crystalline, volatile substance which ignites on contact with water.

M. Bagaroff sent in a memoir on affinity.

M. Kanonikoff communicated a second memoir on the relation existing between the specific refractive energy of chemical compounds and their composition.

M. Menschutkine gave an account of his researches on the formation of the amides on setting out from the ammoniacal salts.

The first part of vol. xvi., of the *Journal of the Russian Chemical Society*, contains the following memoirs:—

"On the Expansion of Liquids," by M. Mendeleeff, and "On the Vapour-tension of Solutions," by M. Kononoff.

Researches on Detonating Gaseous Mixtures.—MM. Berthelot and Vieille.

Influence of the Density of Gaseous Detonating Mixtures under Pressure: Isomeric Mixtures.—MM. Berthelot and Vieille.

The Specific Heat of Gaseous Elements at very High Temperatures.—MM. Berthelot and Vieille.

Specific Heats of Water and Carbonic Acid at very High Temperatures.—MM. Berthelot and Vieille.

On the Scale of Temperatures, and on Molecular Weights.—M. Berthelot.

Relative Speed of Combustion of Detonating Gaseous Mixtures.—MM. Berthelot and Vieille.

The Reciprocal Displacements between Hydrofluoric Acid and other Acids.—MM. Berthelot and Guntz.

Equilibria between Hydrochloric and Hydrofluoric Acids.—MM. Berthelot and Guntz.

These last eight papers are substantially reproductions of matter which has appeared in the *Comptes Rendus*.

No. 12, June 20, 1884.

Production of Coke and the Utilisation of the Secondary Products of its Manufacture.—M. Scheurer-Kestner.—A compilation chiefly derived from a paper read by Mr. Watson Smith at the Southport Meeting of the British Association and from an article in the *Journal of Chemical Industry*.

On Selenio-Urea.—M. A. Verneuil. — Selenio-urea, $C_2N_2H_4Se_2$, is very soluble in hot water, but much less so in cold, which at 19° takes up only 10·70 per cent. Absolute alcohol at 18° dissolves 2·88 per cent, and ether at the same temperature only 0·56 per cent. If suddenly heated it melts without apparent decomposition, but if its temperature is gradually raised in order to determine its melting-point it fuses at about 200°, experiencing a thorough decomposition.

THE LONDON HOSPITAL and MEDICAL

COLLEGE, MILK END, E.—The SESSION 1884-5 will commence on Wednesday, October 1st, 1884, when the Prizes for the past Session and the Nursing Probationers' Prizes will be distributed at 8 p.m., by the Right Hon. the Lord Mayor, M.P., accompanied by the Lady Mayoress. There will be a Conversation, to which all past and present students are invited. FOUR ENTRANCE SCHOLARSHIPS value £60, £40, £30, and £20, will be offered for competition at the end of September to new students. Fees for Lectures and Hospital Practice, 90 guineas in one payment, or 100 guineas in three instalments. All resident and other Hospital appointments are free, and the holders of all the Resident Appointments are provided with rooms and board entirely free of expense. The Resident Appointments consist of Five House-Physicians, Five House-Surgeons, and one Accoucheurship; Two Dressers and Two Maternity Pupils also reside in the Hospital. Special entries may be made for Medical and Surgical Practice. The London Hospital is now in direct communication by rail and tram with all parts of the Metropolis, and the Metropolitan, District, East London, and South-Eastern Railways have stations within a minute's walk of the Hospital and College.

For prospectus and particulars apply personally or by letter to
Milk End, E. MUNRO SCOTT, Warden.

PATENTS DESIGNS & TRADE MARKS ACT, 1883.

In the matter of Letters Patent granted to WILLIAM GEORGE STRYPE for the Invention of "Improvements in the Treatment of Blood to prepare it for use as a Manure or for other Purposes." Dated the 5th day of January, 1884, No. 787.

NOTICE IS HEREBY GIVEN that the said William George Strype has applied under Sections 18 to 21 of the Patents, &c., Act, 1883, and Rules 48 to 56 of the Rules made thereunder, for leave to amend the Complete Specification filed by him on the 9th February, 1884.

The Specification as proposed to be amended is open to inspection at the Patent Office, and full details of the proposed amendment were advertised in the Official Journal of the Patent Office published on the 1st August, page 279.

Any persons intending to oppose such application must leave particulars in writing of their objections to the proposed amendment at the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C., within one calendar month from the date hereof.

Dated this 1st day of August, 1884.

H. READER LACK,
Comptroller General.

J. HENRY JOHNSON,
47, Lincoln's Inn Fields, London.
Agent for the said William George Strype.

ON LOGARITHM TABLES.

By W. DITTMAR.

WOLLASTON'S logarithmic sliding scale for the execution of chemical calculations has never been popular, and is now all but forgotten. The cause of this is easily apprehended: a four-place logarithm table does all that the best made scale can do, and a great deal more, with unerring certainty. But even four-place logarithm tables, although they just supply the degree of precision which we need for our ordinary analytical routine, are not much seen in chemical laboratories for the simple reason that the existing tables of this kind are not what they ought to be. They are all edited by professional arithmeticians who do not feel as an inconvenience what to most of us chemists appear as a positive nuisance. I refer to the trouble and time lost over the interpolations, which become particularly troublesome when the number for the logarithmic sum obtained has to be sought for.

All the four-place tables which have hitherto been published are arranged on the "double entry" system, which works so well with five- or more-place tables, but for four-place ones is not convenient. The logarithms, for instance, the numbers 100, 101 . . . 109, are all in one line, and within this line the difference between two successive logarithms is a variable quantity. Hence, if certain tables supply a ready calculated list of proportional parts for this line, it can be correct only for the mean value of $\Delta \log$, and when applied to other values leads to inaccuracies which a conscientious calculator does not care to tolerate. He rather calculates the correction from the particular value of $\Delta \log$ which comes into consideration, and thus goes to an amount of trouble which renders the advantages offered by the logarithmic over the ordinary method of computing questionable, in the case of single calculations at least. This inconvenience, it is true, gets less and less as we proceed from num. = 1000 towards num. = 999, but in the beginning of the table it does exist to one's annoyance.

Many years ago I constructed for my own use a four-place table, arranged on the single entry system (like the well-known Lalande's five-place table), in which the intervals in the series of numbers were so chosen that the difference between two consecutive logarithms oscillated between about 0.0008 and 0.0011. The space thus gained was utilised for tables of proportional parts (customarily headed "P. P."), which gave directly the increments corresponding to $\Delta n = 1, 2, 3, \dots$ and those corresponding to $\Delta \log = 1, 2, 3, \dots$ units.

I never came to finally correct this MS. table because shortly after its compilation I hit upon what I thought was a better idea. For the execution of calculations for which four-place logarithms do not afford a sufficient degree of exactitude, I had procured a copy of the (now defunct) "Tafel der flinfstelligen Logarithmen und Anti-logarithmen von Stegmann" (Marburg), and to make it more convenient in use I provided it with a lateral index (like that of a "where-is-it" book) which enabled one to put his finger on and turn up the couple of pages which contained the logarithm or anti-logarithm sought for. I subsequently came to substitute Wittstein's (beautifully printed) five-place table for Stegmann's, and did not miss the anti-logarithms much. In the case of the latter of course each individual index bore the (first three) figures of the initial logarithm as well as the initial numerals of the respective couple of pages.

By means of such an indexed five-place table four-place

logarithms are furnished promptly, and, in general, without interpolation; and an un-interpolated four-place logarithm is uncertain by only what corresponds to 1-8600, &c., of the number, while the uncertainty in an interpolated logarithm from a four-place table is double this quantity, even if the correction be calculated in the orthodox fashion.

In a collection of "Tables to facilitate chemical calculations," which I compiled some time ago for myself and my students, and which is now passing through the Press, I have come back to my original idea, but carried it out in a slightly modified form. The series of numbers is as follows:—1000, 1002 . . . 2004, 2006; 2010, 2015 . . . 4100, 4105; 4110, 4120 . . . 9990, 10000. The P. P. columns are placed, each opposite the interval in the table to which it belongs, and they give the values of Δ (num.) corresponding to Δ (log) = 1, 2, 3 . . . units respectively. For the interval num. = 3690 to 3790; for instance, the P. P.'s read as follows:—

$\Delta n =$	0.9	1.7	2.6	3.4	4.3	5.2	6.0	6.9	7.7	8.6
$\Delta \log =$	1	2	3	4	5	6	7	8	9	10

Now, the proposition $\Delta \log = k \Delta$ (num.), which we discount in interpolating, holds for negative increments as well as for positive ones; hence, in using the table there is no occasion ever to correct either a logarithm or a number for more than five units in the other variable. Interpolation thus is reduced to a very easy, in fact to an almost purely mechanical, operation.

A similar system might be adapted for the P. P. columns in five- or six-place tables; only in the case of the former it would be necessary to somehow make space for the lengthy P. P. columns. One mode would be to begin the table at numerus 2000 and carry it on to 20,000; such a table would just occupy the space of a table of logarithms and anti-logarithms for numeri 1000 to 10,000, and, apart from other advantages, in regard to the finding of the number for a given logarithm, be at more than a par with an anti-logarithm table of the ordinary range. Another method, less wasteful of space, would be to let the table cover the cycle num. = 1500 to 15,000; and from 1500 to 2000 or 2500, print on only every second or third line, so that page one, for instance, would go only from 150 to 162 (in its first column) instead of to 200. In this particular interval the difference between every two consecutive logarithms oscillates among 29, 28, and 27; and the P. P.'s for 29 would read as follows:—

$\Delta \log =$	1	2	3	...	27	28	29
Δ num. =	0.3	0.7	1.0		9.3	9.7	10

(For reasons which I have no space to explain, it would not do, in a five-place table arranged on the double-entry system, to let a P. P. column serve just for the interval opposite which it stands without either spreading out the table immoderately or introducing an appreciable uncertainty in addition to the unavoidable one.)

In looking up $\log(n + \Delta n)$ substitute for this given Δn the nearest Δn of the P. P. column, and add on (or subtract) the $\Delta \log$ standing opposite to (in this article above) it. To find num. ($\log = l + \Delta l$), simply add to numerus ($\log = l$) the Δn opposite the Δl given. The latter operation would positively be easier than the former.

I originally intended to append such a five-place table to my "Tables," but shrunk from the expense, and, besides, found another good reason for at least shelving the idea.

Though not in the ordinary analytical routine, there are cases where one needs a higher degree of precision than that attainable with even a five-place table. Six-place logarithms suffice, we may well say, in all cases that present themselves in the chemical or physical laboratory. My practice hitherto used to be to use that beautiful seven-place table of Edward Sang's,* and cut off the last

* "Seven-place Logarithms of all Numbers from 10,000 to 200,000," by Edward Sang. Williams and Norgate.

figure. Of the existence of six-place tables I was hardly aware until I came across a review of such a table by Bremiker in a German journal. To satisfy my curiosity I procured a copy and used it for a series of calculations. I was quite surprised by the facility with which the table worked (in opposition to using a seven-place as a six-place) whenever I had to interpolate. It is, in fact, not easy to interpolate for six places direct from a seven-place table, and not to make blunders; one usually comes to interpolate to the seventh figure, and only at the end to cut off the seventh figure from the corrected logarithm. The result, then, is uncertain by only what corresponds to 1-860,000th of the number, while an interpolated logarithm taken from a six-place table is infected with twice this uncertainty. But even 1-430,000 is a higher degree of precision than we ever need even in high-class specific gravity determinations.

Having once got accustomed to lateral indices, I provided my six-place Bremiker with a system of indices contrived so that, by means of what I will call the principal index, I can at once open the book at the place where the left-hand page commences with the numerus 1000, 2000, 3000 . . . 9000, while subsidiary indices enable me to find the couple of pages commencing with numerus 4100, 4200, 4300 . . . for instance, at a second stroke.

A Bremiker arranged in this manner is the perfection of a five- or six-place table. It is only a pity that, like all German books, it is printed on very thin paper, and with a kind of type which, though magnificent in its way, is far too small to be the thing for my eyes, at any rate.

A table like it, but printed on good hand-made paper, and typographically at a level with Sang's, would be a boon to the chemical, physical, and perhaps I may add, astronomical community.

Anderson's College, Glasgow,
August 7, 1884.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING JULY 31ST, 1884.

By WILLIAM CROOKES, F.R.S.

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford.

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To the Water Examiner, Metropolitan Water Act, 1871.

London, August 6th, 1884.

SIR,—We submit herewith the results of our analyses of the 189 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily from July 1st to July 31st inclusive. The purity of the water, in respect of organic matter, has been determined by the Oxygen and the Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter, and the quantities of free oxygen present in the whole of the samples submitted to analysis.

Of these 189 samples of water, the whole were, without exception, clear, bright, and well filtered.

Altogether, the quality of water supplied to the Metropolitan during the past month, as indicated by its state of

aëration and by its freedom from turbidity and excess of colour and organic matter, continued excellent. As commonly happens in July, the proportion of organic carbon found in the water, though still low, was a little in excess of that met with in June. Thus the mean quantity of organic carbon present in the Thames-derived water supply of the past month amounted to 0.123 part in 100,000 parts of the water, as against 0.114 part met with in the preceding month. This habitual slight rise in July is ordinarily followed by a more decided fall in August and September, to be succeeded, however, in its turn, by an appreciable rise in October and November.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES,
WILLIAM ODLING,
C. MEYMOTT TIDY.

A CONTRIBUTION TO THE STUDY OF THE ARTIFICIAL BLUE COLOURS, WITH REFERENCE TO WOOL-DYEING.

By W. ROSPENDOWSKI.

BEFORE proceeding to an enumeration of the products which we have to study it may be useful to call attention to a method of ascertaining whether a body is a homogeneous product or a mixture of several colouring matters. This very simple process consists in throwing a little of the powder into a glass of cold water. If the water in the glass is at rest we see coloured veins descend separately from each particle and fall to the bottom of the glass. If the specimen is a mixture of various dyes we obtain thus veins of different colours. It is of course evident that this method of examination cannot be applied to colours in solution or in a paste. By way of comparison there are given, firstly, the reactions of extract of indigo.

1. Extract of Indigo.

Sulphuric acid at 66° B. The colour does not change even if strongly heated with a large excess of acid. There is an escape of hydrochloric acid from the sodium chloride which is present here as well as in many aniline colours.

Caustic soda gives a light green precipitate, which if heated with a large excess passes to a yellowish brown and dissolves at a boil. If the yellow solution is acidified it turns to a blue lighter than the original colour.

Ammonia acts like soda, though the solution remains green and does not turn yellow.

Stannous chloride destroys the colour, whilst a grey turbidity remains.

With zinc powder the solution is decolourised on heating, becoming previously green. Ammonia or soda colours it yellow, which on exposure to the air passes gradually to orange and to a deep red, of the colour of iron sulphocyanide. This reddish brown solution, if shaken up with air in a test-tube, becomes first green and finally yellow. If the reduced solution has been mixed with ammonia and not with soda the final colouration is green. Both the yellow and the green solutions, if acidified, return to the original blue.

This change of colours is very characteristic of extract of indigo.

2. Nicholson Blue B B B.

(Of A. Poirrier and G. Dalsace, of St. Denis.)

Sulphuric acid at 66° B. The dry product gives with strong acid an orange-red solution. The dissolved product, with dilute acid, an abundant, very fine blue precipitate, quite insoluble even at a boil. An excess of strong acid dissolves this precipitate with a bronze-maroon colour, or in presence of a larger excess of acid, a brown

colour. This solution, if poured into a large excess of water, colours it the original blue shade.

Caustic soda: the solution does not change in the cold. On heating it becomes a red-brown. If acidified it resumes its original colour.

Ammonia: no change in the cold; a yellowish brown on heating; blue on acidifying.

Stannous chloride: the solution becomes turbid in the cold. On heating, a blue flocculent precipitate, very plentiful and completely insoluble. The liquid colourless.

Zinc-powder: the neutral or alkaline solution is not reduced even at a boil, but in this latter case it becomes yellowish brown, though without being reduced. An acid solution is decolourised on heating. This yellowish solution is not coloured on exposure to the air, but if heated with oxidising agents, such as potassium permanganate, it resumes its greenish blue colour.

Nicholson blue is a mono-sulpho-derivative of rosaniline blue (bleu de Lyon).

3. Soluble Blue B B.

(Lembach and Schleicher, of Biebrich on the Rhine.)

Sulphuric acid at 66° B. The aqueous solution gives with a little acid an abundant blue precipitate like that of the strong acid, from which it is distinguished by being slightly soluble in the acid liquid.

With an excess of the strong acid it behaves like Nicholson blue.

Caustic soda: the blue solution, with the very first drops and in the cold passes to a reddish brown, and on heating to a yellowish brown a little lighter. The blue colour returns on acidulating.

Ammonia: in the cold no change; on boiling it is decolourised, but the blue colour returns on acidulating.

Stannous chloride: a very delicate blue precipitate.

Zinc-powder: even the neutral solution is decolourised at a boil, but more easily if a few drops of sulphuric acid have been added. The colourless liquid when filtered does not change in the air, but if heated with permanganate in an acid solution the blue colour returns.

This blue is probably a bisulpho-derivative of rosaniline-blue. On wool it dyes directly, like indigo, taking care to acidify the beck gradually and to raise the temperature by slow degrees. Otherwise the colour becomes uneven.

4. Induline B B B.

(Williams, Thomas, and Dower, Brentford.)

With sulphuric acid at 66° B. the solution gives a heavy greenish blue precipitate in the form of a powder, and not flocculent, like Nicholson blue. This precipitate dissolves in an excess of the strong acid with a greenish blue colour.

Soda or ammonia: each of these reagents colours the solution of induline a reddish violet without any precipitate. At a boil the violet appears a little more pronounced.

Stannous chloride: a greenish blue precipitate, which is almost completely soluble at a boil with the same colour, and which reappears on cooling.

Zinc-powder: in a neutral solution induline is decolourised, but this liquid, slightly greenish, becomes quickly oxidised in the air, and resumes its blue colour. Zinc-powder mixed with sulphate of soda reduces it in the cold. The greenish yellow solution resulting is oxidised by the air with difficulty. In acid solutions the reduction is carried further. The liquid, when thus decolourised, does not resume its colour either in the air or on treatment with chromic acid, permanganate, &c. The molecule of the colouring matter is evidently broken up.

5. Blue S S.

(E. Patry and Co., Puteaux, Seine.)

Sulphuric acid: the solution is precipitated by the dilute acid as a very delicate blue powder; more distinct at a boil. With the strong acid there is formed at first a blue flocculent precipitate, which dissolves in an excess of the strong acid with a blue colour rather more greenish

than that of the aqueous solution. This colour does not perceptibly change even on boiling with a large excess of acid.

Soda or ammonia: this colour behaves exactly like induline; soda reddens the colour slightly more than ammonia.

Stannous chloride: a very delicate green precipitate, which on boiling becomes paler, but more decided.

Zinc-powder: the neutral solution is decolourised on heating, but resumes its colour in the air. Zinc-powder with sodium sulphate reduces it even in the cold to a greenish yellow liquid, which does not change in the air. Oxidising agents restore its original blue colour.

The primitive solution, decolourised by zinc-powder and sulphuric acid, even at a boil, resumes its colour with potassium permanganate and sulphuric acid.

Blue S S is very analogous to Couper's blue, or sulphonised triphenyl-rosotoluidine.

This is a very fast colour, possessing such an affinity for wool that it must be dyed in a neutral bath which is very gently acidified.

6. Marine Blue B B.

(E. Patry and Co., Puteaux.)

Sulphuric acid: the dilute acid gives a very fine blue precipitate. With the strong acid this colour behaves exactly like Nicholson blue.

Soda or ammonia: the colour of the solution passes even in the cold to a reddish brown violet, which does not change on boiling.

Stannous chloride: a very copious and plentiful precipitate, either cold or hot. Zinc-powder: the solution is decolourised on boiling. The liquid thus reduced is only reoxidised with difficulty in the air, but it returns to its original intensity on boiling with permanganate and sulphuric acid.

This colour is closely analogous to the "Soluble Blue B B."

7. Solid Blue.

(Meister, Lucius, and Brüning, of Höchst.)

Sulphuric acid: absolutely like "Blue S S."

Caustic soda: violet-brown colour, not changing at a boil.

Ammonia: exactly as with "Blue S S."

Stannous chloride: a delicate greenish grey precipitate.

Zinc-powder: the liquid becomes a light yellowish green on boiling, but oxidises immediately in the air. In acid solutions the reduction by means of zinc-powder is more complete. The liquid is brown, and if filtered and mixed with permanganate it only turns to violet-red at a boiling, changing to a blue in presence of an excess of sulphuric acid. An excess of permanganate destroys this blue.

The aqueous solution of Solid Blue is slightly more reddish than that of Blue S S. It is probably a more alkaline salt than the latter, with which it is otherwise identical.

Solid Blue is dyed upon wool in the same manner as Blue S S.

8. Solid Black Blue.

(Meister, Lucius, and Brüning, of Höchst.)

Sulphuric acid at 66° B.: throws down from the aqueous solution a deep blue powder, soluble in an excess of the strong acid, with a colour like that of indigo extract, and not changing at a boil.

Soda or ammonia: colour passes to a violet-red, not changing at a boil.

Stannous chloride: deep blue precipitate, becoming lighter on boiling.

Zinc-powder: complete decolourisation on boiling, but resuming its colour in the air. If reduced in an acid solution it presents exactly the same reactions as Solid Blue.

The properties of these two latter colours present no essential differences.

9. *Blue-Black B.*
(Baden Aniline Company).

Sulphuric acid at 66° B: at first a copious, flocky, deep blue precipitate, turning to green with an excess of acid. This intense green precipitate, if heated with a large excess of strong acid, gives a green solution, which changes to a bronze, and finally to a dirty yellow-brown. The colour is completely destroyed, being restored neither by excess of water nor by alkalis.

Caustic soda: the solution becomes more blue and does not change even at a boil with a large excess of soda. On cooling, there is a plentiful blue precipitate and a reddish liquid.

Ammonia: solution blue both cold and hot; no precipitate.

Stannous chloride: decolourised on heating; colour entirely destroyed.

Zinc-powder: like the foregoing. This colour seems to be an induline and contains a considerable quantity of dextrine or of leucome. Alcohol dissolves it with a reddish brown. The hot aqueous solution is of a reddish blue. When cold, there is formed a blue jelly, and the liquid becomes a light yellow-brown.

10. *Neutral Blue.*
(Cassella and Co., of Frankfurt).

Sulphuric acid: in aqueous solution violet red.

An excess of strong acid turns it blue, which blackens a little when heated, but recovers on cooling. The blue solution, when poured into water, resumes its original colour.

Caustic soda: thick, tarry deposit, more blue than the aqueous solution; insoluble even at a boil.

Ammonia: precipitate and liquid more blue than with soda. This precipitate dissolves at a boil in an excess of ammonia with a violet-red colour, much more blue than the aqueous solution of the neutral colour.

Stannous chloride: black precipitate liquid, almost colourless.

Zinc powder: decolourised at a boil and on exposure to the air or on boiling with permanganate and sulphuric acid takes merely a light bluish rose colour. If reduced with zinc-powder in an acid solution it becomes a yellow liquid, which turns to a red-brown in the air or on treatment with oxidisers.

11. *Vat Indigotine.*
(Williams, Brothers, and Ekin).

Sulphuric acid: solution turns very slightly green; if boiled with a very large excess of the strong acid turns a dirty green.

Soda or ammonia: turns a violet-red, becoming slightly blue if boiled with an excess of the reagent.

Stannous chloride: deep blue precipitate, becoming lighter on boiling and apparently partially dissolved.

Zinc-powder: decolourised on heating, but resuming its colour in the air. Zinc-powder with sulphuric acid reduces it immediately; the yellow solution thus obtained becomes brown in the air. After being filtered, mixed with sulphuric acid, and heated, the blue colour is regenerated.

This colour must be applied to the fibre in the reduced state like vat indigo. It is not capable of direct application, like extract of indigo.

12. *Indigotine for Wool.*
(Santerre, Bourgeois, and Co.)

Sulphuric acid at 66° B: green flocculent precipitate, very plentiful; dissolves in an excess of the reagent with a bluish green colour, which scarcely changes on heating.

Soda or ammonia: solution reddened, more with the former than the latter. No change on boiling.

Zinc-powder: solution reduced at a boil, turning greenish yellow, turning to a reddish blue in the air. With zinc-powder and sulphuric acid a yellow-brown on boiling, turning to a bronze-black in the air, and resuming

its intense blue on the addition of permanganate and sulphuric acid. An excess of permanganate destroys the colour.

13. *Topping Blue (Bleu Remontage).*
(Ch. Firmenich, of Geneva).

Sulphuric acid at 66° B: blue precipitate, soluble in excess, with a black colour. With a greater excess of strong acid the solution takes an orange-brown, which does not change on heating. If poured into water the blue colour returns.

Soda: brown colouration in the cold; considerable decolouration on boiling; blue colour restored on acidulation.

Ammonia: violet colouration; at a boil more complete decolouration than with soda; acid restores the original blue.

Stannous chloride: copious blue precipitate, soluble in excess, but re-appearing on boiling.

Zinc-powder: complete decolouration on boiling. The reduced solution is not changed in the air, but resumes its blue colour if heated with permanganate and sulphuric acid.

This compound should be a tri- or tetra-sulpho-derivative of rosaniline blue. It dyes wool directly in an acid bath.

14. *Gallocyanine and Solid Violet.*
(Durand and Huguenin, of Bâle).

Sulphuric acid at 66° B. The first drops give a red flocky precipitate, which dissolves afterwards with an amaranth red colour. With an excess of strong acid this colouration passes through a violet blue (the colour of an aqueous solution of gallocyanine) to a pure blue, very bright and intense.

On gradually diluting this blue solution with water, we have the same change of colours in the reverse direction.

Soda: on heating, the solution reddens a little, and loses its brightness.

Ammonia: reddens and loses more of its brightness.

Stannous chloride: in the cold a very copious blue, flocculent precipitate; liquid quite colourless; at a boil, with an excess of stannous chloride, the precipitate is decolourised and finally dissolved. The solution becomes blue again if heated with permanganate.

Zinc-powder: completely decolourised in the cold and more rapidly in heat, passing through a green. The colourless liquid readily becomes blue again on exposure to the air. If reduced by a mixture of zinc-powder and sulphuric acid the colour is only restored by oxidisers, and then but partially.

Chrome-alum: all the colour is precipitated in the form of maroon-brown flocks, the liquid becoming colourless. On heating, the precipitate turns to a violet-red.

It dissolves in ammonia with a fine blue, and in sulphuric acid with a rose-red.

Alum: a violet precipitate even in the cold, soluble in ammonia with a dull violet.

Gallocyanine dyes wool directly in an acid bath.

15. *Acid Myrtle.*
(L. Freund, St. Louis, Alsace).

16. *Liquid Green B.*
(P. Monnet and Co., La Plaine, Geneva).

17. *Solid Green, B, 2B, 3B.*
(P. Monnet and Co., La Plaine).

18. *Liquid Greens, No. 1, No. 2.*
(Verein Chem. Fabriken, of Mannheim).

All these colours are mixtures of malachite green and Paris violet.

Sulphuric acid: with very dilute acid a green colour; with strong acid, a yellowish brown, which blackens on heating and turns green on dilution with water. The yellowish brown solution, if poured into water, colours it blue.

Soda or ammonia: copious precipitate, at first a red-violet and then a chocolate colour; liquid colourless. When dried, the precipitate is a deep violet. On boiling, the precipitate disappears almost entirely, and the liquid resumes its blue colour when acidified.

Stannous chloride: green precipitate, soluble at a boil; solution green.

Zinc-powder: at a boil, complete decoloration and destruction of the colour.

After dyeing, the beck remains green, as the violet takes on the fibre better than the green.—*Moniteur Scientifique*.

A RECALCULATION OF THE ATOMIC WEIGHTS.*

By FRANK WIGGLESWORTH CLARKE, S.B.,
Chief Chemist to the U.S. Geological Survey, Washington.

APPENDIX.

ON DUMAS'S CORRECTION AND PROUT'S HYPOTHESIS.

In the year 1815 Prout put forth his famous hypothesis that the atomic weights of all the elements were multiples of that of hydrogen. His views were adopted by many chemists, but opposed by others; among them Berzelius and Turner; and down to the present day "Prout's Law" has been the subject of earnest controversy. Of course the fact was early recognised that in its original form the hypothesis could not stand, and accordingly it was modified by Dumas in such manner that half and quarter multiples of the atomic weight of hydrogen were considered as well as the whole numbers.

But of late years Prout's hypothesis, even with its elastic modification, has been in disfavour. Only a few chemists still clung to it as the representative of a veritable law. The researches of Stas were especially directed towards ascertaining its truth or falsity; and his results, as well as those obtained by Marignac, were such as to lead most chemists to the belief that it had been for ever overthrown. The atomic weights determined by Stas agreed neither with whole, half, nor quarter multiples of that of hydrogen, and the variations seemed to be wholly outside the range of recognisable experimental errors.

In 1878, however, a probable source of error in some of Stas's researches was pointed out by Dumas.† Many of Stas's ratios had involved the use of pure metallic silver, which had been fused under a cover of borax containing a little nitre. Such silver Dumas heated to redness in a Sprengel vacuum, and found that it gave up weighable quantities of oxygen, which had been absorbed by the metal when in the melted state. In one experiment a kilogram of silver gave 82 milligrams of occluded gas, and in three other cases 226, 140, and 249 milligrams respectively were found. In other words, the silver which had been considered pure by Stas and others was really not pure, and a correction became necessary in nearly all series of atomic weight determinations.

The amount of this correction, which I think may hereafter be appropriately designated as "Dumas's correction," will naturally vary in different cases, and in no particular case can we tell, without actual examination of the silver employed, exactly how great it should be. We may, however, assume that all the metallic silver heretofore used in establishing atomic weight ratios was subject to it; and, reckoning from the largest error indicated in the experiments of Dumas, namely, 249 milligrams of oxygen in the kilogramme of metal, we may ascertain its tendency with reference to Prout's law.

In the chapter upon the atomic weights of silver, chlo-

rine, bromine, iodine, potassium, sodium, and sulphur, twenty ratios are given, of which nine are subject to Dumas's correction. Applying it as suggested above, we get the following results. The values previously found and given in the chapter just quoted, we may designate as uncorrected. For convenience in future reference I assume that $O = 16$:—

	Uncorrected.	Corrected.	Difference.
Silver	107.923	107.896	-0.027
Chlorine	35.451	35.478	+0.027
Bromine	79.951	79.978	+0.027
Iodine	126.848	126.875	+0.027
Potassium	39.109	39.083	-0.026
Sodium	23.051	23.024	-0.027
Sulphur	32.058	32.058	—

The result of the correction, it will be seen, is generally favourable to Prout's hypothesis. Of the seven elements under consideration, one has its atomic weight unaffected, one is rendered less in accord with the hypothesis, and five approximate more closely than before to even multiples or multiples half of hydrogen.

In the later chapters of this work the effect of Dumas's correction is generally less striking. One general statement, however, may be made concerning it. Whenever the atomic weight of a metal is calculated from the ratio between its haloid salts and metallic silver, the total effect of Dumas's correction, including the above corrections for the halogens themselves, will be to lower the final result. This point will be further considered presently. Only chlorine, bromine, and iodine have their atomic weights raised by the correction.

In view of Dumas's correction the question naturally arises as to how far other metals, used in atomic weight researches, may occlude gaseous impurities. For example, when the atomic weight of oxygen is fixed by the synthesis of water over copper oxide, may not the copper occlude appreciable quantities of the hydrogen in which it cools? If it does, then the apparent weight of metallic copper would be too high, and the atomic weight of oxygen would come out too low. Such an error might possibly account for the difference between 16 and 15.9633 in the atomic weight of oxygen, and it would also increase the atomic weight of copper as determined by the same process. At all events, every metal of which the atomic weight has been determined by the reduction of its compounds in hydrogen ought to be scrupulously investigated with reference to the possible occlusion of gaseous impurities. With all of these metals the effect of such impurities would be to render the apparent atomic weights decidedly too high.

Although every series of atomic weight determinations must be considered by itself, and weighed on its own merits, it may not be out of place for me just here to point out two general sources of error in addition to the one we have been considering. First, every value after oxygen, with one or two partial exceptions, involves whatever error may attach to the atomic weight of oxygen. If the latter be 16, instead of 15.9633, this error in some instances becomes multiplied to a large fraction of a unit, as the subjoined example will show.

If $O = 16$, the atomic weight of uranium = 239.030
If $O = 15.9633$, " " = 238.482

Difference 0.548

Other similar errors are repeated continually. The value assigned to any element is necessarily affected by whatever errors may attach to the atomic weights of those other elements through whose medium it is compared with the standard, hydrogen. Thus, the atomic weight of carbon depends upon that of oxygen; calcium depends upon both carbon and oxygen; and fluorine, as determined from calcium fluoride, involves the foregoing elements, together with sulphur, silver, and chlorine. Since, however, some atomic weights are affected by plus errors and others by minus errors, there is a fortunate tendency to compen-

* Smithsonian Miscellaneous Collections. "The Constants of Nature."

† *Ann. Chim. Phys.* (5 s.), 14, 289.

ation of errors in cases like that of fluorine, and, in reality, better results are obtained than considerations such as these would lead us to look for.

Another general source of error is to be found in the fact that some of the weighings involved in our discussions had been reduced to absolute standards, while others were merely uncorrected weighings in air. The errors thus introduced into the work are doubtless small, but still they ought not to be absolutely ignored.

Now, having considered the larger classes of errors, we may properly pass on to a comparison of our atomic weights with reference to Prout's hypothesis. In order to facilitate work I have tabulated the figures in two columns, one giving atomic weights referred to hydrogen as unity, the other based upon the standard of oxygen as exactly sixteen. Such imperfectly known elements as decipium, philippium, samarium, terbium, and thulium are not included.

At the close of his admirable paper on the atomic weight of aluminum Mallet makes substantially the following argument in favour of Prout's hypothesis. Citing the atomic weights of eighteen elements which he considers well determined, he shows that ten of them have values falling within one-tenth of a unit of whole numbers. Now, what is the mathematical probability that this close approximation to conformity with Prout's law, in ten cases out of eighteen, is purely accidental, as those chemists who reject the hypothesis seem to hold? Working this problem out, Mallet finds the probability in favour of mere coincidence to be in the ratio of 1 : 1097·8, and hence he concludes that Prout's views are still worthy of respectful consideration.

Applying Mallet's reasoning to the table of atomic weights now before us, we find that in the first column, when $H=1$, twenty-five elements out of sixty-six have values falling within the limits of one-tenth of a unit variation from whole numbers. But many of the figures which fall without this limit involve the variation of oxygen multiplied many times over. We must therefore study the second column, which assumes that the atomic weight of oxygen is exactly sixteen. Here we have forty elements falling within the limit of variation assigned by Mallet, and twenty-six falling without. The variations we may properly study in some detail.

Taking first the elements whose atomic weights vary from even multiples of unity by less than a tenth of a unit, we have to consider the following:—Aluminum, arsenic, barium, bismuth, boron, bromine, cadmium, caesium, calcium, carbon, cobalt, columbium, didymium, fluorine, gallium, hydrogen, iridium, iron, lead, lithium, magnesium, manganese, nickel, nitrogen, osmium, oxygen, palladium, phosphorus, scandium, selenium, silver, sodium, sulphur, thorium, tin, titanium, tungsten, uranium, yttrium, and zinc. Of these, aluminum, arsenic, barium, bismuth, cadmium, calcium, carbon, cobalt, columbium, fluorine, hydrogen, iridium, iron, lithium, magnesium, manganese, nickel, nitrogen, phosphorus, scandium, sodium, sulphur, tungsten, uranium, yttrium, and zinc have plus variations, while boron, bromine, caesium, didymium, gallium, lead, osmium, palladium, selenium, silver, thorium, tin, and titanium, fall slightly under the units to which they approximate. Oxygen, as the standard of comparison, of course shows here no variation, its possible error having been transferred to hydrogen.

Of the foregoing elements it will be seen that twenty-six have plus variations from whole numbers, while thirteen are minus. Among the latter, boron, gallium, osmium, palladium, thorium, and titanium have been but roughly determined. Bromine, by Dumas's correction, has its variation diminished. In the cases of lead, caesium, selenium, and tin, the cause of variation, supposing one to exist, remains to be determined. The value for osmium is undoubtedly several units too high, so that its agreement with Prout's law may be considered purely accidental. As for didymium, the figure assigned is the mean of all determinations; whereas Cleve's data, calculated with SO_3

=80, make $Di=147\cdot021$, a variation which, like most of the others, is far within the limits of ordinary experimental error. In the case of silver it has already been shown that Dumas's correction is unfavourable to it considered in its bearings upon Prout's law. Silver is the only element among those having minus variations which could carry very much weight against the hypothesis.

Among the elements whose variations are plus, columbium, uranium, and yttrium have been poorly determined. Yttrium especially may be considered doubtful. The atomic weights of aluminum, arsenic, barium, cadmium, lithium, phosphorus, and sodium involve Dumas's correction to a greater or less extent, and will be lowered by its application, that is, brought nearer to whole numbers. For aluminum, certain other causes for variation were pointed out in the chapter upon that metal; and it may be noted that the direct ratio between it and hydrogen gives $Al=27\cdot998 \pm 0\cdot007$. Here the variation is less than the probable error. For calcium, and consequently for fluorine also, sources of plus error were indicated in the discussion of their respective atomic weights, and reiteration here is unnecessary. Cobalt, iridium, iron, nickel, and tungsten all involve such errors as may arise from the possible occlusion of hydrogen by the metals after reduction from their compounds. For scandium, the atomic weight, calculated with $SO_3=80$, becomes $44\cdot032$, a variation much within the limits of experimental error. For carbon and bismuth the variations are insignificant. In short, in the majority of instances the errors may be diminished by corrections which are in all probability needed, and which can be easily pointed out. The more carefully we scrutinise the data the more probable Prout's hypothesis appears.

Among the twenty-six elements whose atomic weights are removed by more than a tenth of a unit from whole numbers, chlorine, rubidium, and strontium have values nearly half multiples of that of hydrogen, and in each case Dumas's correction will make the approximation still closer. Erbium, gold, indium, lanthanum, rhodium, ruthenium, silicon, and zirconium, may be dismissed from consideration as too imperfectly determined to carry much weight in the present discussion. For chromium, copper, molybdenum, and vanadium I have no criticisms to offer; but the remaining elements may be considered individually.

The value assigned to antimony, $120\cdot231$, is the general mean of Cooke's and Schneider's work upon the bromide, iodide, and sulphide. If $Ag=108$, $Br=80$, and $I=127$, Cooke's data for the bromide and iodide give the following values for Sb, all of which fall within a tenth of a unit of the whole number 120:—

Early bromide series		Sb=219·901
Late		" 120·009
Iodide series		" 119·973

In the case of cerium, the value assigned in the table is the general mean of all reputable determinations. But it is subject to doubt on account of the facts observed by Wolf and by Wing, whose ceroso-ceric oxide was white, while that of all other observers was yellowish. Wolf's and Wing's data, calculated with $O=16$, give $Ce=138\cdot039$. Cerium, then, is not an established exception to Prout's law.

Glucinum and ytterbium have their atomic weights calculated from analyses of the sulphates. But if Prout's law is true, $SO_3=80$. Calculated with this figure, we have $Gl=9\cdot096$ and $Yb=173\cdot016$. Both elements thus fall within reasonable limits of variation from the hypothetical values.

Iodine is one of the most important seeming exceptions. If we assume $Ag=108$, and calculate the atomic weight of iodine only from the direct ratio between iodine and silver, we have with Dumas's correction applied, $I=126\cdot996$; that is, it comes within one-tenth of a unit of the whole number 127.

The atomic weight of mercury depends upon analyses

TABLE OF ATOMIC WEIGHTS.

	H = 1.	O = 16.	REMARKS.
Aluminum	27'009 ± 0'003	27'075	
Antimony	119'955 0'036	120'231	Cooke's and Schneider's data.
Arsenic	74'918 0'016	75'090	
Barium	136'763 0'031	137'007	
Bismuth	207'523 0'082	208'001	From Schneider's data.
Boron	10'941 0'023	10'966	
Bromine	79'768 0'019	79'951	
Cadmium	111'835 0'024	112'092	
Cæsium	132'583 0'024	132'918	
Calcium	39'990 0'010	40'082	
Carbon	11'9736 0'0028	12'0011	
Cerium	140'424 0'017	140'747	Buehrig's data give 141'523. (O = 16).
Chlorine	35'370 0'014	35'451	
Chromium	52'009 0'025	52'129	From Siewert's data.
Cobalt	58'887 0'008	59'023	
Columbium	93'812 0'011	94'027	From one ratio only.
Copper	63'173 0'031	63'318	
Didymium	144'573 0'031	144'906	Cleve's data give 147'021 (SO ₃ = 80).
Erbium	165'891 0'0065	166'273	From Cleve's data only.
Fluorine	18'984 0'0055	19'027	Imperfectly determined.
Gallium	68'854 0'0095	68'963	Nilson and Pettersson's data.
Glucinum	9'085 0'0000	9'106	
Gold	196'155 0'047	196'606	
Hydrogen	1'0000 0'022	1'0023	
Indium	113'398 0'033	113'659	
Iodine	126'557 0'012	126'848	
Iridium	192'651 0'012	193'094	Seubert's data.
Iron	55'913 0'030	56'042	
Lanthanum	138'526 0'021	138'844	
Lead	206'471 0'007	206'946	
Lithium	7'0073 0'005	7'0235	
Magnesium	23'959 0'012	24'014	Marchand and Scheerer's data.
Manganese	53'906 0'042	54'029	Schneider and Rawack's data.
Mercury	199'712 0'051	200'171	
Molybdenum	95'527 0'022	95'747	
Nickel	57'928 0'0035	58'062	Schneider, Sommaruga, and Lee.
Nitrogen	14'0210 0'0035	14'029	
Osmium	198'494 0'0035	198'951	Very doubtful.
Oxygen	15'9633 0'007	16'000	
Palladium	105'737 0'007	105'981	Badly determined.
Phosphorus	30'958 0'049	31'029	
Platinum	194'415 0'012	194'867	Seubert's data.
Potassium	39'019 0'018	39'109	
Rhodium	104'055 0'015	104'285	Badly determined.
Rubidium	85'251 0'011	85'529	
Ruthenium	104'217 0'066	104'457	Badly determined.
Scandium	43'980 0'0096	44'081	
Selenium	78'797 0'011	78'978	
Silicon	28'195 0'066	28'260	Very badly determined.
Silver	107'675 0'011	107'923	
Sodium	22'998 0'032	23'051	
Strontium	87'374 0'012	87'575	
Sulphur	31'984 0'166	32'058	
Tantalum	182'144 0'034	182'562	
Tellurium	127'960 0'0365	128'254	Imperfectly determined.
Thallium	203'715 0'073	204'183	Crookes's data.
Thorium	233'414 0'040	233'951	
Tin	117'698 0'064	117'968	
Titanium	49'846 0'032	49'961	Imperfectly determined.
Tungsten	183'610 0'082	184'032	
Uranium	238'482 0'024	239'030	
Vanadium	51'256 0'038	51'373	
Ytterbium	172'761 0'067	173'158	If SO ₃ = 80, Yb = 173'016.
Yttrium	89'816 0'019	90'023	Doubtful.
Zinc	64'9045 0'037	65'054	Axel Erdmann's data.
Zirconium	89'367 0'037	89'573	Doubtful.

of the chloride, oxide, and sulphide. Of these three compounds the purity of the chloride is most easily assured. Calculated from its composition, with Cl=35'5 Hg=199'971. With so high an atomic weight small errors are easily multiplied.

For the atomic weight of platinum Seubert's data give five values, ranging both above and below the round number 195. Calculated with integer values for the other elements, three of these figures fall very close to 195, as follows:—

From p. c. Pt in $(\text{NH}_4)_2\text{PtCl}_6$	Pt=194.906
" " K_2PtCl_6	" 194.933
From chlorine estimation in K_2PtCl_6	" 194.955

Potassium is the most serious exception of all. But if $O=16$ and Dumas's correction be applied, the general mean from all the available data becomes $K=39.083$. That is, potassium falls within the limit of 0.1 variation.

The atomic weight assigned to tantalum is the mean of four values. Two of these, re-calculated with integers, come out as follows:—

From p. c. K_2SO_4 in K_2TaF_7	Ta=181.912
" Ta_2O_5 from $(\text{NH}_4)_2\text{TaF}_7$	" 182.020

For tellurium I need only call attention to the discrepancies between the several sets of determinations made by Wills. A reference to the chapter on tellurium will show that his figures give results ranging from $\text{Te}=126.07$ to $\text{Te}=129.34$. The mean value is therefore too much subject to doubt to carry weight as an exception.

As for thallium, the last case to be considered, I have already shown that Crookes's data, re-calculated with integer values for N and O, give $\text{Tl}=204.008$. That is, instead of an exception, we have here an admirable instance in support of Prout's hypothesis.

Enough has been said in this brief resumé to show that none of the seeming exceptions to Prout's law are inexplicable. Some of them, indeed, carefully investigated, support it strongly. In short, admitting half multiples as legitimate, it is more probable that the few apparent exceptions are due to undetected constant errors, than that the great number of close agreements should be merely accidental. I began this recalculation of the atomic weights with a strong prejudice against Prout's hypothesis, but the facts as they came before me have forced me to give it a very respectful consideration. All chemists must at least admit that the strife over it is not yet ended, and that its opponents cannot thus far claim a perfect victory.

The following additional note has been communicated by the author:—

This chapter, which here stands as it was originally written, was first published in January, 1882. Since then, new determinations have appeared concerning the atomic weights of C, Rb, Mg, Zn, Mn, Cu, Ni, Cr, Al, Sb, Bi, Ti, Th, Di, La, Y, and Sm. Many of these indicate no serious changes in the values I had adopted; but, as will be seen by referring back to my footnotes, fundamental alterations must be made in the cases of Mn, Ti, Th, La, Di, Y, and Sm. These, however, do not affect in any general way the conclusions herein drawn relative to Prout's law; in fact, their tendency is rather to confirm it. Hence I have felt that it is hardly yet necessary to re-write or revise the chapter, but have preferred to leave it as it first appeared. The following figures may, however, be substituted for those given in the table:—

	H=1.	O=16.
Mn.. ..	54.855 $\pm$ 0.016	54.981
Ti	47.980 0.032	48.100
Th	232.020 0.032	232.554
La	138.019 0.025	138.336
Di	142.121	142.502
Y	88.900 0.027	89.104
Sm	149.801	150.145

F. W. C.

Theoretic Figure of Certain Simple Bodies forming a Series.—The author proposes to examine what may be the relations of forms between the atomic weights of the metals of the first series. He attempts to localise geometrically the proto-atoms (of hydrogen according to Prout) on the summits, or surfaces, or ridges of regular figures.—*Comptes Rendus*.

PASTEUR AND THE GERM THEORY.*

By FREDERICK J. FARADAY, F.R.S.

(Concluded from p. 74).

12. MODERN scientific ideas and discoveries do not so much displace old ideas as spring from them. There is usually a certain basis of experience for the old ideas, and experience is really a basis of fact which much be true. Hence it is natural that enquirers into the variability of germs and their pathogenic relations should turn to oxygen as being likely to play an important part in this connection. The influence of oxygen as a purifier of water attracted the attention of Dr. Angus Smith long before Pasteur's attenuation experiments. As he himself has explained, this was a natural consequence of the ideas of the older chemists as to the influence of oxygen as the active agent of decay. Again, the value of ventilation and fresh air in cases of consumption was insisted upon by medical men long before Koch's discovery of the *Bacillus tuberculosis*. From the beginning of his enquiries Pasteur has been strongly disposed to regard oxygen as an attenuating agent, or, in other words, as an agent for reducing the parasitic virulence of germs. For it may be suggested that the ability or habit of a ferment to tear highly complex organic compounds to pieces, so to speak, in order to procure the oxygen which, under other circumstances, it would obtain in the free state, is a kind of parasitic quality. Philosophically, the anaerobic which feeds upon dead organic matter may be considered as an intermediate between the innocent aerobic saprophyte and the deadly anaerobic parasite which feeds upon the living tissues or fluids. Therefore the question presents itself whether the presence of free oxygen, and the proportion in which it is present with other gases, may be regarded as having really an educational influence upon the innocent saprophyte. In an early report upon graveyards Mr. David Chadwick mentions a case of a man having been struck dead by a single puff of air from a long-closed vault in which the dead had been interred, whereas no such accidents happen in country churchyards. Again, Dr. Angus Smith has called our attention to the fact that the emanations from moving waters like the Clyde, open to the free air, though they may cause sickness, do not cause fevers; whereas the emanations from covered sewers, where the atmosphere will have a very different character to that over the Clyde, and from closed tombs and vaults, do cause fevers, and, as in the case mentioned above, even sudden death. But surely we cannot assume that the specific germs of typhoid, say, deliberately remain in the sewer and shun the river; or that specific agents of decay enter the vault beneath the city church and shun the country churchyard. We can scarcely draw a line beyond which no disease germ will venture to go. After all, therefore, the difference between the typhoid germ in the sewer and the germs in the river, the ferments in the country churchyard and those in the unventilated vault, is one of virulence; in other words, the river germ is an attenuated germ, and the reason why it produces nausea, let us say, only, and not fever, is because it is not strong enough to overcome the vital force of the person attacked. Undoubtedly there are various degrees of virulence. Apart even from Pasteur's wonderful "vaccine" experiments we know that there are mild and severe fevers, various degrees of diarrhoea, of which Asiatic cholera (according to Jules Guerin and Sir William Hunter) may be the most virulent form, and various degrees of small-pox. In the Board of Health Reports on the cholera epidemic of 1848-9 it is stated that distinct warning of its approach was given in every European city by the prevalence of intermittent fever, dysentery, and especially diarrhoea; and reports on subsequent epidemics have so fully confirmed this observation that it may be taken as an axiom that cholera is always preceded

* A paper read before the Manchester Literary and Philosophical Society, April 15, 1884.

by epidemic diarrhoea. To a certain extent we may therefore provisionally regard the nature of the gases in which microbes find themselves, in comparison with what I will call the standard of pure air, as determining the degree of parasitic virulence. In a paper read at the meeting of the British Association at Southampton I ventured to suggest that the development of the tubercle bacillus as a deadly parasite might be due, so to speak, to its imprisonment in lungs inefficiently aerated, either in consequence of hereditary structure inducing weak breathing habits, the habitual breathing of air containing less than the healthy proportion of oxygen, or the choking of the air passages through catarrh or the inhaling of dust. Miquel points out that the proportion of "young" microbes is exceptionally large in sewers, where old or exhausted microbes are rare.

13. But if we assume degrees of virulence from harmless to deadly in one and the same species, we imply a gradation from saprophyte to parasite, and from aerobic to anaerobic. For even if attenuation by means of free oxygen be regarded as the slow killing of the parasite, we can scarcely assume that free oxygen has been always fatal to the parent forms; for in that case how could we realise the possibility of [zymotic] diseases having ever begun, unless we trace them back to some time when poisonous vapours enfolded the earth? And, granted various stages of virulence from harmless to deadly in one and the same species, how are we to define the difference of species? We may define species pathologically by the different symptoms of the diseases with which they are associated, and to some extent possibly by the forms of the microbes. We may also classify microbes by the marked differences of their own constitutions. For the susceptibility of these organisms seems to differ in the most extraordinary fashion. What is meat for one appears to be poison for another. Thus, in his latest report on the cholera bacillus, Koch tells us that the smallest proportion of acid is fatal to the life of that organism, yet we know that other bacilli live and thrive in strongly acid solutions. Ideas bearing upon these later discoveries have long been current; witness Dr. Angus Smith's remark in 1848, that a man might be capable of one disease on one day and another disease on the following day. Perhaps the peculiar susceptibilities of the microbes may be developed and fixed as the peculiar virulence is developed and fixed. The desirableness of further experiments on the cultivation of organisms in various gases, and particularly on the cultivation of the spores, is strongly suggested by these considerations. It would also be worth while to test further the specific consequences of the presence or absence of light.

14. The presence or absence of oxygen is associated with the question of spore formation. In this connection the varying susceptibility or vigour of microbes, not only in different animals, but in different *milieux* in the same animal, must not be overlooked. Thus the virus of the *Maladie de Chabert*, or *Charbon symptomatique*, formerly supposed to be the same disease as anthrax, acts as a vaccine if injected directly into the blood, while in solid tissues the same culture produces fatal results, according to the experiments of MM. Arloing, Cornevin, and Thomas. The law which M. Paul Bert has deduced from such observations is, that any condition which arrests the development of a virus converts it into a vaccine, and this implies the principle that specific microbes thrive better, or attain their maximum virulence, in certain tissues or juices, and are attenuated in others. Most remarkable series of observations have been made with respect to the varying effects from harmlessness to fatality of special microbes in different animals. These have led Pasteur and his assistants, MM. Chamberland and Roux, to the idea that differences of temperature affect the vigour of the microbes, and thermal conditions have been employed as a means of attenuation in the production of protective cultures. Thus the usual immunity of birds against anthrax inoculations is attributed by Pasteur to the high

temperature of their blood, and he claims to have developed anthrax in the fowl by keeping its body in cold water. We must not, however, overlook, nor does Pasteur overlook, the possibility of the variation in the susceptibility, or vigour, being not on the side of the microbe, but on the side of the animal. Thus Koch claims to have developed anthrax in birds in spite of their high temperature, and he suggests that the fowl in Pasteur's experiment fell a victim, not because of any change in the microbe, but because the fowl's own vitality was lowered, weak animals succumbing to ailments which in health they would successfully throw off. These views distinctly admit the idea of a definite struggle for existence between the microbe and the cells of the living animal. Pasteur's views as to the influence of a few degrees more or less of heat on the specific vitality of the microbe are, however, supported by the experiments of Willems, and later of Arloing, Cornevin, and Thomas, on the development of inoculations in different parts of the body. Thus inoculations in the tails of cattle proved ineffective, but when the temperature was artificially increased the specific disease developed. These ideas have a bearing upon the greater or less success of vaccinations according to the time of year when they are practised and the surrounding conditions of temperature; and also upon the appearance of epidemics at particular seasons and in particular years. Finally, with respect to the special relations between the specific microbe and different tissues, it may be mentioned that the special nidus of the virus of rabies appears to be the nerve-centres.

15. In regard to all these phenomena, the question of spore formation cannot fail to attract attention, and the relation between spore formation and the presence of oxygen might prove a fruitful subject of inquiry. Klein's most ingenious experiments on the cultivation of *Bacillus anthracis* in gelatine pork tend to show that spores are not formed except in the presence of free oxygen, and in opposition to Pasteur he maintains that anthrax spores are never formed in the bodies of animals. On the other hand, Miquel's observations on bacilli in general appear to agree to some extent with Pasteur's opinions. He says: "We may experimentally induce the formation of bacillus spores by depriving the bacilli of oxygen, or in determining the slow death of the adult forms by antiseptics, but evidently not by killing them rapidly, as then all vital phenomena cease and spores cannot be formed. The best way in which to obtain bacillus spores rapidly appears to me to be by enclosing nutritive infusions charged with filamentous bacilli in sealed tubes containing very little air." There is much obscurity and contradiction on this point, which may be due to all the conditions not having been duly considered, and it seems to offer a most promising field for investigation. Meanwhile the question arises whether the so-called spores are really the terrible things we are inclined to suppose them. There are some noteworthy phenomena connected with spore formation. Pasteur maintains that anthrax has been spread amongst cattle and sheep by the bringing up of spores from buried carcasses by earthworms, which is opposed to the opinions of Koch and Klein that no spores are ever formed in the bodies of animals. Again, Klein has found that cultures of *Bacillus anthracis*, which are fatal to rabbits and guinea-pigs, whether forming spores or not, are only fatal to mice when they are spore-forming cultures. In considering all these various results we must bear in mind that there are several modes in which the life of the higher organism may be destroyed. The phenomenon may be simply a struggle for existence between the microbes and the vital cells of the animal body, in which the strongest survives, death resulting from the destruction of the function of the parts invaded, the loss of nutriment, or their absolute change into another form of life, morbid growths or microbe life resulting from the dissolution of the tie which holds the cells together as a community; or the products of the fermentive action of the microbes may

be poisonous, or may be poisonous in the particular channels in which they are produced; or finally, as Dr. Cameron has suggested, the fatal result may be due merely to the mechanical obstruction offered by millions of microbes blocking up the capillary circulation. Vastly extended threads of mycelium growth would, of course, have such a mechanical effect. Now, from the vitality of spores, the fact that they resist destruction up to 110° C. of heat, and that they seem to retain their specific life for indefinite periods, it is possible that we may be too much disposed to malign them. Of the two modes of reproduction, the multiplication by scissiparity and the multiplication by spores, may not the former be, at least in some cases, the true disease form? Spores, if cultivated in suitable infusions, will apparently reproduce the *Bacillus anthracis* of the parent cultures, and inoculations with such cultures will kill with typical anthrax. But have we sure evidence that inoculation with pure spores would be fatal? Klein's mice experiments already referred to seem to show this. It is conceivable, however, that spores may require a suitable dead medium for their development, and that only the living organism, when developed, is able to contend as a parasite with the living cells of the animal body. It is at least a remarkable fact that experiment and observation are more and more tending to associate the communication of disease with liquids and moisture in which the bacilli are developed, rather than with atmospheric influences. Koch finds that desiccation is speedily fatal to the cholera germ, and we know that the communication of the disease is apparently associated peculiarly with the washing of infected linen. The statement of Miquel that he has entirely failed to develop disease in rabbits or guinea-pigs by means of germs collected from the atmosphere may have a bearing on this question. Of course, as Miquel observes, failure with rabbits and guinea-pigs would not necessarily imply failure with human beings, on whom experiments have not been tried. This does not affect the question of septic germs in hospitals. There may well be spores which, though unable to develop in living and healthy tissues or fluids, may find the suitable preliminary medium of culture in morbid secretions or dying tissues, as in wounds or in accumulations in the lungs or intestines when the bodily functions are disordered. Thus the spores of the cholera bacillus may pass safely with undissolved food through the acids of the stomach which would destroy the bacillus, and subsequently develop in the intestines. The general principle would be that a body in a bad state of health affords the preliminary conditions of nourishment necessary for the development of the vigorous parasite.

16. The consideration of the question of spores, of nuclei, and of the granulations into which non-spore producing bacillus threads crumble, leads to the inquiry, whence come all the varied forms of microbe life? There is scarcely any, if there is any fluid, in which these minute forms are not present. Dr. Angus Smith tells us that even in very pure spring water he finds them doing chemical work. They are present in the saliva, apparently elaborating a specific alkaloid; they are traceable in every organic fluid which has not been sterilised by heat. Under the microscope they "come like shadows, so depart." Leeuwenhoek wondered that his mouth should contain more living beings than there were people in the States of Holland, and modern microscopic investigation is certainly giving a kind of basis to the fancies of Rabelais and Swift. Are our failures to convert different species of microbes, to establish physiological polymorphism, due to the circumstance that we do not begin with the original forms? The essence of Darwinism is not that the cat has been developed from the lion, or the tiger from either, but that all have proceeded from some more primitive form. Possibly *Bacillus anthracis* is not a "sport" from *Bacillus subtilis*, but both are parallel developments from some more simple organism. There is a certain fascination in the ideas of Béchamp. According to Béchamp it is from the granulations, from certain apparently amorphous

structures observable in organic liquids under the microscope, that all the forms of organised life are evolved, according to the conditions of culture. Béchamp believes in the continued existence of such microzymes in chalk and other geological formations of the life of past geological epochs. The rocks themselves include the germs of life. This seems to be a reproduction of the idea of Buffon respecting the existence of organic molecules, as Pasteur has pointed out; and Béchamp in fact admits that it is. As already remarked, Pasteur does not absolutely refuse to admit the possibility of such an hypothesis; all that he says is that the experiments which are said to have proved its truth are unsatisfactory, and that it is so far absolutely without proof, no such evolution as that implied having been artificially accomplished. The idea in Béchamp's mind is, however, essentially different from the idea of spontaneous generation; Béchamp's granulations are latent germs to begin with, which may, according to their special surroundings, be differentiated into all the forms of life. In the egg they are subservient to the special life-history of the animal and are differentiated with organs resembling those of the parent structure. But freed from that mysterious vital bond which holds the community of cells together, each microzyme falls away into an independent existence and may become a bacterium, or bacillus, or vibron. Thus, the apparently dead body is not dead, it is simply the bond of union and co-operation which is broken, and the structure is resolved into its still living molecules. Nothing, says Béchamp, is the prey of death; all is the prey of life. Such an hypothesis would of course explain the appearance of microbes in organic fluids without the intervention of germs from the atmosphere being invoked. To the experiments of Pasteur showing the non-development of life in solutions previously heated, if atmospheric germs are rigorously excluded, Béchamp replies that the heat which has sterilised the fluids has destroyed the microzymes. Pasteur in reply has carefully introduced blood direct from the living animal into purified tubes from which all atmospheric germs were excluded, and still without developing fermentation or life in such fluids. This almost seems like a conclusive experiment, but Béchamp is not convinced, and may indeed reply that a negative result proves nothing in this case, as the conditions may not have been suitable for the development of the special microzymes present in the blood. On the other hand, there are analogies which are worth noting, and which suggest that there may be truth on both sides. Béchamp cites the fermentation of ostrich eggs, whose thick, ivory-like, and unbroken shells excluded, he contends, all atmospheric life. In these cases, however, his microzymes do not appear to have become microbes. To Pasteur's discovery of the corpuscles of *pebrine* in the eggs of the silkworm, he replies that eggs contain many microzymes, and that the peculiar disease corpuscles are simply microzymes which have inherited the bad tendency developed in the microzymes of the parent moth and chrysalis. Without forming any decisive opinion on this mysterious and profound question (for what can appear more astonishing than the continued life of a parasite, not merely in the body of the parent worms, but actually in the eggs laid by the moths?) attention may be drawn to the analogy between the remarkable variety in the susceptibilities of microbes and the apparently specialised chemical work of different ferments, and the specialised chemical elaborations of the cells of different organs of the animal body. Are not many diseases of the human system, for instance, apparently due to the excessive activity of specialised secreting cells, or to the development of similar power of chemical elaboration by other cells; to an apparent change of function, as though secreting cells of a given order were working in the wrong places? And are not such phenomena analogous to the introduction into the blood or tissues of disease microbes endowed with special chemical activities of their own?

17. In the course of this paper, mention has been made of the education of microbes. The idea has a bearing

upon Pasteur's astonishing protective vaccination discoveries, and seems to have a relation to the mysterious phenomenon of heredity. The microbes of particular diseases, when passed from animal to animal, increase in virulence; thus, as Pasteur has shown, the microbe, which was originally powerless to kill a guinea-pig a week old, but which killed a guinea-pig a day old, has been nursed into a breed capable of killing a sheep. Yet there is apparently no specific change in the successive generations of bacilli; we must assume that the chemical constitution of their bodies remains unchanged, that they are essentially identical in structure; the only change is in the vigour of their life, developed hereditarily. What is vigour, what is life, what is heredity? When we turn now to the animals in whom the zymotic diseases do not recur, and to the phenomena of protective vaccination, may we not assume that some educational influence of the same kind is exerted upon the living cells of the animal body?

The microbe which kills the unvaccinated animal is the same, in all respects, as the microbe which fails to kill the vaccinated animal; the difference is in the cells of the animal attacked. When it is suggested, as in the case of small-pox for instance, that the vaccination has used up some material, only rarely elaborated, in the body, and necessary for the development of the microbe, are we not guilty of as crude an attempt to represent the fact, as was the old notion of a material caloric? May we not with more philosophy regard the phenomenon as some mysterious educational influence, in the one case, as well as in the other. Regarding the contest between the microbe and the living cells of the body as a struggle for existence, may we not assume that resisting vigour is developed in the one, as attacking vigour is developed in the other? Miquel records a most remarkable instance which he says "seemed to show that bacteria are endowed with instinctive movements." A bacillus making a circular movement was arrested by a mass of germs. It vigorously attacked the mass, and by rapid backward and forward pushes, attacking now right, and now left, cleared a *cul-de-sac*, which it finally developed into a complete canal; then it appeared to rest from its efforts. Miquel was utterly astonished by the "address" with which the bacillus thus disengaged itself from the vicious circle in which it found itself engaged. Is there anything more wonderful in this than in the apparently instinctive movements observed by Darwin in the tips of the radicles of plants, the apparently muscular memory to which Romanes calls attention as the real import of the phrase that "practice makes perfect"? Smokers, for instance, know that they have overcome the nausea of the first mild cigar, and educated the cells of which they consist into the enjoyment even of strong Havanas. It would seem as though in nature no experience fails to leave its impress and its influence. When we consider how minute is the germ, even of the most intelligent vertebrate, which reproduces not only the specific form and structure of the parent, but its instincts and—excepting perhaps man—the influence of the experience of its ancestors, it cannot seem too wonderful to suppose that the protective influence of vaccines may be due to the operation of the same mysterious principle, and that the discoverer of the physical cause of protective vaccination will discover the nature of memory and heredity. Such a problem may well be insoluble, and the scientific man, like the Athenians of old, may have to content himself simply with the recognition of the existence of the unknown; but there is no more reason for discrediting the facts of protective vaccination because they are beyond explanation, than there would be for discrediting the facts of memory, heredity, or life itself. Reasoning from analogy, there is an inherent probability in protective vaccination. Reduced to its ultimate expression, animated nature would appear to consist of Buffon's organic molecules *plus* the principle of organic memory, as inorganic nature is inert matter *plus* the principle of motion.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 4, July 28, 1884.

Researches on Flour: Distribution of Acidity and Sugar in the Various Products of Grinding.—M. Balland.—Acidity is unequally distributed, being less plentiful in the flour than in the other products. The normal acidity of flour estimated as sulphuric acid appears to range from 15 to 40 grms. per metric quintal. In recent flour sugar exists from 0.80 to 2.20 grms. per cent.

Temperature and Critical Pressure of Liquid Air. Relation between the Temperature of the Liquid Air and Atmospheric Pressure.—K. Olzewski.—The author uses air as a refrigeratory agent. He has obtained 6 c.c. in a liquid state and submitted it to evaporation at the pressure of 1 atmosphere or even in a vacuum. In the latter case he has obtained a temperature of -205° . That of nitrogen evaporating in a vacuum he supposes to be -213° .

New Method for the Direct Measurement of Absolute Magnetic Intensities.—A. Leduc.—The author applies for this purpose the mercurial galvanometer recently discovered by M. Lippman.

Combustion of Detonating Gases in Different States of Dilution.—A. Witz.—The author concludes that the action of the sides of the containing vessel or tube is the great regulator of explosive phenomena. The dilution of an explosive mixture produces a somewhat similar effect.

Determination of Nitric Acid by Precipitation as Cinchonamine Nitrate. Application of this Process to the Determination of Nitrates in Natural Waters and in Plants.—M. Arnaud.—This paper will be inserted in full.

On the Tri-acetic Ether of a Butylic Glycerin.—L. Prunier.—The existence of this tri-acetine contributes to fix the tri-atomic function of the butylic homologue of ordinary glycerin.

Method for Determining the Dry Extract of Wines.—E. H. Amagat.—For the determination of the dry residue the author proposes to substitute that of the specific gravity after the alcohol has been expelled by boiling and the sample has been restored to its original volume by the addition of water. For a wine containing 35 grms. of extract per litre taken in a vacuum the specific gravity of the de-alcoholised liquid is 1.0140; for one yielding 10 grms. it is 1.0040.

Moniteur Scientifique, Quasneville.

Review of Chemical Researches Published Abroad.—M. G. de Bechi.—Abstracts from the *Berichte der Deut. Chem. Gesell.*

Quantitative Determination of Morphia in Opium.—Dr. von Perger.—From the *Journal f. Prakt. Chemie.*

Tar and Ammonia.—An account of the attempts for utilising the by-products of the coke manufacture. The processes of Jameson, Simon-Carvès, Mellor, Davis, &c., are noticed, as also the criticisms of Weldon, Scheurer-Kestner, Forster, and Jameson.

Certain Recent Improvements in the Manufacture of Sugar.—E. G. von Lippmann.—The author particularly notices the method of Siegert, double or triple defecation alternating with filtration, which generally renders treatment with animal charcoal unnecessary.

Chemical Patents.—Abstracts of the specifications of a number of German patents relating to chemical manufactures.

Bulletin de la Société Chimique de Paris.
No. 12, June 20, 1884.

Crystalline Ammoniacal Silver Chloride and Ammoniacal Silver Iodide.—M. Terreil.—These compounds have hitherto been known only in the amorphous state. The author obtains them in crystals by introducing the amorphous compounds along with a saturated solution of ammonia into a flask sealed at the lamp and exposes the whole to the temperature of boiling water.

Constitution of Chloride of Lime.—E. Dreyfus.—The author, after reviewing the various hypotheses of Balard, Crace-Calvert, Fresenius, Lunge and Schäppi, Kolbe, Davis, and others, objects that not one of them gives a satisfactory explanation of the presence of an excess of hydrate of lime always observed in this compound. Stahlschmidt is the first who attained this object by representing the active principle of chloride of lime as hydrate of lime in which the hydrogen of one hydroxyl is replaced by chlorine. The author, with him, considers CaHClO_2 as the active principle of chloride of lime.

VOL. L. No. 1292.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

MONTREAL MEETING, AUGUST 27, 1884.

INAUGURAL ADDRESS OF THE PRESIDENT,
THE RIGHT HON. LORD RAYLEIGH, M.A., D.C.L., F.R.S.,
F.R.A.S., F.R.G.S., Professor of Experimental
Physics in the University of Cambridge.

LADIES AND GENTLEMEN,—It is no ordinary meeting of the British Association which I have now the honour of addressing. For more than fifty years the Association has held its Autumn gathering in various towns of the United Kingdom, and within those limits there is, I suppose, no place of importance which we have not visited. And now, not satisfied with past successes, we are seeking new worlds to conquer. When it was first proposed to visit Canada, there were some who viewed the project with hesitation. For my own part, I never quite understood the grounds of their apprehension. Perhaps they feared the thin edge of the wedge. When once the principle was admitted, there was no knowing to what it might lead. So rapid is the development of the British Empire, that the time might come when a visit to such out-of-the-way places as London or Manchester could no longer be claimed as a right, but only asked for as a concession to the susceptibilities of the English. But seriously, whatever objections may have at first been felt soon were outweighed by the consideration of the magnificent opportunities which your hospitality affords of extending the sphere of our influence and of becoming acquainted with a part of the Queen's dominion which, associated with splendid memories of the past, is advancing daily by leaps and bounds to a position of importance such as not long ago was scarcely dreamed of. For myself, I am not a stranger to your shores. I remember well the impression made upon me, seventeen years ago, by the wild rapids of the St. Lawrence, and the gloomy grandeur of the Saguenay. If anything impressed me more, it was the kindness with which I was received by yourselves, and which I doubt not will be again extended not merely to myself but to all the English members of the Association. I am confident that those who have made up their minds to cross the ocean will not repent their decision, and that apart altogether from scientific interests, great advantage may be expected from this visit. We Englishmen ought to know more than we do of matters relating to the Colonies, and anything which tends to bring the various parts of the Empire into closer contact can hardly be overvalued. It is pleasant to think that this Association is the means of furthering an object which should be dear to the hearts of all of us; and I venture to say that a large proportion of the visitors to this country will be astonished by what they see, and will carry home an impression which time will not readily efface.

To be connected with this meeting is, to me, a great honour, but also a great responsibility. In one respect, especially, I feel that the Association might have done well to choose another President. My own tastes have led me to study mathematics and physics rather than geology and biology, to which naturally more attention turns in a new country, presenting as it does a fresh field for investigation. A chronicle of achievements in these

departments by workers from among yourselves would have been suitable to the occasion, but could not come from me. If you would have preferred a different subject for this address, I hope, at least, that you will not hold me entirely responsible.

At annual gatherings like ours the pleasure with which friends meet friends again is sadly marred by the absence of those who can never more take their part in our proceedings. Last year my predecessor in this office had to lament the untimely loss of Spottiswoode and Henry Smith, dear friends of many of us, and prominent members of our Association. And now, again, a well-known form is missing. For many years Sir W. Siemens has been a regular attendant at our meetings, and to few indeed have they been more indebted for success. Whatever the occasion, in his Presidential Address of two years ago, or in communications to the Physical and Mechanical Sections, he had always new and interesting ideas, put forward in language which a child could understand, so great a master was he of the art of lucid statement in his adopted tongue. Practice with Science was his motto. Deeply engaged in history, and conversant, all his life, with engineering operations, his opinion was never that of a mere theorist. On the other hand, he abhorred rule of thumb, striving always to master the scientific principles which underlie rational design and invention.

It is not necessary that I should review in detail the work of Siemens. The part which he took, during recent years, in the development of the dynamo machine must be known to many of you. We owe to him the practical adoption of the method, first suggested by Wheatstone, of throwing into a shunt the coils of the field magnets, by which a greatly improved steadiness of action is obtained. The same characteristics are observable throughout—a definite object in view and a well-directed perseverance in overcoming the difficulties by which the path is usually obstructed.

These are, indeed, the conditions of successful invention. The world knows little of such things, and regards the new machine or the new method as the immediate outcome of a happy idea. Probably, if the truth were known, we should see that, in nine cases out of ten, success depends as much upon good judgment and perseverance as upon fertility of imagination. The labours of our great inventors are not unappreciated, but I doubt whether we adequately realise the enormous obligations under which we lie. It is no exaggeration to say that the life of such a man as Siemens is spent in the public service; the advantages which he reaps for himself being as nothing in comparison with those which he confers upon the community at large.

As an example of this it will be sufficient to mention one of the most valuable achievements of his active life—his introduction, in conjunction with his brother, of the Regenerative Gas Furnace, by which an immense economy of fuel (estimated at millions of tons annually) has been effected in the manufacture of steel and glass. The nature of this economy is easily explained. Whatever may be the work to be done by the burning of fuel, a certain temperature is necessary. For example, no amount of heat in the form of boiling water would be of any avail for the fusion of steel. When the products of combustion are cooled down to the point in question, the heat which they still contain is useless as regards the purpose in view. The importance of this consideration depends entirely upon the working temperature. If the object be the evaporation of water or the warming of a house, almost all the heat may be extracted from the fuel without special arrangements. But it is otherwise when the temperature required is not much below that of combustion itself, for then the escaping gases carry away with them the larger part of the whole heat developed. It was to meet this difficulty that the regenerative furnace was devised. The products of combustion, before dismissal into the chimney, are caused to pass through piles of loosely stacked fire-

brick, to which they give up their heat. After a time the fire-brick, upon which the gases first impinge, becomes nearly as hot as the furnace itself. By suitable valves the burnt gases are then diverted through another stack of brickwork, which they heat up in like manner, while the heat stored up in the first stack is utilised to warm the unburnt gas and air on their way to the furnace. In this way almost all the heat developed at a high temperature during the combustion is made available for the work in hand.

As it is now several years since your presidential chair has been occupied by a professed physicist, it may naturally be expected that I should attempt some record of recent progress in that branch of science, if indeed such a term be applicable. For it is one of the difficulties of the task that subjects as distinct as Mechanics, Electricity, Heat, Optics, and Acoustics, to say nothing of Astronomy and Meteorology, are included under Physics. Any one of these may well occupy the life-long attention of a man of science, and to be thoroughly conversant with all of them is more than can be expected of any one individual, and is probably incompatible with the devotion of much time and energy to the actual advancement of knowledge. Not that I would complain of the association sanctioned by common parlance. A sound knowledge of at least the principles of general physics is necessary to the cultivation of any department. The predominance of the sense of sight as the medium of communication with the outer world, brings with it dependence upon the science of optics; and there is hardly a branch of science in which the effects of *temperature* have not (often without much success) to be reckoned with. Besides, the neglected borderland between two branches of knowledge is often that which best repays cultivation, or, to use a metaphor of Maxwell's, the greatest benefits may be derived from a cross fertilisation of the sciences. The wealth of material is an evil only from the point of view of one of whom too much may be expected. Another difficulty incident to the task, which must be faced but cannot be overcome, is that of estimating rightly the value, and even the correctness, of recent work. It is not always that which seems at first the most important that proves in the end to be so. The history of science teems with examples of discoveries which attracted little notice at the time, but afterwards have taken root downwards and borne much fruit upwards.

One of the most striking advances of recent years is in the production and application of electricity upon a large scale—a subject to which I have already had occasion to allude in connection with the work of Sir W. Siemens. The dynamo machine is indeed founded upon discoveries of Faraday now more than half a century old; but it has required the protracted labours of many inventors to bring it to its present high degree of efficiency. Looking back at the matter, it seems strange that progress should have been so slow. I do not refer to details of design, the elaboration of which must always, I suppose, require the experience of actual work to indicate what parts are structurally weaker than they should be, or are exposed to undue wear and tear. But with regard to the main features of the problem, it would almost seem as if the difficulty lay in want of faith. Long ago it was recognised that electricity derived from chemical action is (on a large scale) too expensive a source of mechanical power, notwithstanding the fact that (as proved by Joule in 1846) the conversion of electrical into mechanical work can be effected with great economy. From this it is an evident consequence that electricity may advantageously be obtained from mechanical power: and one cannot help thinking that if the fact had been borne steadily in mind, the development of the dynamo might have been much more rapid. But discoveries and inventions are apt to appear obvious when regarded from the standpoint of accomplished fact; and I draw attention to the matter only to point the moral that we do well to push the attack persistently when we can be sure beforehand that the

obstacles to be overcome are only difficulties of contrivance, and that we are not vainly fighting unawares against a law of nature.

The present development of electricity on a large scale depends, however, almost as much upon the incandescent lamp as upon the dynamo. The success of these lamps demands a very perfect vacuum—not more than about one-millionth of the normal quantity of air should remain—and it is interesting to recall that, twenty years ago, such vacua were rare even in the laboratory of the physicist. It is pretty safe to say that these wonderful results would never have been accomplished had practical applications alone been in view. The way was prepared by an army of scientific men whose main object was the advancement of knowledge, and who could scarcely have imagined that the processes which they elaborated would soon be in use on a commercial scale and entrusted to the hands of ordinary workmen.

When I speak in hopeful language of practical electricity, I do not forget the disappointment within the last year or two of many over-sanguine expectations. The enthusiasm of the inventor and promoter are necessary to progress, and it seems to be almost a law of nature that it should overpass the bounds marked out by reason and experience. What is most to be regretted is the advantage taken by speculators of the often uninstructed interest felt by the public in novel schemes by which its imagination is fired. But looking forward to the future of electric lighting, we have good ground for encouragement. Already the lighting of large passenger ships is an assured success, and one which will be highly appreciated by those travellers who have experienced the tedium of long winter evenings unrelieved by adequate illumination. Here, no doubt, the conditions are in many respects especially favourable. As regards space, life on board ship is highly concentrated; while unity of management and the presence on the spot of skilled engineers obviate some of the difficulties that are met with under other circumstances. At present we have no experience of a house-to-house system of illumination on a great scale and in competition with cheap gas; but preparations are already far advanced for trial on an adequate scale in London. In large institutions, such as theatres and factories, we all know that electricity is in successful and daily extending operation.

When the necessary power can be obtained from the fall of water, instead of from the combustion of coal, the conditions of the problem are far more favourable. Possibly the severity of your winters may prove an obstacle, but it is impossible to regard your splendid river without the thought arising that the day may come when the vast powers now running to waste shall be bent into your service. Such a project demands of course the most careful consideration, but it is one worthy of an intelligent and enterprising community.

The requirements of practice react in the most healthy manner upon scientific electricity. Just as in former days the science received a stimulus from the application to telegraphy, under which everything relating to measurement on a small scale acquired an importance and development for which we might otherwise have had long to wait, so now the requirements of electric lighting are giving rise to a new development of the art of measurement upon a large scale, which cannot fail to prove of scientific as well as practical importance. Mere change of scale may not at first appear a very important matter, but it is surprising how much modification it entails in the instruments, and in the processes of measurement. For instance, the resistance coils on which the electrician relies in dealing with currents whose maximum is a fraction of an ampere, fail altogether when it becomes a question of hundreds, not to say thousands, of amperes.

The powerful currents, which are now at command, constitute almost a new weapon in the hands of the physicist. Effects, which in old days were rare and difficult of observation, may now be produced at will on the most conspicuous scale. Consider for a moment Faraday's

day's great discovery of the "Magnetisation of Light," which Tyndall likens to the Weisshorn among mountains, as high, beautiful, and alone. This judgment (in which I fully concur) relates to the scientific aspect of the discovery, for to the eye of sense nothing could have been more insignificant. It is even possible that it might have eluded altogether the penetration of Faraday, had he not been provided with a special quality of very heavy glass. At the present day these effects may be produced upon a scale that would have delighted their discoverer, a rotation of the plane of polarisation through 180° being perfectly feasible. With the aid of modern appliances, Kundt and Röntgen in Germany, and H. Becquerel in France, have detected the rotation in gases and vapours, where, on account of its extreme smallness, it had previously escaped notice.

Again, the question of the magnetic saturation of iron has now an importance entirely beyond what it possessed at the time of Joule's early observations. Then it required special arrangements purposely contrived to bring it into prominence. Now in every dynamo machine, the iron of the field-magnets approaches a state of saturation, and the very elements of an explanation of the action require us to take the fact into account. It is indeed probable that a better knowledge of this subject might lead to improvements in the design of these machines.

Notwithstanding the important work of Rowland and Stoleto, the whole theory of the behaviour of soft iron under varying magnetic conditions is still somewhat obscure. Much may be hoped from the induction balance of Hughes, by which the marvellous powers of the telephone are applied to the discrimination of the properties of metals, as regards magnetism and electric conductivity.

The introduction of powerful alternate-current in machines by Siemens, Gordon, Ferranti, and others, is likely also to have a salutary effect in educating those so-called practical electricians whose ideas do not easily rise above ohms and volts. It has long been known that when the changes are sufficiently rapid, the phenomena are governed much more by induction, or electric inertia, than by mere resistance. On this principle much may be explained that would otherwise seem paradoxical. To take a comparatively simple case, conceive an electro-magnet wound with two contiguous wires, upon which acts a given rapidly periodic electro-motive force. If one wire only be used, a certain amount of heat is developed in the circuit. Suppose now that the second wire is brought into operation in parallel—a proceeding equivalent to doubling the section of the original wire. An electrician accustomed only to constant currents would be sure to think that the heating effect would be doubled by the change, as much heat being developed in each wire separately as was at first in the single wire. But such a conclusion would be entirely erroneous. The total current, being governed practically by the self-induction of the circuit, would not be augmented by the accession of the second wire, and the total heating effect, so far from being doubled, would, in virtue of the superior conductivity, be halved.

During the last few years much interest has been felt in the reduction to an absolute standard of measurements of electro-motive force, current, resistance, &c., and to this end many laborious investigations have been undertaken. The subject is one that has engaged a good deal of my own attention, and I should naturally have felt inclined to dilate upon it, but that I feel it to be too abstruse and special to be dealt with in detail upon an occasion like the present. As regards resistance, I will merely remind you that the recent determinations have shown a so greatly improved agreement, that the Conference of Electricians assembled at Paris, in May, have felt themselves justified in defining the ohm for practical use as the resistance of a column of mercury of 0°C ., one square millimetre in section, and 106 centimetres in length—a definition differing by a little more than one per cent. from that arrived at twenty years ago by a committee of this Association.

A standard of resistance once determined upon can be embodied in a "resistance coil," and copied without much trouble, and with great accuracy. But in order to complete the electrical system, a second standard of some kind is necessary, and this is not so easily embodied in a permanent form. It might conveniently consist of a standard galvanic cell, capable of being prepared in a definite manner, whose electro-motive force is once for all determined. Unfortunately, most of the batteries in ordinary use are for one reason or another unsuitable for this purpose, but the cell introduced by Mr. Latimer Clark, in which the metals are zinc in contact with saturated zinc sulphate and pure mercury in contact with mercurous sulphate, appears to give satisfactory results. According to my measurements, the electro-motive force of this cell is 1.435 theoretical volts.

We may also conveniently express the second absolute electrical measurement necessary to the completion of the system by taking advantage of Faraday's law, that the quantity of metal decomposed in an electrolytic cell is proportional to the whole quantity of electricity that passes. The best metal for the purpose is silver, deposited from a solution of the nitrate or of the chlorate. The results recently obtained by Professor Kohlrausch and by myself are in very good agreement, and the conclusion that one ampere flowing for one hour decomposes 4.025 grains of silver, can hardly be in error by more than a thousandth part. This number being known, the silver voltameter gives a ready and very accurate method of measuring currents of intensity, varying from 1-10th ampere to four or five amperes.

The beautiful and mysterious phenomena attending the discharge of electricity in nearly vacuous spaces have been investigated and in some degree explained by De la Rue, Crookes, Schuster, Moulton, and the lamented Spottiswoode, as well as by various able foreign experimenters. In a recent research Crookes has sought the origin of a bright citron-coloured band in the phosphorescent spectrum of certain earths, and after encountering difficulties and anomalies of a most bewildering kind, has succeeded in proving that it is due to yttrium, an element much more widely distributed than had been supposed. A conclusion like this is stated in a few words, but those only who have undergone similar experience are likely to appreciate the skill and perseverance of which it is the final reward.

A remarkable observation by Hall of Baltimore, from which it appeared that the flow of electricity in a conducting sheet was disturbed by magnetic force, has been the subject of much discussion. Mr. Sheldford Bidwell has brought forward experiments tending to prove that the effect is of a secondary character, due in the first instance to the mechanical force operating upon the conductor of an electric current when situated in a powerful magnetic field. Mr. Bidwell's view agrees in the main with Mr. Hall's division of the metals into two groups according to the direction of the effect.

Without doubt the most important achievement of the older generation of scientific men has been the establishment and application of the great laws of thermo-dynamics, or, as it is often called, the Mechanical Theory of Heat. The first law, which asserts that heat and mechanical work can be transformed one into the other at a certain fixed rate, is now well understood by every student of physics, and the number expressing the mechanical equivalent of heat resulting from the experiments of Joule, has been confirmed by the researches of others, and especially of Rowland. But the second law, which practically is even more important than the first, is only now beginning to receive the full appreciation due to it. One reason of this may be found in a not unnatural confusion of ideas. Words do not always lend themselves readily to the demands that are made upon them by a growing science, and I think that the almost unavoidable use of the word equivalent in the statement of the first law is partly responsible or the little attention that is given to the second. For

the second law so far contradicts the usual statement of the first, as to assert that equivalents of heat and work are not of equal value. While work can always be converted into heat, heat can only be converted into work under certain limitations. For every practical purpose the work is worth the most, and when we speak of equivalents, we use the word in the same sort of special sense as that in which chemists speak of equivalents of gold and iron. The second law teaches us that the real value of heat, as a source of mechanical power, depends upon the temperature of the body in which it resides; the hotter the body in relation to its surroundings, the more available the heat.

In order to see the relations which obtain between the first and the second law of thermo-dynamics, it is only necessary for us to glance at the theory of the steam-engine. Not many years ago calculations were plentiful, demonstrating the inefficiency of the steam-engine on the basis of a comparison of the work actually got out of the engine with the mechanical equivalent of the heat supplied to the boiler. Such calculations took into account only the first law of thermo-dynamics, which deals with the equivalents of heat and work, and have very little bearing upon the practical question of efficiency, which requires us to have regard also to the second law. According to that law the fraction of the total energy which can be converted into work depends upon the relative temperatures of the boiler and condenser; and it is, therefore, manifest that, as the temperature of the boiler cannot be raised indefinitely, it is impossible to utilise all the energy which, according to the first law of thermo-dynamics, is resident in the coal.

On a sounder view of the matter, the efficiency of the steam-engine is found to be so high, that there is no great margin remaining for improvement. The higher initial temperature possible in the gas engine opens out much wider possibilities, and many good judges look forward to a time when the steam-engine will have to give way to its younger rival.

To return to the theoretical question, we may say with Sir W. Thomson, that though energy cannot be destroyed, it ever tends to be dissipated, or to pass from more available to less available forms. No one who has grasped this principle can fail to recognise its immense importance in the system of the universe. Every change—chemical, thermal, or mechanical—which takes place, or can take place, in nature does so, at the cost of a certain amount of available energy. If, therefore, we wish to inquire whether or not a proposed transformation can take place, the question to be considered is whether its occurrence would involve dissipation of energy. If not, the transformation is (under the circumstances of the case) absolutely excluded. Some years ago, in a lecture at the Royal Institution, I endeavoured to draw the attention of chemists to the importance of the principle of dissipation in relation to their science, pointing out the error of the usual assumption that a general criterion is to be found in respect of the development of heat. For example, the solution of a salt in water is, if I may be allowed the phrase, a downhill transformation. It involves dissipation of energy, and can therefore go forward; but in many cases it is associated with the absorption rather than with the development of heat. I am glad to take advantage of the present opportunity in order to repeat my recommendation, with an emphasis justified by actual achievement. The foundations laid by Thomson now bear an edifice of no mean proportions, thanks to the labours of several physicists, among whom must be especially mentioned Willard Gibbs and Helmholtz. The former has elaborated a theory of the equilibrium of heterogeneous substances, wide in its principles, and we cannot doubt far-reaching in its consequences. In a series of masterly papers Helmholtz has developed the conception of *free energy* with very important applications to the theory of the galvanic cell. He points out that the mere tendency to solution bears in some cases no small proportion to the affinities

more usually reckoned chemical, and contributes largely to the total electro-motive force. Also in our own country Dr. Alder Wright has published some valuable experiments relating to the subject.

From the further study of electrolysis we may expect to gain improved views as to the nature of the chemical reactions, and of the forces concerned in bringing them about. I am not qualified—I wish I were—to speak to you on recent progress in general chemistry. Perhaps my feelings towards a first love may blind me, but I cannot help thinking that the next great advance, of which we have already some foreshadowing, will come on this side. And if I might without presumption venture a word of recommendation, it would be in favour of a more minute study of the simpler chemical phenomena.

Under the head of scientific mechanics it is principally in relation to fluid motion that advances may be looked for. In speaking upon this subject I must limit myself almost entirely to experimental work. Theoretical hydro-dynamics, however important and interesting to the mathematician, are eminently unsuited to oral exposition. All I can do to attenuate an injustice, to which theorists are pretty well accustomed, is to refer you to the admirable reports of Mr. Hicks, published under the auspices of this Association.

The important and highly practical work of the late Mr. Froude in relation to the propulsion of ships is doubtless known to most of you. Recognising the fallacy of views then widely held as to the nature of the resistance to be overcome, he showed to demonstration that, in the case of fair-shaped bodies, we have to deal almost entirely with resistance dependent upon skin friction, and at high speeds upon the generation of surface waves by which energy is carried off. At speeds which are moderate in relation to the size of the ship, the resistance is practically dependent upon skin friction only. Although Professor Stokes and other mathematicians had previously published calculations pointing to the same conclusion, there can be no doubt that the view generally entertained was very different. At the first meeting of the Association which I ever attended, as an intelligent listener, at Bath in 1864, I well remember the surprise which greeted a statement by Rankine that he regarded skin friction as the only legitimate resistance to the progress of a well-designed ship. Mr. Froude's experiments have set the question at rest in a manner satisfactory to those who had little confidence in theoretical prevision.

In speaking of an explanation as satisfactory in which skin friction is accepted as the cause of resistance, I must guard myself against being supposed to mean that the nature of skin friction is itself well understood. Although its magnitude varies with the smoothness of the surface, we have no reason to think that it would disappear at any degree of smoothness consistent with an ultimate molecular structure. That it is connected with fluid viscosity is evident enough, but the *modus operandi* is still obscure.

Some important work bearing upon the subject has recently been published by Professor O. Reynolds, who has investigated the flow of water in tubes as dependent upon the velocity of motion and upon the size of the bore. The laws of motion in capillary tubes, discovered experimentally by Poiseuille, are in complete harmony with theory. The resistance varies as the velocity, and depends in a direct manner upon the constant of viscosity. But when we come to the larger pipes and higher velocities with which engineers usually have to deal, the theory which presupposes a regularly stratified motion evidently ceases to be applicable, and the problem becomes essentially identical with that of skin friction in relation to ship propulsion. Professor Reynolds has traced with much success the passage from the one state of things to the other, and has proved the applicability under these complicated conditions of the general laws of dynamical similarity as adapted to viscous fluids by Professor Stokes. In spite of the difficulties which beset both the theoretical

and experimental treatment, we may hope to attain before long to a better understanding of a subject which is certainly second to none in scientific as well as practical interest.

As also closely connected with the mechanics of viscous fluids, I must not forget to mention an important series of experiments upon the friction of oiled surfaces, recently executed by Mr. Tower for the Institution of Mechanical Engineers. The results go far towards upsetting some ideas hitherto widely admitted. When the lubrication is adequate, the friction is found to be nearly independent of the load, and much smaller than is usually supposed, giving a coefficient as low as 1-1000th. When the layer of oil is well formed, the pressure between the solid surfaces is really borne by the fluid, and the work lost is spent in shearing, that is, in causing one stratum of the oil to glide over another.

In order to maintain its position, the fluid must possess a certain degree of viscosity, proportionate to the pressure; and even when this condition is satisfied, it would appear to be necessary that the layer should be thicker on the ingoing than on the outgoing side. We may, I believe, expect from Professor Stokes a further elucidation of the processes involved. In the meantime, it is obvious that the results already obtained are of the utmost value, and fully justify the action of the Institution in devoting a part of its resources to experimental work. We may hope indeed that the example thus wisely set may be followed by other public bodies associated with various departments of industry.

I can do little more than refer to the interesting observations of Professor Darwin, Mr. Hunt, and M. Forel on Ripplemark. The processes concerned would seem to be of a rather intricate character, and largely dependent upon fluid viscosity. It may be noted indeed that most of the still obscure phenomena of hydro-dynamics require for their elucidation a better comprehension of the laws of viscous motion. The subject is one which offers peculiar difficulties. In some problems in which I have lately been interested, a circulating motion presents itself of the kind which the mathematician excludes from the first when he is treating of fluids destitute altogether of viscosity. The intensity of this motion proves, however, to be independent of the coefficient of viscosity so that it cannot be correctly dismissed from consideration as a consequence of a supposition that the viscosity, is infinitely small. The apparent breach of continuity can be explained, but it shows how much care is needful in dealing with the subject, and how easy it is to fall into error.

The nature of gaseous viscosity, as due to the diffusion of momentum, has been made clear by the theoretical and experimental researches of Maxwell. A flat disc moving in its own plane between two parallel solid surfaces is impeded by the necessity of shearing the intervening layers of gas, and the magnitude of the hindrance is proportional to the velocity of the motion and to the viscosity of the gas, so that under similar circumstances this effect may be taken as a measure, or rather definition, of the viscosity. From the dynamical theory of gases, to the development of which he contributed so much, Maxwell drew the startling conclusion that the viscosity of a gas should be independent of its density—that within wide limits the resistance to the moving disc should be scarcely diminished by pumping out the gas, so as to form a partial vacuum. Experiment fully confirmed this theoretical anticipation—one of the most remarkable to be found in the whole history of science, and proved that the swinging disc was retarded by the gas, as much when the barometer stood at half an inch as when it stood at thirty inches. It was obvious, of course, that the law must have a limit, that at a certain point of exhaustion the gas must begin to lose its power; and I remember discussing with Maxwell, soon after the publication of his experiments, the whereabouts of the point at which the gas would cease to produce its ordinary effect. His apparatus, however, was quite unsuited for high degrees of exhaustion, and the

failure of the law was first observed by Kundt and Warburg, as pressures below 1 m.m. of mercury. Subsequently the matter has been thoroughly examined by Crookes, who extended his observations to the highest degrees of exhaustion as measured by McLeod's gauge. Perhaps the most remarkable results relate to hydrogen. From the atmospheric pressure of 760 m.m. down to about $\frac{1}{4}$ m.m. of mercury the viscosity is sensibly constant. From this point to the highest vacua, in which less than one-millionth of the original gas remains, the coefficient of viscosity drops down gradually to a small fraction of its original value. In these vacua Mr. Crookes regards the gas as having assumed a different, ultra-gaseous, condition; but we must remember that the phenomena have relation to the other circumstances of the case, especially the dimensions of the vessel, as well as to the condition of the gas.

Such an achievement as the prediction of Maxwell's law of viscosity has, of course, drawn increased attention to the dynamical theory of gases. The success which has attended the theory in the hands of Clausius, Maxwell, Boltzman, and other mathematicians, not only in relation to viscosity, but over a large part of the entire field of our knowledge of gases, proves that some of its fundamental postulates are in harmony with the reality of Nature. At the same time, it presents serious difficulties; and we cannot but feel that while the electrical and optical properties of gases remain out of relation to the theory, no final judgment is possible. The growth of experimental knowledge may be trusted to clear up many doubtful points, and a younger generation of theorists will bring to bear improved mathematical weapons. In the meantime we may fairly congratulate ourselves on the possession of a guide which has already conducted us to a position which could hardly otherwise have been attained.

In Optics attention has naturally centred upon the spectrum. The mystery attaching to the invisible rays lying beyond the red has been fathomed to an extent that, a few years ago, would have seemed almost impossible. By the use of special photographic methods Abney has mapped out the peculiarities of this region with such success that our knowledge of it begins to be comparable with that of the parts visible to the eye. Equally important work has been done by Langley, using a refined invention of his own based upon the principle of Siemens's pyrometer. This instrument measures the actual energy of the radiation, and thus expresses the effects of various parts of the spectrum upon a common scale, independent of the properties of the eye and of sensitive photographic preparations. Interesting results have also been obtained by Becquerel, whose method is founded upon a curious action of the ultra-red rays in enfeebling the light emitted by phosphorescent substances. One of the most startling of Langley's conclusions relates to the influence of the atmosphere in modifying the quality of solar light. By the comparison of observations made through varying thicknesses of air, he shows that the atmospheric absorption tells most upon the light of high refrangibility; so that, to an eye situated outside the atmosphere, the sun would present a decidedly bluish tint. It would be interesting to compare the experimental numbers with the law of scattering of light by small particles given some years ago as the result of theory. The demonstration by Langley of the inadequacy of Cauchy's law of dispersion to represent the relation between refrangibility and wavelength in the lower part of the spectrum must have an important bearing upon optical theory.

The investigation of the relation of the visible and ultra-violet spectrum to various forms of matter has occupied the attention of a host of able workers, among whom none have been more successful than my colleagues at Cambridge, Professors Living and Dewar. The subject is too large both for the occasion and for the individual, and I must pass it by. But, as more relating to Optics proper, I cannot resist recalling to your notice a beautiful

application of the idea of Doppler to the discrimination of the origin of certain lines observed in the solar spectrum. If a vibrating body have a general motion of approach or recession, the waves emitted from it reach the observer with a frequency which in the first case exceeds, and in the second case falls short of, the real frequency of the vibrations themselves. The consequence is that, if a glowing gas be in motion in the line of sight, the spectral lines are thereby displaced from the position that they would occupy were the gas at rest—a principle which, in the hands of Huggins and others, has led to a determination of the motion of certain fixed stars relatively to the solar system. But the sun is itself in rotation, and thus the position of a solar spectral line is slightly different according as the light comes from the advancing or from the retreating limb. This displacement was, I believe, first observed by Thollon; but what I desire now to draw attention to is the application of it by Cornu to determine whether a line is of solar or atmospheric origin. For this purpose a small image of the sun is thrown upon the slit of the spectroscope, and caused to vibrate two or three times a second, in such a manner that the light entering the instrument comes alternately from the advancing and retreating limbs. Under these circumstances a line due to absorption within the sun appears to tremble, as the result of slight alternately opposite displacements. But if the seat of the absorption be in the atmosphere, it is a matter of indifference from what part of the sun the light originally proceeds, and the line maintains its position in spite of the oscillation of the image upon the slit of the spectroscope. In this way Cornu was able to make a discrimination which can only otherwise be effected by a difficult comparison of appearances under various solar altitudes.

The instrumental weapon of investigation, the spectroscopic itself, has made important advances. On the theoretical side, we have for our guidance the law that the optical power in gratings is proportional to the total number of lines accurately ruled, without regard to the degree of closeness, and in prisms that it is proportional to the thickness of glass traversed. The magnificent gratings of Rowland are a new power in the hands of the spectroscopist, and as triumphs of mechanical art seem to be little short of perfection. In our own report for 1882, Mr. Mallock has described a machine, constructed by him, for ruling large diffraction gratings, similar in some respects to that of Rowland.

The great optical constant, the velocity of light, has been the subject of three distinct investigations by Cornu, Michelson, and Forbes. As may be supposed, the matter is of no ordinary difficulty, and it is therefore not surprising that the agreement should be less decided than could be wished. From their observations, which were made by a modification of Fizeau's method of the toothed wheel, Young and Forbes drew the conclusion that the velocity of light *in vacuo* varies from colour to colour, to such an extent that the velocity of blue light is nearly two per cent greater than that of red light. Such a variation is quite opposed to existing theoretical notions, and could only be accepted on the strongest evidence. Mr. Michelson, whose method (that of Foucault) is well suited to bring into prominence a variation of velocity with wavelength, informs me that he has recently repeated his experiments with special reference to the point in question, and has arrived at the conclusion that no variation exists comparable with that asserted by Young and Forbes. The actual velocity differs little from that found from his first series of experiments, and may be taken to be 299,800 kilometres per second.

It is remarkable how many of the playthings of our childhood give rise to questions of the deepest scientific interest. The top is, or may be understood, but a complete comprehension of the kite and of the soap-bubble would carry us far beyond our present stage of knowledge. In spite of the admirable investigations of Plateau, it still remains a mystery why soapy water stands almost alone

among fluids as a material for bubbles. The beautiful development of colour was long ago ascribed to the interference of light, called into play by the gradual thinning of the film. In accordance with this view the tint is determined solely by the thickness of the film, and the refractive index of the fluid. Some of the phenomena are however so curious, as to have led excellent observers like Brewster to reject the theory of thin plates, and to assume the secretion of various kinds of colouring matter. If the rim of a wine-glass be dipped in soapy water, and then held in a vertical position, horizontal bands soon begin to show at the top of the film, and extend themselves gradually, downwards. According to Brewster these bands are not formed by the "subsidence and gradual thinning of the film," because they maintain their horizontal position when the glass is turned round its axis. The experiment is both easy and interesting; but the conclusion drawn from it cannot be accepted. The fact is that the various parts of the film cannot quickly alter their thickness, and hence when the glass is rotated they rearrange themselves in order of superficial density, the thinner parts floating up over, or through, the thicker parts. Only thus can the tendency be satisfied for the centre of gravity to assume the lowest possible position.

When the thickness of a film falls below a small fraction of the length of a wave of light, the colour disappears and is replaced by an intense blackness. Professors Reinold and Rücker have recently made the remarkable observation that the whole of the black region, soon after its formation, is of uniform thickness, the passage from the black to the coloured portions being exceedingly abrupt. By two independent methods they have determined the thickness of the black film to be between seven and fourteen thousandths of a millimetre; so that the thinnest films correspond to about one-seventieth of a wave-length of light. The importance of these results in regard to molecular theory is too obvious to be insisted upon.

The beautiful inventions of the telephone and the phonograph, although in the main dependent upon principles long since established, have imparted a new interest to the study of Acoustics. The former, apart from its uses in every day life, has become in the hands of its inventor, Graham Bell, and of Hughes, an instrument of first-class scientific importance. The theory of its action is still in some respects obscure, as is shown by the comparative failure of the many attempts to improve it. In connection with some explanations that have been offered, we do well to remember that molecular changes in solid masses are inaudible in themselves, and can only be manifested to our ears by the generation of a to and fro motion of the external surface extending over a sensible area. If the surface of a solid remains undisturbed, our ears can tell us nothing of what goes on in the interior.

In theoretical acoustics progress has been steadily maintained, and many phenomena, which were obscure twenty or thirty years ago, have since received adequate explanation. If some important practical questions remain unsolved, one reason is that they have not yet been definitely stated. Almost everything in connection with the ordinary use of our senses presents peculiar difficulties to scientific investigation. Some kinds of information with regard to their surroundings are of such paramount importance to successive generations of living beings, that they have learned to interpret indications which, from a physical point of view, are of the slenderest character. Every day we are in the habit of recognising, without much difficulty, the quarter from which a sound proceeds, but by what steps we attain that end has not yet been satisfactorily explained. It has been proved that when proper precautions are taken we are unable to distinguish whether a pure tone (as from a vibrating tuning fork held over a suitable resonator) comes to us from in front or from behind. This is what might have been expected from an *a priori* point of view; but what would not have been expected is

that with almost any other sort of sound, from a clap of the hands to the clearest vowel sound, the discrimination is not only possible but easy and instinctive. In these cases it does not appear how the possession of two ears helps us, though there is some evidence that it does; and even when sounds come to us from the right or left, the explanation of the ready discrimination which is then possible with pure tones is not so easy as might at first appear. We should be inclined to think that the sound was heard much more loudly with the ear that is turned towards than with the ear that is turned from it, and that in this way the direction was recognised. But if we try the experiment, we find that at any rate with notes near the middle of the musical scale, the difference of loudness is by no means so very great. The wave-lengths of such notes are long enough in relation to the dimensions of the head to forbid the formation of anything like a sound shadow in which the averted ear might be sheltered.

In concluding this imperfect survey of recent progress in physics, I must warn you emphatically that much of great importance has been passed over altogether. I should have liked to speak to you of those far reaching speculations, especially associated with the name of Maxwell, in which light is regarded as a disturbance in an electromagnetic medium. Indeed, at one time, I had thought of taking the scientific work of Maxwell as the principal theme of this address. But, like most men of genius, Maxwell delighted in questions too obscure and difficult for hasty treatment, and thus much of his work could hardly be considered upon such an occasion as the present. His biography has recently been published, and should be read by all who are interested in science and in scientific men. His many-sided character, the quaintness of his humour, the penetration of his intellect, his simple but deep religious feeling, the affection between son and father, the devotion of husband to wife, all combine to form a rare and fascinating picture. To estimate rightly his influence upon the present state of science, we must regard not only the work that he executed himself, important as that was, but also the ideas and the spirit which he communicated to others. Speaking for myself as one who in a special sense entered into his labours, I should find it difficult to express adequately my feeling of obligation. The impress of his thoughts may be recognised in much of the best work of the present time. As a teacher and examiner he was well acquainted with the almost universal tendency of uninstructed minds to elevate phrases above things: to refer, for example, to the principle of the conservation of energy for an explanation of the persistent rotation of a fly-wheel, almost in the style of the doctor in "Le Malade Imaginaire," who explains the fact that opium sends you to sleep by its soporific virtue. Maxwell's endeavour was always to keep the facts in the foreground, and to his influence, in conjunction with that of Thomson and Helmholtz, is largely due that elimination of unnecessary hypothesis which is one of the distinguishing characteristics of the science of the present day.

In speaking unfavourably of superfluous hypothesis, let me not be misunderstood. Science is nothing without generalisations. Detached and ill-assorted facts are only raw material, and in the absence of a theoretical solvent, have but little nutritive value. At the present time and in some departments, the accumulation of material is so rapid that there is danger of indigestion. By a fiction as remarkable as any to be found in law, what has once been published, even though it be in the Russian language, is usually spoken of as "known," and it is often forgotten that the re-discovery in the library may be a more difficult and uncertain process than the first discovery in the laboratory. In this matter we are greatly dependent upon annual reports and abstracts, issued principally in Germany, without which the search for the discoveries of a little-known author would be well-nigh hopeless. Much useful work has been done in this direction in connection with our Association. Such critical reports as those upon

Hydro-dynamics, upon Tides, and upon Spectroscopy guide the investigator to the points most requiring attention, and in discussing past achievements contribute in no small degree to future progress. But though good work has been done, much yet remains to do.

If, as is sometimes supposed, science consisted in nothing but the laborious accumulation of facts, it would soon come to a stand-still, crushed, as it were, under its own weight. The suggestion of a new idea, or the detection of a law, supersedes much that had previously been a burden upon the memory, and by introducing order and coherence facilitates the retention of the remainder in an available form. Those who are acquainted with the writings of the older electricians will understand my meaning when I instance the discovery of Ohm's law as a step by which the science was rendered easier to understand and to remember. Two processes are thus at work side by side, the reception of new material and the digestion and assimilation of the old; and as both are essential, we may spare ourselves the discussion of their relative importance. One remark, however, should be made. The work which deserves, but I am afraid does not always receive, the most credit is that in which discovery and explanation go hand in hand, in which not only are new facts presented, but their relation to old ones is pointed out.

In making oneself acquainted with what has been done in any subject, it is good policy to consult first the writers of highest general reputation. Although in scientific matters we should aim at independent judgment, and not rely too much upon authority, it remains true that a good deal must often be taken upon trust. Occasionally an observation is so simple and easily repeated, that it scarcely matters from whom it proceeds; but as a rule it can hardly carry full weight when put forward by a novice whose care and judgment there has been no opportunity of testing, and whose irresponsibility may tempt him to "take shots," as it is called. Those who have had experience in accurate work know how easy it would be to save time and trouble by omitting precautions and passing over discrepancies, and yet, even without dishonest intention, to convey the impression of conscientious attention to details. Although the most careful and experienced cannot hope to escape occasional mistakes, the effective value of this kind of work depends much upon the reputation of the individual responsible for it.

In estimating the present position and prospects of experimental science, there is good ground for encouragement. The multiplication of laboratories gives to the younger generation opportunities such as have never existed before, and which excite the envy of those who have had to learn in middle life much that now forms part of an undergraduate course. As to the management of such institutions there is room for a healthy difference of opinion. For many kinds of original work, especially in connection with accurate measurement, there is need of expensive apparatus; and it is often difficult to persuade a student to do his best with imperfect appliances when he knows that by other means a better result could be attained with greater facility. Nevertheless it seems to me important to discourage too great reliance upon the instrument maker. Much of the best original work has been done with the homeliest appliances; and the endeavour to turn to the best account the means that may be at hand develops ingenuity and resource more than the most elaborate determinations with ready-made instruments. There is danger otherwise that the experimental education of a plodding student should be too mechanical and artificial, so that he is puzzled by small changes of apparatus much as many school-boys are puzzled by a transposition of the letters in a diagram of Euclid.

From the general spread of a more scientific education, we are warranted in expecting important results. Just as there are some brilliant literary men with an inability, or at least a distaste practically amounting to inability, for scientific ideas, so there are a few with scientific tastes

whose imaginations are never touched by merely literary studies. To save these from intellectual stagnation during several important years of their lives is something gained; but the thorough-going advocates of scientific education aim at much more. To them it appears strange, and almost monstrous, that the dead languages should hold the place they do in general education; and it can hardly be denied that their supremacy is the result of routine rather than of argument. I do not, myself, take up the extreme position. I doubt whether an exclusively scientific training would be satisfactory; and where there is plenty of time and a literary aptitude I can believe that Latin and Greek may make a good foundation. But it is useless to discuss the question upon the supposition that the majority of boys attain either to a knowledge of the languages or to an appreciation of the writings of the ancient authors. The contrary is notoriously the truth; and the defenders of the existing system usually take their stand upon the excellence of its discipline. From this point of view there is something to be said. The laziest boy must exert himself a little in puzzling out a sentence with grammar and dictionary, while instruction and supervision are easy to organise and not too costly. But when the case is stated plainly, few will agree that we can afford so entirely to disregard results. In after life the intellectual energies are usually engrossed with business, and no further opportunity is found for attacking the difficulties which block the gateways of knowledge. Mathematics, especially, if not learned young, are likely to remain unlearned. I will not further insist upon the educational importance of mathematics and science, because with respect to them I shall probably be supposed to be prejudiced. But of modern languages I am ignorant enough to give value to my advocacy. I believe that French and German, if properly taught, which I admit they rarely are at present, would go far to replace Latin and Greek from a disciplinary point of view, while the actual value of the acquisition would, in the majority of cases, be incomparably greater. In half the time usually devoted, without success, to the classical languages, most boys could acquire a really serviceable knowledge of French and German. History and the serious study of English literature, now shamefully neglected, would also find a place in such a scheme.

There is one objection often felt to a modernised education, as to which a word may not be without use. Many excellent people are afraid of science as tending towards materialism. That such apprehension should exist is not surprising, for unfortunately there are writers, speaking in the name of science, who have set themselves to foster it. It is true that among scientific men, as in other classes, crude views are to be met with as to the deeper things of Nature; but that the life-long beliefs of Newton, of Faraday, and of Maxwell are inconsistent with the scientific habit of mind, is surely a proposition which I need not pause to refute. It would be easy, however, to lay too much stress upon the opinions of even such distinguished workers as these. Men who devote their lives to investigation cultivate a love of truth for its own sake, and endeavour instinctively to clear up, and not, as is too often the object in business and politics, to obscure a difficult question. So far the opinion of a scientific worker may have a special value; but I do not think that he has a claim, superior to that of other educated men, to assume the attitude of a prophet. In his heart he knows that underneath the theories that he constructs there lie contradictions which he cannot reconcile. The higher mysteries of being, if penetrable at all by human intellect, require other weapons than those of calculation and experiment.

Without encroaching upon grounds appertaining to the theologian and the philosopher, the domain of natural science is surely broad enough to satisfy the wildest ambition of its devotees. In other departments of human life and interest, true progress is rather an article of faith than a rational belief; but in science a retrograde movement

is, from the nature of the case, almost impossible. Increasing knowledge brings with it increasing power, and great as are the triumphs of the present century, we may well believe that they are but a foretaste of what discovery and invention have yet in store for mankind. Encouraged by the thought that our labours cannot be thrown away, let us redouble our efforts in the noble struggle. In the Old World and in the New, recruits must be enlisted to fill the place of those whose work is done. Happy should I be if, through this visit of the Association, or by any words of mine, a larger measure of the youthful activity of the West could be drawn into this service. The work may be hard, and the discipline severe; but the interest never fails, and great is the privilege of achievement.

RECENT ESTIMATIONS OF THE AMOUNT OF SALICYLIC ACID IN THE CULTIVATED PANSY.

By Dr. A. B. GRIFFITHS, F.C.S. (London and Paris),
Lecturer on Metallurgy, City of London College, &c.; and

E. C. CONRAD, F.O.S. (London and Paris),
Manager and Chemist to Betts and Co.'s Works, Bordeaux, &c.

SALICYLIC acid ($C_7H_6O_3$) was first discovered as a product of plant-life in certain plants by Piria, in 1838. In 1844 Gerhardt and Cahours obtained it from *Gaultheria procumbens* (Winter green), and Professor K. Mandelin has discovered salicylic acid or acids of the $C_nH_{2n-8}O_3$ series in the different varieties of violets and the Violaceae generally.

Recently we have determined the amount of salicylic acid in the garden pansy with the following results:—

	I.	II.
The leaves yielded, per cent,	0.1329	0.1330
The stems " "	0.0852	0.0856
The roots " "	0.0531	0.0529

While the flowers gave evidence of only a trace of this acid. From these analyses it will be seen that the leaves of the plant contain the largest amount of this acid, and the flowers the smallest. We cut several thin sections of the leaves, stem, and root, and examined them under the highest powers of the microscope, but were unable to discover any crystals of salicylic acid in the cells, &c., of the plant, whence we conclude that it is dissolved in the cell-sap, or perhaps the protoplasm itself.

What the physiological functions of this organic acid are as regards the life of the plant we are at present unable to say, nor are we able to state how this salicylic acid is formed in the plant.

REACTIONS OF QUININE, NARCOTINE, AND MORPHINE WITH BROMINE.

By ARNOLD EILOART, B.Sc.

Quinine.—Professor Vogel's red colour obtained by successive addition of bromine water, potassium ferrocyanide, and borax (*Anal. Zeits.*, xxiii., p. 78) shows 1-60,000th part of quinine. Substitution of mercuric cyanide for the ferrocyanide, and of precipitated chalk for the borax extends the limit to 1-500,000th. With petroleum spirit instead of mercuric cyanide the limit is 1-50,000th; no debrominating agent being used, the crimson* appears with weak ammonia, or other neutralising agent, e.g., zinc oxide, but the limit is then (with chalk) 1-15,000th only.

* Attempts to isolate the red body failed; dry quinine does not give it with dry bromine vapour, but takes up bromine and is coloured orange; addition of water then gives the crimson, but not if free bromine is first removed.

The rose-pink obtained by Professor Bloxam (CHEMICAL NEWS, xlvii., p. 215) by boiling with bromine water, shows 1-15,000th part in acid solutions of quinine; addition of chalk before the bromine extends the limit to 1-50,000th; a strong solution will then become violet in the cold, changing to blue when heated, and becoming again violet with more bromine.

When a neutral solution of quinine is mixed with bromine in excess, boiled till after the excess is expelled, and cooled, a beautiful green fluorescence appears when the solution contains 1-50,000th of quinine.

Narcotine.—If narcotine be dissolved in HCl, and bromine added in slight excess, the liquid becomes red when neutralised with calcium carbonate; if the solution contains more than 1-1000th of narcotine, the red colour is followed by violet and blue. This is the case even when the solution is set aside for some time after adding the bromine, whereas a brominated solution of quinine gives no colour with chalk if allowed to stand. One part of narcotine in 6000th will give a red colour in this way. The colour is less in presence of tartaric or of acetic acid.

Morphine.—When a solution containing morphine is boiled with excess of bromine water, neutralised with chalk, and again boiled, a bright red colour appears if the solution contain more than 1-1200th part of morphine. With less than this the colour is orange or brown, and is bleached by more bromine water. By dividing the neutralised solution, and adding a drop of bromine to one part, the bleaching was perceptible when only 1-120,000th part of morphine was present.

Strychnine, cinchonine, and caffeine gave no characteristic reaction with bromine and chalk.

The precipitate is dried at 100° and weighed, being perfectly pure.

Cinchonamine nitrate has the formula,—

Its high molecular weight is advantageous for the determination of nitric acid, as 359 parts cinchonamine nitrate represent 54 parts nitric acid, 101 potassium nitrate, or 82 parts calcium nitrate.

In this manner the author has determined the nitric acid contained in natural waters in the state of nitrates, probably as calcium nitrate, and has obtained at different times perfectly accordant results. For well-waters he evaporates 1 litre of the sample to dryness, takes up the residue in alcohol at 40° per cent, and expels the alcohol by evaporation in the water-bath. The aqueous solution resulting from this treatment contains all the nitrates as well as a certain quantity of chlorides. The analysis is continued as indicated above.

For determining the nitrates contained in plants the procedure is slightly modified. The plant is triturated and exhausted with boiling water. The liquid is evaporated to the consistence of an extract and re-dissolved in alcohol at 40 per cent. The alcohol is expelled by evaporation on the water-bath, and in the liquid resulting the chlorides are eliminated by the addition of a small quantity of neutral lead acetate, any small excess of which is removed by means of a few drops of sodium sulphate. In the filtrate the nitrates are determined as above.—*Comptes Rendus.*

DETERMINATION OF NITRIC ACID BY PRECIPITATION AS CINCHONAMINE NITRATE. APPLICATION OF THIS PROCESS TO THE DETERMINATION OF THE NITRATES CON- TAINED IN NATURAL WATERS AND IN PLANTS.

By M. ARNAUD.

CINCHONAMINE nitrate is almost insoluble in water acidified with from 10 to 15 per cent of hydrochloric acid. It is therefore very easy to detect the nitrates qualitatively by bringing the solution to this condition. But for an exact determination it is impossible to employ this means, as, in drying, the acid becomes concentrated, and finally attacks not only the paper of the filter but the cinchonamine nitrate itself.

After many attempts the author has succeeded in obtaining very good results by operating as follows:—

The liquid containing the nitrates is neutralised with soda if acid, and with sulphuric acid if alkaline, the essential point being to obtain neutrality. The chlorine of the chlorides, if any are present, is eliminated with silver acetate, any excess of the latter being removed by the addition of a few drops of sodium phosphate. The filtrate is then evaporated almost to dryness and filtered anew if it is not absolutely clear, acidulated very slightly with a drop of dilute acetic acid. The liquid is then precipitated at a boil with a hot solution of cinchonamine sulphate. Cinchonamine nitrate falls down immediately in a crystalline state. It is let stand for twelve hours in a cool place. It is then brought upon a filter and washed with an aqueous solution of cinchonamine nitrate, saturated at the temperature of the atmosphere so as to remove any cinchonamine sulphate.

The object of this method of washing is to avoid dissolving any trace of the cinchonamine nitrate, however slight. Pure water, employed instead, would dissolve about 2-1000th of its weight of the cinchonamine nitrate.

NOTICES OF BOOKS.

Report of the Metropolitan Board of Works, 1883.

VERY much of the matter contained in this report is not of a nature which can fitly come under our notice. There is a section on "Sewerage and Drainage" but it deals merely with the construction of sewers and does not enter upon the purification of the sewage. The "State of the Thames" is briefly referred to. We are told that the Board denies the charges brought concerning the pollution of the river. Hence it would appear that this important body is still satisfied with the method which it has adopted for dealing with the sewage of the metropolis.

As regards the gas supply we notice a curious concession to the Companies. Sulphur, during the months from April to October, 1883, was allowed to the extent of 17 grains in 100 feet. "From October till next April (1884) the maximum is to be 22 grains." Why the standard of purity should thus be reduced it is not easy to see.

The electric light is very briefly touched upon. There is a complaint that on the Victoria Embankment and on Waterloo Bridge, which were lighted by the Jablockhoff Electric Light and Power Company, "the Board has on several occasions lately had to complain of the sudden extinction of many of the lights during the hours when the company is bound by the agreement to keep them shining."

The notice of the water supply, though expressing dissatisfaction with existing arrangements, raises no question concerning the purity of the water.

It appears that 2718 diseased animals have been killed during the year in the Metropolitan district, under the provisions of the "Contagious Diseases Act." An alarming fact is that persons still drive or lead glandered or farcied horses through the streets, to the public danger. Ten persons have been convicted of this offence, and penalties varying from 5s. (1) to £10 were imposed. As the result of this negligence may be to infect any passer-by with a loathsome and incurable disease, it seems that such penalties do not err on the side of severity.

Oxidation of Mercury Diethyl with Potassium Permanganate.—M. Seidl.—The result of the reaction is ethyl-mercuric chloride.—*Journ. f. Prakt. Chemie.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Justus Liebig's Annalen der Chemie,
Vol. 223, Part 3.

Communications from the Laboratory of the Technical High School of Stuttgart on Examinations of Wax.—These consist of a memoir by Carl Hell on a method for determining the molecular weight and the atomicity of the higher fatty alcohols; and a paper by H. Stürke on the chemical constituents of carnauba wax. This compound contains a hydrocarbon melting at 59° to 59.5° , an alcohol, $C_{26}H_{53}CH_2OH$, melting at 76° , myricylic alcohol, a bi-acid alcohol melting at 103.5° , an acid, $C_{23}H_{47}COOH$, isomeric with lignoceric acid, and melting at 72.5° , an acid, $C_{26}H_{53}COOH$, identical or isomeric with cerotic acid, and an oxy acid melting at 103.5° .

Some Reactions of Iodine upon Organic Compounds at Elevated Temperatures.—Bohuslaw Ráymán and Karl Preis.—At 250° alcohol acts upon aromatic compounds in such a manner that the lateral catenæ are separated and broken up into methyls, which latter then enter the nucleus as substituents.

On Tin Bromides.—B. Ráymán and Karl Preis.—The authors have examined tin dibromide, a crystalline, faintly yellowish, translucent mass, fusible at 215.5° , specific gravity 5.117. It is partially decomposed by water, forming a white oxy-bromide. The aqueous dibromide formed by the action of warm hydrobromic acid upon metallic tin forms colourless acicular or thin prismatic crystals, which form a turbid solution in water. Tin tetra-bromide is a white substance of nacreous lustre. When melted it very readily dissolves iodine and sulphur. The tetra-bromide dissolves in cold water without decomposition, but on heating, stannic acid is separated out. Heated tetra-bromide absorbs ammonia energetically, and is converted into a white mass, $SnBr_4 \cdot 2NH_3$. Tin bromide hydrobromate was obtained during the action of tin tetrabromide and bromine upon alcohols. The authors describe its sodium, calcium, strontium, magnesium, manganese, iron, nickel, and cobalt salts. They have also studied the oxy-bromides.

Communications from the Chemical Laboratory of the University of Jena.—These consist of a memoir on the polysulphides of sodium, by Dr. H. Böttger; three others, by the same author respectively on the constitution of the alkaline polysulphides, on the action of sulphur upon sodium mercaptide, and on sulphethyl; a paper by Dr. Hugo Prinz on the constitution of sulphur chloride, and one by the same author on experiments on combining sulphur with sulphur. The result reached in this last paper is that no such combination is formed by the reciprocal action of compounds from which such a result might be expected, but that the sulphur oxy-chlorides are so decomposed in contact with other sulphur compounds as if the residue, SCl_4 , was contained in them.

Journal für Praktische Chemie.
New Series, Vol. xxix., Part 3.

Quantitative Determination of Morphine in Opium.—H. von Perger.—This paper will be inserted at length.

Studies on Milk.—H. Struve.—A series of investigations on human milk.

On so-called Rubean-Hydrogen.—R. Wollner.—The compound in question, $C_2N_2H_4S_2$, is formed by passing dry cyanogen gas into an alcoholic solution of sodium sulphhydrate. The author considers that this compound is a derivative of a still unknown compound—thio-oxalic acid.

A Pneumatic Trough without a Shelf and with freely-suspended Cylinders.—Dr. F. Gottschalk.—This apparatus cannot be described intelligibly without the accompanying diagram.

Oxy-base of Cyan-methine, $C_6H_8N_2O$.—R. Wollner.—This base is obtained by the action of nitrous acid upon cyan-methine in an acetic solution when hydroxyl is substituted for the amide.

Action of Potassium Permanganate upon Mercury Diphenyl.—Robert Otto.—A correction of a statement made by the author in the *Annalen der Chemie und Pharmacie*, 154, p. 93.

Trichlor-methyl-sulphon Chloride.—G. McGowan.—In this preliminary communication the author announces that he is examining in what manner the nature of the compounds in question is affected by the introduction of one or more atoms of chlorine. Methyl-sulphon chloride yields with ammonia the amide, and with aniline the anilide of methyl-sulphonic acid.

Remarks on the Chemical Constitution of Anthraquinone, Anthracene, and accompanying Compounds.—E. von Meyer.—The author regards anthraquinone not as a diketone, but as a derivation of phthalide. Numerous experimental facts concerning anthraquinone are in perfect harmony with the view that anthraquinone is an orthophenylen-phthalide, in which orthophenylen takes the place of two atoms hydrogen of the phthalide.

Vol. xxix., Parts 4 and 5.

Action of Reducing Agents upon Ortho-nitro-phenoxy-acetic Acid.—Alexander Thate.—The best method for preparing ortho-nitro-phenoxy-acetic acid is to heat equivalent quantities of ortho-nitro-phenol sodium and sodium mono-chloracetate to 100° for 10 to 12 hours in a concentrated aqueous solution. By the reduction of ortho-nitro-phenoxy-acetic acid in an alkaline solution by means of sodium amalgam, there are obtained in succession azoxy-ortho-phenoxy-acetic acid, azortho-phenyloxy-acetic acid, hydrazo-ortho-phenoxy-acetic acid, and ortho-amido-phenoxy-acetic acid. By the reduction of ortho-nitro-phenoxy-acetic acid with iron filings and acetic acid, it is easy to obtain ortho-amido-phenoxy-acetic anhydride, but not the azo-compounds derivable from ortho-nitro-phenoxy-acetic acid. By the reduction of ortho-nitro-phenoxy-acetic acid with stannous chloride in a hydrochloric solution, there is formed, firstly monochlor-ortho-amido-phenoxy-acetic anhydride, and along with it, especially if the reduction is imperfect, ortho-amido-phenoxy-acetic anhydride.

A Uranium Mineral from Moss, and on Naturally-occurring Uranates in General.—C. W. Blomstrand.—The mineral in question is found in the felspar quarries, near Moss, on the eastern side of the Christianiafjord. It contains nearly 81 per cent of uranoso-uranic oxide, along with 0.38 of the cerium earths, and 2.42 of the yttrium earths.

Electrolyses and Electro-syntheses.—E. Drechsel.—The author has studied electrolyses with alternating currents, employing electrodes of different metals, and the electro-synthesis of sulpho-phenol ether. The products obtained are in part the same as those formed in the animal body from phenol, the ether-sulphacids of phenol, hydroquinone, and pyrocatechin.

Letter of a Young Chemist to the Editor of the Journal.—An anonymous letter, in which the writer describes his conversion from the structural views of Beyer. He says, "Rau's work ('The Theories of Modern Chemistry') has changed me from a chemical Saul to a chemical Paul. There remains for me now the task of completely freeing myself from the chains of modern structural chemistry, and of becoming, as I have resolved, a zealous disciple of classical chemistry as planned by Berzelius, developed by Gay-Lussac, Graham, Liebig,

Wöhler, Bunsen, &c., and which will again become dominant in an early future."

Bulletin de la Société Chimique de Paris.
Vol. xlii., No. 1, July 5, 1884.

On certain Double Tungstates of Sodium and of the Metals of the Rare Earths.—M. A. Högbon.—The author has prepared these salts by dissolving the oxides in question and tungstic acid in melting sodium tungstate, or common salt, or in a mixture of both. All the salts described are insoluble in water. Acids attack them in the cold after some time. Hydrochloric acid, if concentrated, decomposes them perfectly. The author has obtained and examined the double tungstates of sodium and didymium, of sodium and yttrium, of sodium and cerium, of sodium and samarium, of sodium and erbium, and of sodium and thorium. M. Cleve remarks in a note, "It is very remarkable that all these double salts, in spite of their different compositions, crystallise in the same forms or in the form of scheelite; this latter mineral is also isomorphous with fergusonite.

No. 2, 1884.

The Decomposition of Sulphonic Acids by means of Hydrated Sulphuric Acid.—C. Friedel and J. M. Crafts.—The sulphonic acid, or one of its salts, is mixed with three or four times its weight of sulphuric acid diluted with about one-third its weight of water; a thermometer is placed in the liquid; a current of steam passed into the mixture, which is then heated in a retort up to the point at once the hydrocarbon begins to separate. The decomposition is rapid about 160°, and the temperature may be raised up to 175° to 180°.

On Bromo-nitrated Camphor.—P. Cazeneuve.—This compound crystallises from boiling alcohol at 83 per cent in magnificent prisms of an intense whiteness, insoluble in water, very soluble in ether, and melting at 103° to 104°. This compound is lævo-rotatory, like chloro-nitrated camphor a.

Combination of Gold Chlorides with Phosphorus Chlorides.—L. Lindet.—The author has obtained a compound of aurous chloride and phosphorus which crystallises in large oblique prisms, perfectly colourless. Its composition is $\text{Au}_2\text{Cl}_2\text{PCl}_3$. It is soluble in phosphorus proto-chloride; neither fusible nor volatile, but becomes decomposed above 100°, liberating phosphorus monochloride, and leaving a complex residue not yet examined. The auric compound, $\text{Au}_2\text{Cl}_3\text{PCl}_3$, appears in the form of a light flocculent precipitate formed of fine microscopic needles of a citron yellow.

Reaction of Albumen and of a Synthetic Nitrogenous Colloid.—E. Grimaux.—A solution of an amido-benzoic colloid prepared by the author gives almost exactly the same reactions as a 1 per cent solution of albumen. The chief difference is that the amido-benzoic compound is precipitated by acetic acid, whilst that of albumen is not. The author remarks that the facts obtained demonstrate the error of physiologists who maintain that the substances of the greatest importance for life no longer present the character of chemical compounds. The author's researches on the contrary prove that the albumenoids owe their complex reactions to their character as colloidal bodies; they are chemical species or mixtures of species, which, when once removed from the living organism, obey physico-chemical laws.

Composition of the Saline Mineral Water of Salies-du-Salat.—P. Sabatier.—This water approaches in composition that of the Mediterranean, from which it is distinguished by a greater quantity of sulphates and a smaller proportion of bromides and iodides.

Water-Glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S Ardwick Chemical Works Manchester.

UNIVERSITY COLLEGE, BRISTOL. CHEMICAL DEPARTMENT.

PROFESSOR—W. RAMSAY, Ph.D.
LECTURER—SYDNEY YOUNG, D.Sc.

The SESSION 1884-85 begins on 7th OCTOBER. Lectures on Inorganic, Organic, Advanced, and Technical Chemistry will be delivered during the Session. The Laboratories are fitted with the most recent improvements for the study of Practical Chemistry in all its branches. In the evening, Lectures on Inorganic Chemistry at reduced fees are delivered; and a Special Course of Lectures on Technical Chemistry is also given, with the co-operation of the Worshipful Company of Clothworkers. A Correspondence Class especially adapted for those engaged in the Clothworking and Dyeing Industries will begin in October. Several Scholarships are tenable at the College. Calendar, containing full information, price 1s. (by post 1s. 3d.). For prospectus and further information apply to the Registrar.

THE MASON COLLEGE, BIRMINGHAM. SESSION 1884-85.

FACULTIES OF SCIENCE AND ARTS.

The SESSION will commence on FRIDAY, the 3rd of OCTOBER NEXT.

All departments of the College are open to both sexes on the same terms. Special arrangements are made for the convenience of ladies. Syllabuses containing full information as to Admission of Students, Courses of Instruction, Fees, Entrance and other Scholarships, &c., may be had from Cornish Bros., Birmingham, or from the undersigned. Price 6d.; by post, 7d.

GEO. H. MORLEY, Secretary.

OWENS COLLEGE, MANCHESTER (VICTORIA UNIVERSITY).

A COMPLETE COURSE OF TECHNOLOGICAL CHEMISTRY, extending over three or four years, is given at the College. It appeals to Students intending to devote themselves more especially to Applied Chemistry a thorough training in three branches of instruction which form the scientific foundation of the subject.

The College Certificate is granted to Students on the successful completion of the Course.

Syllabuses of the Course, containing particulars of the several Classes, Fees, &c., will be forwarded on application.

J. HOLME NICHOLSON, Registrar.

THE LONDON HOSPITAL AND MEDICAL COLLEGE, MILK END, E.

The SESSION 1884-5 will commence on Wednesday, October 1st, 1884, when the Prizes for the past Session and the Nursing Probationers' Prizes will be distributed at 8 p.m., by the Right Hon. the Lord Mayor, M.P., accompanied by the Lady Mayoress. There will be a Conversation, to which all past and present students are invited. FOUR ENTRANCE SCHOLARSHIPS value £64, £40, £30, and £20, will be offered for competition at the end of September to new students. Fees for Lectures and Hospital Practice, 90 guineas in one payment, or 100 guineas in three instalments. All resident and other Hospital appointments are free, and the holders of all the Resident Appointments are provided with rooms and board entirely free of expense. The Resident Appointments consist of Five House-Physicians, Five House-Surgeons, and one Accoucheurship; Two Dressers and Two Maternity Pupils also reside in the H. spital. Special entries may be made for Medical and Surgical Practice. The London Hospital is now in direct communication by rail and tram with all parts of the Metropolis, and the Metropolitan, District, East London, and South-Eastern Railways have stations within a minute's walk of the H. spital and College.

For prospectus and particulars apply personally or by letter to

Milk End, E.

THE CHEMICAL NEWS.

VOL. L. No. 1293.

ADDRESS TO THE CHEMICAL SECTION OF THE BRITISH ASSOCIATION.

By Prof. HENRY FIELD ROSCOE, PH.D., LL.D., F.R.S.,
F.C.S., President of the Section.

With the death of Berzelius in 1848 ended a well-marked epoch in the history of our science; with that of Dumas—and, alas! that of Wurtz—also—in 1884 closes a second. It may not perhaps be unprofitable on the present occasion to glance at some few points in the general progress which chemistry has made during this period, and thus to contrast the position of the science in the “sturm und drang” year of 1848, with that in the present, perhaps, quieter period.

The differences between what may properly be termed the Berzelian era and that with which the name of Dumas will for ever be associated show themselves in many ways, but in none more markedly than by the distinct views entertained as to the nature of a chemical compound.

According to the older notions, the properties of compounds are essentially governed by the qualitative nature of their constituent atoms, which were supposed to be so arranged as to form a binary system. Under the new ideas, on the other hand, it is mainly the number and arrangement of the atoms within the molecule which regulate the characteristics of the compound, which is to be looked on not as built up of two constituent groups of atoms, but as forming one group.

Amongst those who successfully worked to secure this important change of view on a fundamental question of chemical theory, the name of Dumas himself must first be mentioned, and, following upon him, the great chemical twin-brethren Laurent and Gerhardt, who, using both the arguments of test-tube and of pen in opposition to the prevailing views, gradually succeeded, though scarcely during the lifetime of the first, in convincing chemists that the condition of things could hardly be a healthy one when chemistry was truly defined “as the science of bodies which do not exist.” For Berzelius, adhering to his preconceived notions, had been forced by the pressure of new discovery into the adoption of formulæ which gradually became more and more complicated, and led to more and more doubtful hypotheses, until his followers at last could barely succeed in building up the original radical from its numerous supposed component parts. Such a state of things naturally brought about its own cure, and the unitary formulæ of Gerhardt began to be generally adopted.

It was not, however, merely as an expression of the nature of the single chemical compound that this change was beneficial, but, more particularly, because it laid open the general analogies of similarly constituted compounds, and placed fact as the touchstone by which the constitution of these allied bodies should be ascertained. Indeed, Gerhardt, in 1852, gave evidence of the truth of this in his well-known theory of types, according to which, organic compounds of ascertained constitution can be arranged under the four types of hydrogen, hydrochloric acid, water, and ammonia, and of which it is, perhaps, not too much to say that it has, more than any other of its time, contributed to the clearer understanding of the relations existing amongst chemical compounds.

Another striking difference of view between the chemistry of the Berzelian era and that of what we sometimes term the modern epoch is illustrated by the so-called sub-

stitution theory. Dumas, to whom we owe this theory, showed that chlorine can take the place of hydrogen in many compounds, and that the resulting body possesses characters similar to the original. Berzelius opposed this view, insisting that the essential differences between these two elements rendered the idea of a substitution impossible, and notwithstanding the powerful advocacy of Liebig, and the discovery by Melsens of reverse substitutions (that is the re-formation of the original compound from its substitution-product), Berzelius remained to the end unconvinced, and that which was in reality a confirmation of his own theory of compound radicals, which, as Liebig says, “illumined many a dark chapter in organic chemistry,” was looked upon him as an error of the deepest dye. This inability of many minds to see in the discoveries of others confirmation of their own views is not uncommon; thus Dalton, we may remember, could never bring himself to admit the truth of Gay-Lussac's laws of gaseous volume-combination, although, as Berzelius very truly says, if we write *atom* for *volume* and consider the substance in the solid state in place of the state of gas, the discovery of Gay-Lussac is seen to be one of the most powerful arguments in favour of Dalton's hypothesis.

But there is another change of view, dating from the commencement of the Dumas epoch, which has exerted an influence equal, if not superior, to those already named on the progress of our science. The relative weights of the ultimate particles, to use Dalton's own words, which up to this time had been generally adopted by chemists, were the equivalent weights of Dalton and Wollaston, representing, in the case of oxygen and hydrogen, the proportions in which these elements combine, viz., as 8 to 1. The great Swedish chemist at this time stood almost alone in supporting another hypothesis: for, founding his argument on the simple laws of volume-combination enunciated by Gay-Lussac, he asserted that the true atomic weights are to be represented by the relations existing between equal volumes of the two gases, viz., as 16 to 1. Still these views found no favour in the eyes of chemists until Gerhardt, in 1843, proposed to double the equivalent weights of oxygen, sulphur, and carbon, and then the opposition which this suggestion met with was most intense, Berzelius himself not even deigning to mention it in his annual account of the progress of the science, thus proving the truth of his own words: “That to hold an opinion habitually often leads to such an absolute conviction of its truth that its weak points are unregarded, and all proofs against it ignored.” Nor were these views generally adopted by chemists until Cannizzaro, in 1858, placed the whole subject on its present firm basis by clearly distinguishing between equivalent and molecular weights, showing how the atomic weights of the constituent elements are derived from the molecular weights of their volatile compounds based upon the law of Avogadro and Ampère, or where, as is the case with many metals, no compounds of known vapour-density exist, how the same result may be ascertained by the help of the specific heat of the element itself. Remarkable as it may appear, it is nevertheless true that it is in the country of their birth that Gerhardt's atomic weights and the consequent atomic nomenclature have met with most opposition, so much so that within a year or two of the present time there was not a single course of lectures delivered in Paris in which these were used.

The theory of organic radicals, developed by Liebig so long ago as 1834, received numerous experimental confirmations in succeeding years. Bunsen's classical research on acetyl, proving the possibility of the existence of metallo-organic radicals capable of playing the part of a metal, and the isolation of the hydrocarbon ethyl by Frankland in 1849, laid what the supporters of the theory deemed the final stone in the structure.

The fusion of the radical and type theories, chiefly effected by the discovery in 1849 of the compound ammonias by Wurtz, brings us to the dawn of modern

chemistry. Henceforward organic compounds were seen to be capable of comparison with simple inorganic bodies, and hydrogen not only capable of replacement by chlorine, or by metal, but by an organic group or radical.

To this period my memory takes me back. Liebig and Giessen, Wöhler in Göttingen, Bunsen in Marburg, Dumas, Wurtz, and Laurent and Gerhardt in Paris, were the active spirits in continental chemistry. In our own country, Graham, whose memorable researches on the phosphates had enabled Liebig to found his theory of polybasic acids, was working and lecturing at University College, London; and Williamson, imbued with the new doctrines and views of the twin French chemists, had just been appointed to the chair of practical chemistry in the same college vacant by the death of poor Fownes. At the same time Hofmann, in whom Liebig found a spirit as enthusiastic in the cause of scientific progress as his own, bringing to England a good share of the Giessen fire, founded the most successful school of chemistry which this country has yet seen.

At the Edinburgh meeting of this Association in 1850, Williamson read a paper on "Results of a Research on *Ætherification*," which included not only a satisfactory solution of an interesting and hitherto unexplained problem, but was destined to exert a most important influence on the development of our theoretical views. For he proved, contrary to the then prevailing idea, that ether contains twice as much carbon as alcohol, and that it is not formed from the latter by a mere separation of the elements of water, but by an exchange of hydrogen for ethyl, and this fact being in accordance with Avogadro's law of molecular volumes, could only be represented by regarding the molecule of water as containing two atoms of hydrogen to one of oxygen, one of the former being replaced by one of ethyl to form alcohol, and the two of hydrogen by two of ethyl to form ether. Then Williamson introduced the type of water (subsequently adopted by Gerhardt) into organic chemistry, and extended our views of the analogies between alcohols and acids, by pointing out that these latter are also referable to the water-type, predicting that bodies bearing the same relations to the ordinary acids as the ethers do to the alcohols must exist, a prediction shortly afterwards (1852) verified by Gerhardt's discovery of the anhydrides. Other results followed in rapid succession, all tending to knit together the framework of modern theoretical chemistry. Of these the most important was the adoption of condensed types, of compounds constructed on the type of two and three molecules of water, with which the names of Williamson and Odling are connected, culminating in the researches of Brodie on the higher alcohols, of Berthelot on glycerine, and of Wurtz on the dibasic alcohols or glycyls; whilst, in another direction, the researches of Hofmann on the compound amines and amides opened out an entirely new field, showing that either a part or the whole of the hydrogen in ammonia can be replaced by other elements or elementary groups without the type losing its characteristic properties.

Again, in 1852, we note the first germs of a theory which was destined to play an all-important part in the progress of the science, viz., the doctrine of valency or atomicity, and to Frankland it is that we owe this new departure. Singularly enough, whilst considering the symmetry of construction visible amongst the inorganic compounds of nitrogen, phosphorus, arsenic, and antimony, and whilst putting forward the fact that the combining power of the attracting element is always satisfied by the same number of atoms, he does not point out the characteristic tetrad nature of carbon; and it was not until 1858 that Couper initiated, and Kekulé, in the same year, thoroughly established the doctrine of the linking of the tetrad carbon atoms, a doctrine to which, more than to any other, is due the extraordinary progress which organic chemistry has made during the last twenty years, a progress so vast, that it is already found impossible for one individual, even though he devote his whole time and

energies to the task, to master all the details, or make himself at home with the increasing mass of new facts which the busy workers in this field are daily bringing forth.

The subject of the valency of the elements is one which, since the year above referred to, has given chemists much food for discussion, as well as opportunity for experimental work. But whether we range ourselves with Kekulé, who supports the unalterable character of the valency of each element, or with Frankland, who insists on its variability, it is now clear to most chemists that the hard and fast lines upon which this theory was supposed to stand cannot be held to be secure. For if the progress of investigation has shown that it is impossible in many instances to affix one valency to an element which forms a large number of different compounds, it is also equally impossible to look on the opposite view as tending towards progress, inasmuch as to ascribe to an element as many valencies as it possesses compounds with some other element, is only expressing by circuitous methods what the old Daltonian law of combination in multiple proportions states in simple terms. Still we may note certain generally-accepted conclusions: in the first place that of the existence of non-saturated compounds both inorganic and organic, as carbon-monoxide on the one hand, and malic and citraconic acids on the other. Secondly, that the valency of an element is not only dependent upon the nature of the element with which it combines, but that this valency is a periodic function of the atomic weight of the other component. Thus the element of the chlorine group are always monads when combined with positive elements or radicals, but triad, pentad, and heptad with negative ones. Again, the elements of the sulphur group are dyads in the first case, but tetrad and hexad in the second. The periodicity of this property of the atoms, increasing and again diminishing, is clearly seen in such a series as—

as well as in the series of oxides. The difficulties which beset this subject may be judged of by the mention of a case or two:—Is vanadium a tetrad because its highest chloride contains four atoms of chlorine? What are we to say is the valency of lead when one atom unites with four methyls to form a volatile product, and yet the vapour-density of the chloride shows that the molecule contains one of metal to two of chlorine? Or, how can our method be said to determine the valency of tungsten when the hexachloride decomposes in the state of vapour, and the penta-chloride is the highest volatile stable compound? How again are we to define the point at which a body is volatile without decomposition?—thus sulphur tetra-chloride, one of the most unstable of compounds, can be vapourised without decomposition at all temperatures below -22° , whilst water, one of the most stable of known compounds, is dissociated into its elements at the temperature of melting platinum.

But, however, many doubts may have been raised in special instances against a thorough application of the law of valency, it cannot be denied that the general relations of the elements which this question of valency has been the means of bringing to light are of the highest importance, and point to the existence of laws of nature of the widest significance; I allude to the periodic law of the elements first foreshadowed by Newlands, but fully developed by Mendeleeff and Lothar Meyer. Guided by the principle that the chemical properties of the elements are a periodic function of their atomic weights, or that matter becomes endowed with analogous properties when the atomic weight of an element is increased by the same or nearly the same number, we find ourselves for the first time in possession of a key which enables us to arrange the hitherto *disjecta membra* of our chemical household in something like order, and thus gives us means of indicating the family resemblances by which these elements are characterised.

And here we may congratulate ourselves on the fact

that, by the recent experiments of Brauner, and of Nilson and Petersen respectively, tellurium and beryllium, two of the hitherto outstanding members, have been induced to join the ranks, so that at the present time osmium is the only important defaulter amongst the sixty-four elements, and few persons will doubt that a little careful attention to this case will remove the stigma which yet attaches to its name. But this periodic law makes it possible for us to do more; for as the astronomer, by the perturbations of known planets, can predict the existence of hitherto unknown ones, so the chemist, though, of course, with much less satisfactory means, has been able to predict with precision the properties, physical and chemical, of certain missing links amongst the elements, such as ekaluminium and ekaboron, then unborn, but which shortly afterwards became well known to us in the flesh as gallium and scandium. We must, however, take care that success in a few cases does not blind us to the fact that the law of nature which expresses the relation between the properties of the elements and the value of the atomic weights is as yet unknown; that many of the groupings are not due to any well-ascertained analogy of properties of the elements, and that it is only because the values of their atomic weights exhibit certain regularities that such a grouping is rendered possible. So, to quote Lothar Meyer, we shall do well in this, as indeed in all similar cases in science, to remember the danger pointed out in Bacon's aphorism, that "The mind delights in springing up to the most general axioms, that it may find rest, but after a short stay here it disdains experience," and to bear in mind that it is only the lawful union of hypothesis with experiment which will prove a fruitful one in the establishment of a systematic inorganic chemistry which need not fear comparison with the order which reigns in the organic branch of our science. And here it is well to be reminded that complexity of constitution is not the sole prerogative of the carbon compounds, and that before this systematisation of inorganic chemistry can be effected we shall have to come to terms with many compounds concerning whose constitution we are at present wholly in ignorance. As instances of such I would refer to the finely crystalline phospho-molybdates, containing several hundred atoms in the molecule, lately prepared by Wolcott Gibbs.

Arising out of Kekulé's theory of the tetrad nature of the carbon atom, came the questions which have caused much debate among chemists: (1) Are the four combining units of the carbon atom of equal value or not? and (2) Is the assumption of a dyad carbon atom in the so-called non-saturated compounds justifiable or not? The answer to the first of these, a favourite view of Kolbe's, is given in the now well-ascertained laws of isomerism; and from the year 1862, when Schorlemmer proved the identity of the hydrides of the alcohol radicals with the so-called radicals themselves, this question may be said to be set at rest; for Lossen himself admits that the existence of his singular isomeric hydroxyl-amine derivatives can be explained otherwise than by the assumption of a difference between each of the combining units of nitrogen, and the differences supposed by Schreiner to hold good between the methyl-ethyl carbonic ethers have been shown to have no existence in fact. With respect to the second point the reply is no less definite, and is recorded in the fact, amongst others, that ethylene chlorhydrin yields on oxidation chloracetic acid, a reaction which cannot be explained on the hypothesis of the existence in ethylene of a dyad carbon atom.

Passing from this subject, we arrive, by a process of natural selection, at more complicated cases of chemical orientation—that is, given certain compounds which possess the same composition and molecular formulæ but varying properties, to find the difference in molecular structure by which such variation of properties is determined. Problems of this nature can now be satisfactorily solved, the number of possible isomers foretold, and this prediction confirmed by experiment. The general method adopted in such an experimental enquiry into the molecu-

lar arrangement or chemical constitution of a given compound is either to build up the structure from less complicated ones of known constitution, or to resolve it into such component parts. Thus, for example, if we wish to discriminate between several isomeric alcohols, distinguishing the ordinary or primary class from the secondary or tertiary class, the existence of which was predicted by Kolbe in 1862, and of which the first member was prepared by Friedel in 1864, we have to study their products of oxidation. If one yields an acid having the same number of carbon atoms as the alcohol, it belongs to the first class and possesses a definite molecular structure; if it splits up into two distinct carbon compounds, it is a secondary alcohol; and if three carbon compounds result from its oxidation, it must be classed in the third category, and to it belongs a definite molecular structure, different from that of the other two.

In a similar way orientation in the much more complicated aromatic hydro-carbons can be effected. This class of bodies forms the nucleus of an enormous number of carbon compounds which, both from a theoretical and a practical point of view, are of the highest interest. For these bodies exhibit characters and possess a constitution totally different from those of the so-called fatty substances, the carbon atoms being linked together more intimately than is the case in the latter-named group of bodies. Amongst them are found all the artificial colouring matters, and some of the most valuable pharmaceutical and therapeutical agents.

The discovery of the aniline colours by Perkin, their elaboration by Hofmann, the synthesis of alizarin by Graebe and Liebermann, being the first vegetable colouring matter which has been artificially obtained, the artificial production of indigo by Baeyer, and lastly the preparation by Fischer, of kairine, a febrifuge as potent as quinine, are some of the well-known recent triumphs of modern synthetic chemistry. And these triumphs, let us remember, have not been obtained by any such "random haphazarding" as yielded results in Priestley's time. In the virgin soil of a century ago, the ground only required to be scratched and the seed thrown in to yield a fruitful crop; now the surface soil has long been exhausted, and the successful cultivator can only obtain results by a deep and thorough preparation, and by a systematic and scientific treatment of his material.

In no department of our science has the progress made been more important than in that concerned with the accurate determination of the numerical, physical, and chemical constants upon the exactitude of which every quantitative chemical operation depends. For the foundation of an accurate knowledge of the first of these constants, viz., the atomic weights of the elements, science is indebted to the indefatigable labours of Berzelius. But "humanum est errare," and even Berzelius's accurate hand and delicate conscientiousness did not preserve him from mistakes, since corrected by other workers. In such determinations it is difficult, if not impossible, always to ascertain the limits of error attaching to the number. The errors may be due in the first place to manipulative faults, in the second to the inaccuracy of the methods, or lastly to mistaken views as to the composition of the material operation upon; and hence the uniformity of any series of similar determinations gives no guarantee of their truth, the only safe guide being the agreement of determinations made by altogether different methods. The work commenced by Berzelius has been worthily continued by many chemists. Stas and Marignac, bringing work of an almost astronomical accuracy into our science, have ascertained the atomic weights of silver and iodine to within one hundred-thousandth of their value, whilst the numbers for chlorine, bromine, potassium, sodium, nitrogen, sulphur, and oxygen may now be considered correct to within a unit in the fourth figure. Few of the elements, however, boast numbers approaching this degree of accuracy, and many may even still be erroneous, from half to a whole unit of hydrogen. And (as Lothar Meyer says)

until the greater number of the atomic weights are determined to within one or two tenths of the unit, we cannot expect to be able to ascertain the laws which certainly govern these numbers, or to recognise the relations which undoubtedly exist between them and the general chemical and physical properties of the elements. Amongst the most interesting recent additions to our knowledge made in this department we may note the classical experiments, in 1880, of J. W. Mallet on aluminium, and in the same year of J. P. Cooke on antimony, and those, in the present year, of Thorpe on titanium.

Since the date of Berzelius's death to the present day no discovery in our science has been so far-reaching, or led to such unforeseen and remarkable conclusions, as the foundation of Spectrum Analysis by Bunsen and Kirchhoff in 1860.

Independently altogether of the knowledge which has been gained concerning the distribution of the elementary bodies in terrestrial matter, and of the discovery of half-a-dozen new elements by its means, and putting aside for a moment the revelation of a chemistry not bounded by this world, but limitless as the heavens, we find that over and above all these results spectrum analysis offers the means, not otherwise open to us, of obtaining knowledge concerning the atomic and molecular condition of matter.

Let me recall some of the more remarkable conclusions to which the researches of Lockyer, Schuster, Liveing and Dewar, Wüllner, and others in this direction have led. In the first place it is well to bear in mind that a difference of a very marked kind, first distinctly pointed out by Alex. Mitscherlich, is to be observed between the spectrum of an element and that of its compounds, the latter only being seen in cases in which the compound is not dissociated at temperatures necessary to give rise to a glowing gas. Secondly, that these compound spectra—as, for instance, those of the halogen compounds of the alkaline-earth metals—exhibit a certain family likeness, and show signs of systematic variation in the position of the lines, corresponding to changes in the molecular weight of the vibrating system. Still this important subject of the relation of the spectra of different elements is far from being placed on a satisfactory basis, and in spite of the researches of Lecoq de Boisbaudran, Ditté, Troost and Hautefeuille, Ciamician, and others, it cannot be said that as yet definite proof has been given in support of the theory that a causal connection is to be found between the emission spectra of the several elements belonging to allied groups and their atomic weights or other chemical or physical properties. In certain of the single elements, however, the connection between the spectra and the molecular constitution can be traced. In the case of sulphur, for example, three distinct spectra are known. The first of these, a continuous one, is exhibited at temperatures below 500°, when, as we know from Dumas's experiments, the density of the vapour is three times the normal, showing that at this temperature the molecule consists of six atoms. The second spectrum is seen when the temperature is raised to above 1000°, when, as Deville and Troost have shown, the vapour reaches its normal density, and the molecule of sulphur, as with most other gases, contains two atoms, and this is a band spectrum, or one characterised by channelled spaces. Together with this band spectrum, and especially round the negative pole, a spectrum of bright lines is observed. This latter is doubtless due to the vibrations of the single atoms of the dissociated molecule, the existence of traces of a band spectrum demonstrating the fact that in some parts of the discharge the tension of dissociation is insufficient to prevent the reunion of the atoms to form the molecule.

To this instance of the light thrown on molecular relations by changes in the spectra, others may be added. Thus the low-temperature spectrum of channelled spaces, mapped by Schuster and myself, in the case of potassium, corresponds to the molecule of two atoms and to the vapour-density of seventy-nine, as observed by Dewar and Dittmar. Again, both oxygen and nitrogen exhibit two,

if not three, distinct spectra; of these the line spectrum seen at the highest temperatures corresponds to the atom; the band spectrum seen at intermediate temperatures represents the molecule of two atoms; whilst that observed at a still lower point would, as in the case of sulphur, indicate the existence of a more complicated molecule, known to us in one instance as ozone.

That this explanation of the cause of these different spectra of an element is the true one, can be verified in a remarkable way. Contrary to the general rule amongst those elements which can readily be volatilised, and with which, therefore, low-temperature spectra can be studied, mercury exhibits but one spectrum, and that one of bright lines, or, according to the preceding theory, a spectrum of atoms. So that, judging from spectroscopic evidence, we infer that the atoms of mercury do not unite to form a molecule, and we should predict that the vapour-density of mercury is only half its atomic weight. Such we know, from chemical evidence, is really the case, the molecule of mercury being identical in weight with its atom.

The cases of cadmium and iodine require further elucidation. The molecule of gaseous cadmium, like that of mercury, consists of one atom; probably, therefore, the cadmium spectrum is also distinguished by one set of lines. Again, the molecule of iodine at 1200° separates, as we know from Victor Meyer's researches, into single atoms. Here spectrum analysis may come again to our aid; but, as Schuster remarks, in his report on the spectra of the non-metallic elements, a more extensive series of experiments than those already made by Ciamician is required before any definite opinion as to the connection of the different iodine spectra with the molecular condition of the gas can be expressed.

It is not to be wondered at that these relations are only exhibited in the case of a few elements. For most of the metals the vapour-density remains, and probably will remain, an unknown quantity, and therefore the connection between any observed changes in the spectra and the molecular weights must also remain unknown. The remarkable changes which the emission spectrum of a single element—iron, for instance—exhibits have been the subject of much discussion, experimental and otherwise. Of these, the phenomenon of long and short lines is one of the most striking, and the explanation that the long lines are those of low temperature appears to meet the facts satisfactorily, although the effect of dilution—that is, a reduction of the quantity of material undergoing volatilisation—is, remarkably enough, the same as that of diminution of temperature. Thus it is possible, by the examination of a spectrum by Lockyer's method, to predict the changes which it will undergo, either on alteration of temperature or by an increase or decrease of quantity. There appears to be no theoretical difficulty in assuming that the relative intensity of the lines may vary when the temperature is altered, and the molecular theory of gases furnishes us with a plausible explanation of the corresponding change when the relative quantities of the luminous elements in a mixture are altered. Lockyer has proposed a different explanation of the facts. According to him every change of relative intensity means a corresponding change of molecular complexity, and the lines which we see strong near the poles would bear the same relation to those which are visible throughout the field as a line spectrum bears to a band spectrum; but then almost every line must be due to a different molecular grouping, a conclusion which is scarcely capable of being upheld without very cogent proof.

The examination of the absorption spectra of salts, saline and organic liquids, first by Gladstone, and afterwards by Bunsen and by Russell, as well as by Hartley for the ultra-violet, and by Abney and Festing for the infra-red region, have led to interesting results in relation to molecular chemistry. Thus Hartley finds that in some of the more complicated aromatic compounds, definite absorption bands in the more refrangible region are only

produced by substances in which three pairs of carbon atoms are doubly linked, as in the benzene ring, and thus the means of ascertaining this double linkage is given. The most remarkable results obtained by Abney and Festing show that the radical of an organic body is always represented by certain well-marked absorption bands, differing, however, in position, according as it is linked with hydrogen, a halogen, or with carbon, oxygen, or nitrogen. Indeed these experimenters go so far as to say that it is highly probable that by this delicate mode of analysis the hypothetical position of any hydrogen which is replaced may be identified, thus pointing out a method of physical orientation of which, if confirmed by other observers, chemists will not be slow to avail themselves. This result, it is interesting to learn, has been rendered more than probable by the recent important researches of Perkin on the connection between the constitution and the optical properties of chemical compound.

One of the noteworthy features of chemical progress is the interest taken by physicists in fundamental questions of our science. We all remember, in the first place, Sir William Thomson's interesting speculations, founded upon physical phenomena, respecting the probable size of the atom, viz., "that if a drop of water were magnified to the size of the earth, the constituent atoms would be larger than small shot, but smaller than cricket balls." Again, Helmholtz in the Faraday lecture, delivered in 1881, discusses the relation of electricity and chemical energy, and points out that Faraday's law of electrolysis, and the modern theory of valency, are both expressions of the fact that when the same quantity of electricity passes through an electrolyte it always either sets free, or transfers to other combinations, the same number of units of affinity at both electrodes. Helmholtz further argues that if we accept the Daltonian atomic hypothesis we cannot avoid the conclusion that electricity, both positive and negative, is divided into elementary portions which behave like atoms of electricity. He also shows that these charges of atomic electricity are enormously large as compared, for example, with the attraction of gravitation between the same atoms; in the case of oxygen and hydrogen, 71,000 billion times larger.

A further subject of interest to chemists is the theory of the vortex-ring constitution of matter thrown out by Sir William Thomson, and lately worked out from a chemical point of view by J. J. Thomson, of Cambridge. He finds that if one such ring be supposed to constitute the most simple form of matter, say the monad hydrogen atom, then two such rings must, on coming into contact with nearly the same velocity, remain enchain'd together, constituting what we know as the molecule of free hydrogen. So, in like manner, systems containing two, three, and four such rings constitute the dyad, triad, and tetrad atoms. How far this mathematical expression of chemical theory may prove consistent with fact remains to be seen.

Another branch of our science which has recently attracted much experimental attention is that of thermochemistry, a subject upon which in the future the foundation of dynamical chemistry must rest, and one which already proclaims the truth of the great principle of the conservation of energy in all cases of chemical as well as of physical change. But here, although the materials hitherto collected are of very considerable amount and value, the time has not yet arrived for expressing these results in general terms, and we must therefore be content to note progress in special lines and wait for the expansion into wider areas. Reference may, however, be properly made to one interesting observation of general significance. It is well known that, while in most instances the act of combination is accompanied by evolution of heat,—that is, whilst the potential energy of most combining bodies is greater than that of most compounds,—cases occur in which the reverse of this is true, and heat is absorbed in combination. In such cases the compound

readily undergoes decomposition, frequently suddenly and with explosion. Acetylene and cyanogen seem to be exceptions to this rule, inasmuch as, whilst their component elements require to have energy added to them in order to enable them to combine, the compounds appear to be very stable bodies. Berthelot has explained this enigma by showing that, just as we may ignite a mass of dynamite without danger, whilst explosion takes place if we agitate the molecules by a detonator, so acetylene and cyanogen burn, as we know, quietly when ignited, but when their molecules are shaken by the detonation of even a minute quantity of fulminate the constituents fly apart with explosive violence, carbon and hydrogen, or carbon and nitrogen being set free, and the quantity of heat absorbed in the act of combination being suddenly liberated.

In conclusion, whilst far from proposing even to mention all the important steps which our science has advanced since the year 1848, I cannot refrain from referring to two more. In the first place, to that discovery, more than foreshadowed by Faraday, of the liquefaction of the so-called permanent gases by Pictet and Cailletet; and secondly, to that of the laws of dissociation as investigated by Deville. The former, including Andrews's discovery of the critical point, indicates a connection, long unseen, between the liquid and the gaseous states of matter; the latter has opened out entirely fresh fields for research, and has given us new views concerning the stability of chemical compounds of great importance and interest.

Turning for a moment to another topic, we feel that, although Science knows no nationalities, it is impossible for those who, like ourselves, exhibit strong national traits to avoid asking whether we Anglo-Saxons hold our own, as compared with other nations, in the part we have played and are playing in the development of our science. With regard to the past, the names of Boyle, Cavendish, Priestley, Dalton, Black, Davy, are sufficient guarantees that the English have, to say the least, occupied a position second to none in the early annals of chemistry. How has it been in the era which I have attempted to describe? What is the present position of English chemistry, and what its look-out for the future? In endeavouring to make this estimate I would take the widest ground, including not only the efforts made to extend the boundaries of our science by new discovery, both in the theoretical and applied branches, but also those which have the no less important aims of spreading the knowledge of the subject amongst the people, and of establishing industries dependent on chemical principles by which the human race is benefitted. Taking this wide view I think we may, without hesitation, affirm that the progress which chemistry has made through the energies of the Anglo-Saxon race is not less than that made by any other nation.

In so far as pure science is concerned I have already given evidence of the not inconsiderable part which English chemists have played in the progress since 1848. We must, however, acknowledge that the number of original chemical papers now published in our language is much smaller than that appearing in the German tongue, and that the activity and devotion displayed in this direction by the heads of German laboratories may well be laid to heart by some of us in England; yet, on the other hand, it must be remembered that the circumstances of different countries are so different that it is by no means clear that we should follow the same lines. Indeed our national characteristics forbid us to do so, and it may be that the bent of the Germanic lies in the assiduous collection of facts, whilst their subsequent elaboration and connection is the natural work of our own race.

As regards the publication of so-called original work by students, and speaking now only for myself as the director of an English chemical laboratory, I feel I am doing the best for the young men who, wishing to become either

scientific or industrial chemists, are placed under my charge, in giving them as sound and extensive a foundation in the theory and practice of chemical science as their time and abilities will allow, rather than forcing them prematurely into the preparation of a new series of homologous compounds, or the investigation of some special reaction, or of some possible new colouring-matter, though such work might doubtless lead to publication. My aim has been to prepare a young man, by a careful and fairly complete general training, to fill with intelligence and success a post either as teacher or industrial chemist, rather than to turn out mere specialists, who, placed under other conditions than those to which they have been accustomed, are unable to get out of the narrow groove in which they have been trained. And this seems a reasonable course, for whilst the market for the pure specialist—as the colour chemist, for example—may easily be overstocked, the man of all-round intelligence will always find opportunity for the exercise of his powers. Far, however, from underrating the educational advantages of working at original subjects, I consider this sort of training to be of the highest and best kind, but only useful when founded upon a sound and general basis.

The difficulty which the English teacher of chemistry—and in this I may include Canada and the United States—has to contend against is, that whilst in Germany the value of this high and thorough training is generally admitted, in England a belief in its efficacy is as yet not generally entertained. "The Englishman," to quote from the recent Report of the Royal Commission on Technical Instruction, "is accustomed to seek for an immediate return, and has yet to learn that an extended and systematic education, up to and including the methods of original research, is now a necessary preliminary to the fullest development of industry; and it is to the gradual but sure growth of public opinion in this direction that we must look for the means of securing to this country in the future, as in the past, the highest position as an industrial nation."

If, in the second place, we consider the influence which Englishmen have exerted on the teaching of our science, we shall feel reason for satisfaction; many of our textbooks are translated into every European language and largely used abroad—often to the exclusion of those written by continental chemists.

Again, Science teaching, both practical and theoretical, in our elementary and many secondary schools, is certainly not inferior to that in schools of similar grade abroad, and the interest in and desire for scientific training is rapidly spreading throughout our working population, and is even now as great as, if not greater than, abroad. The universities and higher colleges are also moving to take their share of the work which has hitherto been far less completely done in our country than on the continent of Europe, especially in Germany, where the healthful spirit of competition, fostered by the numerous State-supported institutions, is much more common than with us, and, being of equal value in educational as in professional or commercial matters, has had its due effect.

Turning lastly to the practical applications of our science, in what department does England not excel? and in which has she not made the most important new departures? Even in colour chemistry, concerning which we have heard, with truth, much of German supremacy, we must remember that the industry is originally an English one, as the names of Perkin and of Maule, Simpson and Nicholson testify; and if we have hitherto been beaten hollow in the development of this branch, signs are not wanting that this may not always be the case. But take any other branch of applied chemistry,—the alkali trade, for instance,—what names but English, with the two great exceptions of Leblanc and Solvay, do we find in connection with real discoveries? In the application of chemistry to metallurgical processes, too, the names of Darby, Cort, Neilson, and Bell in iron; of Bessemer, Thomas, Gilchrist, and Snelus in steel; of

Elkington and Matthey in the noble metals, show that in these branches the discoveries which have revolutionised processes have been made by Englishmen; whilst Young, the father of paraffin, Spence the alum maker, and Abel of gun-cotton fame are some amongst many of our countrymen whose names may be honourably mentioned as having founded new chemical industries.

Hence, whilst there is much to stimulate us to action in the energy and zeal shown by our continental brethren in the pursuit both of pure and applied chemistry, there is nothing to lead us to think that the chemistry of the English-speaking nations in the next fifty years will be less worthy than that of the past half-century of standing side by side with that of her friendly rivals elsewhere.

ESTIMATION OF MANGANESE IN CAST-IRON AND SPIEGELEISEN.

By CHARLES L. BLOXAM.

THE estimation of small quantities of manganese in presence of much iron by converting the latter into ferric acetate, and boiling the largely diluted solution to precipitate the iron as basic ferric acetate, is troublesome on account of the large volume of liquid to be boiled and filtered; an operation which must be repeated, for unless the basic ferric acetate be re-dissolved and re-precipitated, the whole of the manganese is not obtained. Moreover, an unpractised operator frequently fails to effect complete precipitation of the iron, or obtains the precipitate in such a condition that filtration is very difficult.

A more convenient process, which I have not found described elsewhere, consists in precipitating the iron as ferric phosphate in presence of acetic acid, which retains the manganese dissolved. The metal is dissolved in HCl in a small beaker, the solution evaporated to dryness in the beaker, the residue dissolved in water with a little HCl, filtered from graphite and silica, the filtrate peroxidised by adding a few crystals of KClO_3 and heating, diluted with a convenient quantity of water, NH_3 added till the first-formed precipitate dissolves reluctantly on stirring, NH_3 mixed with excess of acetic acid (added in sufficient quantity to convert all the iron into acetate) and an excess of sodium phosphate. The cream-coloured precipitate of ferric phosphate is filtered off, the precipitate re-dissolved (without washing) in HCl, the solution again nearly neutralised with NH_3 and precipitated with the mixture of NH_3 with excess of acetic acid. The two filtrates are mixed, an excess of NH_3 added and boiled, when the manganese is precipitated as the crystalline, very insoluble ammonio-phosphate, which is filtered off and washed. As soon as the washings leave no residue on evaporation, the wet filter, with the precipitate, is placed in a platinum crucible, which is then covered and quickly heated to redness by a Bunsen burner. After ignition, the precipitate is $\text{Mn}_2\text{P}_2\text{O}_7$. (The precipitation of manganese as ammonio-phosphate was recommended by Dr. Wolcott Gibbs; see *CHEMICAL NEWS*, vol. xvii., p. 195.)

It is well, if possible, to keep the ammoniacal solution near its boiling-point for an hour, and to set it aside for the night, though the greater part of the manganese is precipitated at once on ebullition. The ignited precipitate should be re-dissolved in HCl and the solution mixed with ammonium acetate, to detect any ferric phosphate, which, if worth notice, may be ignited, weighed, and deducted.

For the determination of manganese in a sample of spiegeleisen, 10 grains were taken. This required about 100 grains of crystallised sodium phosphate. Three determinations gave,—for the percentage of Mn, 10.1, 10.05, and 9.98.*

Precipitation of the iron as basic acetate, and of the manganese as dioxide by bromine, gave 10.47 per cent;

* The ferric phosphate was found to be free from manganese.

the precipitate containing, in addition to the manganese, the small quantities of copper, &c., which bromine always precipitates from the slightly ammoniacal solution.

To estimate the manganese in a sample of grey cast-iron 50 grains were employed; the iron being precipitated by about 300 grains of crystallised sodium phosphate in a solution diluted to about ten ounces. Two determinations gave for the percentage of Mn 0.92 and 0.87, whilst the basic acetate and bromine process gave, in two cases, 0.87 and 0.83.

Doubtless a closer agreement in the results would be arrived at by constant practice in the process.

King's College, London,
August 20, 1884.

ON THE ELECTRO-DEPOSITION OF CARBON, &c.*

By G. GORE, LL.D., F.R.S.

THE following experiments were made as attempts to electro-deposit carbon, boron, and silicon:—

1. A fused mixture of 200 grains of pure sodic hydrate, 170 grains of pure precipitated silica, and 610 grains of the mixed anhydrous carbonates of potassium and sodium, was electrolysed by means of a current from ten Smee's elements, with a sheet platinum anode, and a thick platinum wire cathode. The conduction was free, and much oxygen, which re-lighted a red-hot splint, was liberated at the anode. Dark streams flowed from the cathode; sodium was also set free, and if the cathode was only slightly immersed, bubbles of sodium vapour were emitted and took fire at the surface of the liquid. After one hour's action the platinum anode had lost 0.37 grain in weight. The cathode had a feebly adherent rough deposit of a dull jet-black colour upon it. This deposit was subsequently washed and dried; a portion of it burned with a glow when heated to redness on platinum, and left a minute residue of grey platinum: it also deflagrated with fused nitre below a red heat, and vividly by heating with potassic chlorate. It did not dissolve nor evolve any gas in a mixture of strong nitric acid and pure concentrated hydrofluoric acid. It was, therefore, not silicon but carbon containing a minute quantity of platinum.

As carbon was not readily deposited from the fused carbonates of potassium and sodium (see Expt. 4), whilst silicon was deposited from the fused silico-fluoride of potassium (see Expt. 3); and as an excess of silicon fused with potassic carbonate sets free carbon, but silicon with an excess of the carbonate liberates carbonic oxide, the carbon liberated in the present experiment may have been a secondary result, and an effect of previously deposited silicon reacting upon the fused mixture. It was with an expectation of this effect that I employed silica in the mixture.

2. I also electrolysed in a platinum cup a fused mixture of 475.2 grains of 97.1 per cent sodic carbonate,† and 217.4 grains of boro-fluoride of sodium, by means of the same current; a sheet platinum anode and thick platinum wire cathode. Conduction was free. Gas arose from the anode. A small amount of black deposit formed on the wire. After having been well washed, the deposit was dried, put on a platinum dish, and heated to redness; it burned with sudden incandescence until nearly the whole was consumed; it was therefore nearly wholly carbon.

3. I electrolysed in a platinum cup a fused mixture of 300 grains of 97.1 per cent pure potassic carbonate and 442 grains of silico-fluoride of potassium, by a current from ten Smee's cells, a sheet platinum anode, and a platinum wire cathode. Gas arose from the anode, and at first only gas arose from the cathode also. After that

streams of black matter poured down from the cathode, and the latter acquired a blackish film, but subsequently became alloyed, and fused on its surface. The deposit was therefore partly or wholly silicon.

4. A mixture of 10 parts of pure anhydrous sodic carbonate and 13 parts of pure anhydrous potassic carbonate was fused in a platinum cup, and electrolysed by a current from eight Smee's cells and platinum electrodes at a red-heat. Very free conduction occurred. Gas was copiously evolved from the anode; an abundant liberation of sodium occurred at the cathode. No gas arose at the cathode, but dark streams issued from it beneath the surface of the liquid. The anode became brown, but had lost only 0.9 grain during an hour-and-a-half's action. The cathode did not alloy with the sodium but became brown, and was corroded at the surface of the liquid. A thin cathode of pure gold soon alloyed with the sodium, and melted at its extremity, although the temperature was below that of melting silver (probably in consequence of alloying with sodium); a thick one also gave off sodium vapour, alloyed and fused. A thick cathode of pure silver gave off sodium freely, but was soon cut in two at the surface of the liquid; its end became arborescent as if it had absorbed vapour of sodium, and expelled it again as does oxygen. No free carbon appeared.

5. I also electrolysed a mixture of 274 grains of pure sodic carbonate, 375 grains of pure potassic carbonate, both anhydrous, and 206 grains of crystallised boracic acid, in a similar manner at a red-heat. There was free conduction, much gas from the anode, and an instant jet-black deposit formed upon the cathode, and could be burned off by a red heat. Metallic sodium was set free at the cathode, especially during deep immersion. The anode was soon much corroded, and acquired a very smooth surface, and platinum was deposited upon the cathode. No free carbon was ultimately found.

6. Potassic cyanide, fused in a porcelain crucible, was electrolysed by means of a current from twenty-five Smee's cells, with a coke anode and an iron cathode. Free action occurred; much gas was evolved from the carbon, and some from the iron. A blackish deposit formed upon the iron and sank to the bottom. A platinum cathode dissolved quickly.

7. Melted potassic cyanide in a porcelain capsule was electrolysed by means of a gas carbon anode, a thin platinum wire cathode, and a current from two cells of zinc and platinum in dilute sulphuric acid. No deposit occurred on the cathode in a quarter of an hour.

8. I electrolysed distilled water by means of a current from thirty Smee's cells and a gas carbon anode of fine quality, and a platinum wire cathode, the two electrodes being very close together. Very faint conduction occurred. The water became brownish in one hour; the carbon of the anode produced this effect. The anode was slightly disintegrated on the side towards the cathode. No deposit of carbon occurred.

9. By means of a current from the same battery, and a plumbago anode, I electrolysed a solution of potassic hydrate (with and without addition of oxalic acid). Free action occurred, and plenty of gas came from both electrodes. Saturated solutions of oxalic acid in hydrochloric acid and in nitric acid were also electrolysed by means of platinum electrodes. No carbon was deposited in either case.

10. I electrolysed a solution of pure formate of sodium and the strongest formic acid, by means of a current from four Smee's cells and electrodes of platinum. A black film deposit formed upon the cathode; it was not platinum nor carbon, but apparently oxide of iron.

11. Some oxalic acid was melted in its water of crystallisation, and the liquid electrolysed by the current from two small Smee's cells with platinum electrodes. Conduction was very feeble. Gas was evolved, but no solid deposit occurred.

12. I passed an electric current during one week from four Smee's cells, by means of platinum wires, through

* Read before the Birmingham Philosophical Society, June, 1884.
† The impurity consisted wholly of water.

pure, very dilute sulphuric acid in a large Y glass tube, one leg of which was kept full of a mixture of carbonic oxide and carbonic anhydride gases. The anode acquired a thin reddish coating, which dissolved soon after the current was stopped. No carbon was deposited.

13. A cold saturated solution of pyrogallic acid in water was electrolysed by means of a current from twenty-five Smee's cells, a large platinum anode, and a platinum wire cathode. Gas came rather freely from the wire, but none from the anode, and the liquid became quite brown by oxidation. No carbon was deposited.

14. Strong hydrochloric acid containing a large gas carbon anode, and a very small platinum wire cathode, was electrolysed by means of a current from thirty strong Smee's cells. Free action took place. Much gas came from both electrodes; apparently chlorine from the anode and hydrogen from the cathode. The cathode soon became black, but not when it was deeply immersed.

15. A carbon anode in pure nitric acid was rapidly disintegrated by a current from two Smee's cells. The conduction was free. A gas carbon anode was also much disintegrated in a solution of potassic chromate by a current from thirty Smee's cells. Gas came from both electrodes.

16. Hydrocyanic acid gas liquefied by cold, and containing a little water, was saturated with carbonic oxide gas, and a current from three to twelve cells of a Smee's battery passed through the liquid by means of two fine platinum wires. Gas was evolved from the cathode only. After three hours action no carbon was deposited.

17. Fuming Nordhausen sulphuric acid, also a syrupy solution of phosphoric acid, were saturated with dry carbonic anhydride, and then electrolysed by means of platinum wire electrodes, and currents from 112 Smee's cells in single series. Carbon was not deposited.

18. A saturated solution of oxalic acid in water was electrolysed by means of a current from ten Smee's cells, a charcoal anode, and platinum wire cathode, in a hermetically closed glass tube. Gas was evolved, and the cathode became black. As the pressure increased the conduction diminished, and at a pressure of about 50 or 60 atmospheres the tube burst. By the electrolysis of a saturated solution of oxalic acid in alcohol, with electrodes of platinum wire, a thin black deposit was formed upon the cathode.

19. The degrees of electric conduction resistance of distilled water, and water saturated with carbonic anhydride at 60° F., were examined. No conspicuous difference was perceived.

20. A current of coal-gas was passed during fourteen days through a glass vessel over dilute sulphuric acid, the acid liquid being constantly electrolysed by means of four Smee's cells and platinum wire electrodes. A little gas was evolved from the wires all the time, but no signs of deposited carbon appeared.

21. The electric current from a battery of three cells, composed of magnesium and palladium wires in water, conducted into water above a layer of CCl_4 by a purified gas carbon anode, and palladium wire cathode, did not set free carbon.

22. The dry brown salt produced by exposing thin sheets of potassium to the vapour of carbonic bisulphide was dissolved in ether, and the solution electrolysed by a current from twenty-five Smee's cells, and platinum wire electrodes. Much gas was evolved from the cathode, but no carbon set free.

Several of these experiments prove that carbon, boron, and silicon may be separated from their melted compounds by means of electrolysis; but although carbon was slowly deposited in several cases, in no instance was it obtained from an aqueous solution or in a crystalline state.

Action of Nascent Hydrogen upon Acetamide.—J. Ch. Essner.—The results obtained are alcohol, aldehyd, and an oily product which is decomposed on distillation. The evolution of ammonia is very distinct.—*Bull. Soc. Chim.*

QUANTITATIVE DETERMINATION OF VERY SMALL QUANTITIES OF SILVER.

By CARL FRIEDRICH FÖHR.

PROPORTIONS of silver which only form fractions of a thousandth per cent can be determined in the dry way. Besides the ordinary methods, which, when the proportion of silver is small, require much material and time, there is another dry process, the blowpipe test, which leads rapidly and accurately to the object required, but demands great skill and experience. The author makes use of a combination of the two methods for the determination of minimum quantities of silver, which gives very good results without requiring more time than an ordinary assay. The resulting bead of silver is measured on a blowpipe gauge.

Before describing the precautions and minutiae of this combination process it may be well to give a short account of the process of measurement employed in the present method as well as in the blowpipe assay.

As in the quantitative blowpipe assay for silver only 0.1 grm. = 1 blowpipe centimetre, is weighed out, the reguli, if the ore is poor, are too small to be weighed. Harkort first came upon the notion of measuring these globules and then calculating the percentage, since the weights of spheres of a metal are as the cubes of their diameter. To ascertain the latter, Harkort, and after him Plattner, made use of a narrow plate of ivory, upon which are drawn two converging lines with a maximum distance of 1 millimetre. These lines were about 15.5 centimetres in length to their point of intersection, and were divided by cross lines into 50 equal parts. In order to determine the values of this scale Harkort proceeded empirically, since the reguli are not mathematical spheres. He determined the proportion of silver in an ore accurately, by a series of assays in the muffle, selected then the most faultless bead of silver and moved it along between the converging lines of his scale till it touched them on both sides. At this point the proportion was noted in percentages calculated in blowpipe proof centners.

The other values were ascertained by calculation. If the necessary precautions are observed in reading off there are obtained with the scale good results, which agree perfectly with those obtained by cupellation. It is possible with the aid of a lens in measuring to determine with ease a proportion of 0.005 per cent of silver.

Sometimes, however, in the examination of poor burnt pyrites, &c., a much higher degree of accuracy is required. This can, however, be readily obtained by a combination of both methods. The bead obtained in the muffle from, e.g., 10 grms. of raw material is measured on the blowpipe scale, and the percentage is calculated according to the quantity taken. But since, as already mentioned, with the aid of the lens a bead may be measured which in the blowpipe assay (0.1 grm. taken) represents a percentage of 0.005 silver, it follows that by the combination method a percentage of $\frac{0.005}{100} = 0.00005$ (10 grms. being taken)

can be quite as readily determined.

Indeed, accuracy can be carried as far as is desirable. If we, for instance, combine the crucible assay with the blowpipe measurement we may determine a percentage of $\frac{0.005}{1000} = 0.000005$, if 100 grms. have been taken.

Besides, the combination method is much more accurate than the blowpipe assay, since an error committed during measuring is divided by 100 if we take 10 grms., and by 1000 if we take 100 grms.

As a degree of accuracy of 1-100000 per cent is sufficient even for the most delicate purposes, for instance, in petrographic researches in the origin of metallic veins, this silver-assay may be easily executed with the aid of a small muffle furnace, such as is generally to be found in laboratories for determining ashes, opening up ores, &c.

In order to determine proportions of silver of 0.0002 to

0.0007 per cent, the author proceeds as follows:—Into a small crucible of fire-clay are put about 20 grms. of a mixture of equal parts flour and potash. Upon this is placed the substance in question, carefully weighed (10 grms.). The whole is thoroughly mixed and covered with about 30 grms. of proof-lead, free from silver. The whole charge is then covered with sodium chloride and the crucible is placed in the muffle, which has been raised to a cherry-red heat, and left there for about three hours at a bright red heat until all the mass has been thoroughly liquefied.

Generally only two crucibles are used, assay and check-assay, placed in the muffle, and only if the silver is below 0.0002 per cent are four crucibles used, each with 10 grms. of the substance, the reguli being scorified together.

The lead reguli are generally too large to be at once driven off; they are generally scorified once and then transferred to the cupels.

In order to obtain a round, even bead, the operation is interrupted when the regulus is about of the size of a poppy seed, and completed in a second cupel. As soon as the cupel begins to fume it is drawn a little forward, and the aperture of the muffle is opened to prevent the bead from spitting by cooling slowly. Even the smallest beads spit if cooled too quickly.

The second driving may be advantageously effected before the blowpipe, as losses of silver are thus more readily avoided.

The bead of silver should be perfectly bright and white; it is carefully, and without great pressure, removed from the cupel by means of a forceps and a pointed knife, and cleansed by rubbing between blotting-paper.

Whilst measuring, the eye, in order to avoid parallax, is kept as nearly as possible vertically above the bead, the latter lying on the same surface as it did in the cupel. The measurement is repeated at least three times, with intervals, turning the bead in the same plane. The arithmetical mean divided by 100, if 10 grms. have been taken, is the proportion of silver.

Of course it is necessary before all things to ascertain whether the proof-bead used is absolutely free from silver. From 10 to 20 grms. are therefore examined according to the method above mentioned. Any silver found must then be deducted in subsequent operations.

Whether the combination method is applicable with the same accuracy to the determination of gold must be decided experimentally.

The method is especially suitable for very poor silicates and requires only from four-and-a-half to five hours for completion.—*Zeitschrift für Analyt. Chemie.*

NOTICES OF BOOKS.

The Retrospect of Medicine: being a Half-yearly Journal containing a Retrospective View of every Discovery and Practical Improvement in the Medical Sciences. Edited by W. BRAITHWAITE, M.D., and JAMES BRAITHWAITE, M.D. Vol. lxxxix., January to June, 1884. London: Simpkin, Marshall, and Co.

THIS volume contains much matter which will be found interesting to many educated men outside the medical profession. We may especially notice an article on malarial poisoning, by Dr. W. Johnstone Fyfe, Deputy Surgeon-General. The author gives the sad history of the Walcheren Expedition, and the almost equally lamentable story of the British army under Lord Raglan whilst encamped for four months in Bulgaria. He gives the following facts as proofs of the existence of a malarial poison germ:—These fevers have a period of incubation, followed by "fever-storm"; they have special organic lesions; the destructive effects of the poison upon the blood are demonstrable by actual observation; the evi-

dence of the communicability of the poison through potable water is very strong; and the influence of antidotes, such as quinine, arsenic, eucalyptus, &c., in counteracting the effects of the poison is clearly manifest. The author glances at the success of the Trappist monks in the sanitation of some of the most unhealthy districts in Italy, and reminds us that in England malarial fever was once a veritable plague, which has yielded to drainage and an improved water-supply, and now lingers in a few spots only, such as the Isle of Sheppey.

Dr. James Adam, in an article on disinfection by heat, points out that the germ-theory of infectious diseases, usually supposed to have been first devised by Pasteur, originated with Kircher 200 years ago, and was endorsed by Linnæus. Exposure to a temperature of from 212° to 230° F. is considered as sufficient for all practical purposes. It is, however, admitted that the spores of bacilli are destroyed only after being confined for three hours in a temperature of 284° F., and instances are recorded, apparently on the authority of Dr. Drysdale and Mr. Dallingier, of certain spores resisting for hours a temperature of 400° F.

An interesting paper, though unsatisfactory as regards its results, is that on the treatment of snake-poisoning, by Sir Joseph Fayrer, F.R.S. The conclusions of the author, based on very wide experience, are the reverse of hopeful. He said in 1868, and still is of opinion, that:—"To conceive of an antidote (as that term is usually understood) we must conceive of a substance so subtle as to follow, overtake, and neutralise the poison in the blood, and that shall have the power of counteracting or neutralising the poisonous and deadly influence it has exerted on vital force. Such a substance has still to be found, nor does our present experience of drugs give hopeful anticipation that we shall find it."

Lacerda, also, whilst maintaining the value of potassium permanganate as a chemical antidote where it can come in contact with the poison, admits that—"As to the idea of finding a physiological antidote for snake-poisoning, I entirely agree with you that it is a Utopia."

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 5, August 4, 1884.

Reply to two Notes by M. Wroblewski.—L. Cailliet.—The author protests against the statements of Wroblewski that all attempts hitherto made to liquefy hydrogen had proved unsuccessful, and that he (Cailliet) admitted that the liquefaction of hydrogen was a problem still to be solved.

Influence of Temperature on the Hygroscopicity of Vegetable Earth.—T. Schloesing.—The author gives his results in the form of a table.

New Apparatus for Collecting Carbon Dioxide in the "Snowy" State.—M. Ducretet.—The author's apparatus cannot be described intelligibly without the aid of the accompanying illustration.

Constitution of Certain Elementary Compounds of Cyanogen.—G. Calmels.—There are cyanides and isocyanides amongst the most simple derivatives of cyanogen, and their constitution is manifested by the fact that among the alkaline cyanides the radicle is fixed upon the carbon, whilst in those of the heavier metals it is fixed upon nitrogen.

On a Filter yielding Water Physiologically Pure.—C. Chamberland.—The author filters water through a

porous vessel of unglazed porcelain, and obtains it absolutely free from microbia. A single such vessel, 0.20 metre long, by 0.025 metre in diameter, yields about 20 litres of water daily.

The Decomposition of White Cast-iron by Heat.—L. Forquignon.—Cast-iron, if heated for several days to about 900° to 1000°, neither melts nor softens, but is converted into malleable iron. Its surface is covered with a greyish efflorescence. The fracture is sometimes of a uniform black, like that of a lead pencil, and sometimes riddled with large black points, regularly distributed in the metallic paste.

The Composition and Qualities of Coal with reference to the Plants which form it.—Ad. Carnot.—The author's experiments show that when all other circumstances are alike different species of plants have given rise to coals of decidedly different properties.

Calcium Oxy-chloride and the Calcium Silicates, Simple and Chlorinated. Artificial Production of Wollastonite.—Alex. Gorgen.—Both chemically, physically, and optically, the artificial wollastonite is identical with the natural mineral.

No. 6, August 11, 1884.

On Globular Lightning.—Gaston Planté.—This paper requires the two accompanying illustrations.

Certain Combinations formed by the Haloid Salts and the Oxy-salts of the same Metal.—H. Le Chatelier.—The author describes the calcium chloro-borate and chloro-ferrite.

Moniteur Scientifique, Quasneville.

Vol. xiv., August, 1884.

Patents Referring to Colouring Matters.—A list of German specifications. Especial mention may be made of the processes of H. Loder, of Amsterdam, who prepares colouring matters by the action of a solution of sugar in alcoholic fermentation on certain aromatic combinations. One of these mixtures consists of resorcin, orcene, saltpetre, and tartaric acid, added to the fermenting solution of sugar.

Synthesis of Xanthine.—A. Gauthier.—The author heats a mixture of dilute hydrocyanic acid and acetic acid to 140° to 150° in sealed tubes. The products are xanthine and methyl-xanthine.

Bulletin de la Société Chimique de Paris.

No. 2, 1884.

Chemical Reactions which accompany the Setting of Hydraulic Mortars.—H. Le Chatelier.—This memoir does not admit of useful abstraction.

Critical Observations on the Use of Gypsum Filters for Sterilising Liquids containing Ferments.—P. Cazeneuve.—The author shows that this method of filtration is open to certain objections. It keeps back soluble ferments and a very considerable proportion of the albumenoid matters. Hence, *e.g.*, blood thus treated is not merely deprived of living organisms, which may have been present, but undergoes other changes.

Action of Acetyl Chloride upon Toluene in Presence of Aluminium Chloride.—J. Ch. Essner and E. Gassin.—The authors obtained a yield of acetyl-toluol not exceeding 10 per cent of the theoretical quantity.

Constitution of the Pyridic Bases derived from Brucine.—Oechsner de Coninck.—An examination of two lutidines obtained from the crude quinoleine derived from brucine.

Action of Cyanogen upon Certain Ortho-diamines.—J. A. Bladin.—Cyanogen unites with the aromatic ortho-diamines forming compounds $C_nH_{2n-8}N_4$ ($n=8, 9, \&c.$),

which are in general more stable than the compounds of cyanogen with the monamines. They are very energetic bases which yield with acids two series of salts, containing 1 and 2 mols. of a mono-basic acid. The salts with 2 mols. of acid are unstable and lose 1 mol. of acid in contact with water.

Mono-chloric Ethyl-benzene.—M. Istrati.—Not suitable for abstraction.

Synthesis of Pyridic Hydrides.—Oechsner de Coninck.—The author has effected the synthesis of certain hexa-hydrides which are violent poisons producing symptoms analogous to those known by physiologists under the name of cicutism.

Journal für Praktische Chemie.

New Series, Vol. xxix., Part 6.

On Para-ethoxy-phenyl-urethan and some of its Derivatives.—H. Kehler.—We have here an account of para-ethoxy-carbanil, nitro-para-ethoxy-phenyl-urethan, amido-para-ethoxy-phenyl-urethan hydrochlorate, non-symmetric ortho-diamido-phenol hydrochlorate, diazo-imid-ethoxy-phenyl-urethan, dinitro-para-ethoxy-phenyl-urethan, a second compound of the same name, diamido-para-ethoxy-phenyl-urethan hydrochlorate, trinitro-para-ethoxy-phenyl-urethan, triamido-para-ethoxy-phenyl-urethan hydrochlorate, trinitro-amido-phenetol, and tetra-amido-phenetol hydrochlorate.

The Action of Mono-chloroacetic Acids upon Ortho- and Paramido-phenetol, and on the Oxyphenyl Glycines.—Heinrich Vater.—Like the amidic acids of the fatty series, and like tyrosine, the solutions of the oxyphenyl glycines are coloured blood-red by a drop of the solution of ferric chloride. The para-compounds form here no exception. The alkylised compounds show the same reaction. Whilst the amido-acids examined by Hofmeister give a blue colour with copper sulphate, the oxyphenyl glycines and their derivatives display a green colour. In the presence of sodium hydrate the amido-acids of the fatty series (except taurine) and tyrosine dissolve copper hydroxide. The oxyphenyl glycines form a light greenish yellow coagulum, which is converted into a voluminous yellow mass (slowly in the cold, but quickly on boiling) containing organic matter in addition to copper. With mercury salts there is no difference in the behaviour of the oxyphenyl glycines and the remaining amido-acids.

On Meta-azo- and Hydrazo-phenetol.—M. Buchstab.—A preliminary communication.

New Formation of Carbostryl.—J. Rotheit.—Tri-chloroxy-chinoline is heated in sealed glass tubes with fuming hydriodic acid. At 250° it yields fine white needles of the composition of a carbostryl.

Action of Ethoxalyl-chloride upon Diphenyl-sulphurea and Triphenyl-guanidine.—M. v. Stojentia.—When ethoxalyl-chloride is cautiously allowed to act upon diphenyl-sulphurea dissolved in benzol there is a violent reaction, and a compound, $C_{21}H_{17}N_3S_2O$, is formed. If the alcoholic solution of this body is treated with silver nitrate it is easily freed from sulphur, and from the filtrate there crystallises out diphenyl-parabanic acid.

On a New Metallic Radicle.—P. Schützenberger.—From the *Comptes Rendus*.

Vol. xxix., Part 7.

Studies on Blood.—H. Struve.—The author regards the hæmoglobine crystals as crystals of a colourless albumenoid substance which hitherto has not been obtained pure, but contaminated with small quantities of one or of several blood-pigments. He dissents from the view of Hoppe-Seyler that "hæmochromogen is formed from hæmoglobine as a single product of splitting up; whilst hæmatine is formed from hæmoglobine or hæmochromogen only by oxidation."

Communications from the Agricultural-Chemical Laboratory of the University of Königsberg.—H. Ritthausen.—We have here an account of melitose from cotton-seed; a notice of the occurrence of citric acid in the seeds of various leguminous plants; a proof of the occurrence of vicine in broad beans (*Vicia faba*); and a paper on the solubility of vegetable proteine substances in water containing hydrochloric acid.

The Thio-lactic and the Thio-dilactic Acids.—J. M. Löwen.—Contrary to the assertion of Schaft and Böttenger pure thio-dilactic acid is a well crystallised and distinctly characterised substance.

Action of Hydroxylamine and Ethylamine upon Komanic Acid.—H. Ost.—Hydroxylamine acts upon komanic acid similarly to ammonia. Ethylamine converts komanic acid quantitatively into a compound, $C_8H_9NO_3 + \frac{1}{2}H_2O$, which the author views as the oxycarbon acid of an ethyl-pyridine.

"De Mortuis nil nisi bene, sed non nimis."—H. Kolbe.—A critique on some recent eulogiums on Dumas.

Neutral Salts of Didymium Oxide and on the Valence of Didymium.—A. Cossa.—From the *Comptes Rendus*.

Parts 9, 10, and 11.

Studies in Chemical Dynamics.—W. Ostwald.—In this paper the author treats of the inversion of cane-sugar.

Relation between Luteo- and Roseo-Salts.—S. M. Jørgensen.—The luteo- and roseo-salts represent each other perfectly, the former containing $2NH_3$ and the latter $2OH_2$.

Formation of Acid Amides from the Salts of Ammonium.—N. Menshutkin.—The isomerism of acids has an influence on the speed of amidation. The primary acids display the greatest rapidity; the secondary acids have a less rapidity and a higher temperature at the beginning of the process. The tertiary acids have the smallest rapidity,—a conclusion drawn from the behaviour of the aromatic acids. Formic acid shows the greatest initial rapidity of amidation. Formic acid displays the smallest limit of normal amidation. The isomerism of the acids (in the first place only the primary and secondary) has no influence on the limit of amidation.

Modification of the Rapidity of Certain Reactions in Connection with the Temperature.—N. Menshutkin.—This paper does not admit of useful abstraction.

Communications from the Agricultural-Chemical Laboratory of the University of Königsberg.—H. Ritthausen.—This paper discusses the composition of the albumenoid bodies of *Vicia faba* and *Phaseolus*, as obtained by means of saline solutions.

Solubility of Solid Bodies in Water at different Temperatures.—Dr. J. L. Andræ.—The author calls attention to several causes of error in the determination of solubilities. The ordinary methods of preparing saturated solutions are that either an excess of the salt is introduced into water at a constant temperature, stirring from time to time, or the water is saturated with the salt at a higher temperature, and the solution is let cool down to the temperature required, at which it is kept for some time with occasional agitation. The first method is apt to give too low and the second too high results. The author recommends that the mixture of salt and water should be kept in incessant agitation for one to one and a half hours. A second source of error lies in the determination of the temperature. The determination of the salt in the saturated solution is generally effected by evaporating a weighed portion to dryness and weighing the residue. If this evaporation is effected at a boil a part of the salt is lost. The purity of the salt employed necessarily affects the results. The author's method of experimentation cannot be explained without the accompanying illustrations.

Influence of Dilution upon the Rapidity of Chemical Reactions.—Waldemar de la Croix.—The author gives his results in the form of tables.

Apparatus for Determining Carbonic Acid and Carbonates.—Prof. R. Baur.—The apparatus cannot be intelligibly described without the illustration.

Anthology of Neo-chemical Utterances.—(Communicated by H. Kolbe).—The utterances in question are to be found in Prof. Baeyer's treatise on the "Combinations of the Indigo-group" (*Berichte Chem. Gesellschaft Berlin*, 1883, p. 2188).

Adolf Baeyer, the Reformer of Chemical Nomenclature.—H. Kolbe.—As specimens of the new nomenclature may be quoted "esotrichlor-exodichlor ethyl benzol; ex-brom-2-3-4 trichlor-cinnamic acid; B-oxy-Py-oxy-ex-oxychinolin cinnamic acid; w brom-4-brom-acetophenon."

Justus Liebig's Annalen der Chemie, Vol. 224, Parts 1 and 2.

On the Acridines.—A. Bernthsen.—In this extensive memoir the author has studied true acridine, obtained from formic acid and diphenylamine, phenyl-acridine, from benzoic acid and diphenylamine; methyl-acridine from acetic acid and diphenylamine; butyl-acridine, from valerianic acid and diphenylamine; and acridyl-benzoic acid, from phthalic acid and diphenylamine.

Researches on the Specific Volumes of Liquid Compounds.—This section (iv.) is a paper by Alb. Zander on the normal fatty acids and the normal fatty alcohols.

Communications from the Main Chemical Laboratory of the University of Tübingen.—These consist of a memoir by G. Kumpf on nitrised phenyl benzyl-ethers, a paper by P. Frische on nitrised para-kresyl-benzyl-ether, and one by M. Rapp on the phenyl- and kresyl-esters of phosphoric acid and their nitration.

Communications from the Chemical Laboratory of the University of Jena.—These papers are a continuation of the researches on sulphur compounds noticed in the last volume, and consist of memoirs by A. Geuther, on calcium oxy-sulphides, on the constitution of poly-sulphides and poly-oxides, and on certain compounds of sulphurous acid.

MISCELLANEOUS.

Gas-tight India-rubber Tubing.—An elastic rubber tubing perfectly gas-tight and free from smell has been urgently needed for many years; in fact, the impossibility of making satisfactory gas connections for gas apparatus which requires to be movable has rendered the use of gas as a fuel in many cases a most objectionable nuisance. A tubing recently brought out by Mr. Fletcher, of Warrington, is made of two layers of rubber, with pure soft tin-foil vulcanised between. It is said to be perfectly and permanently gas-tight under any pressure, and free from smell after long-continued use, whilst it retains the flexibility and elasticity of an ordinary rubber tube. The braided or cloth covered tube, which has been made with the intention of filling this want, has never come into general use owing to the very small quantity it passes, rendering it almost useless except for small lighting burners, and also that special brass connections and screws have to be fitted to every burner and to both ends of every length of tube: both these faults are entirely done away with. This tube fills a want which every user of gas apparatus must feel daily. Mr. Fletcher informs us that this tube has been in practical use for some time, and has been thoroughly tested for months under continuous and heavy pressures of gas.

NOTICE.

The STUDENTS' NUMBER of the CHEMICAL NEWS will be published on Friday, September 19th. Gentlemen holding official positions in the Universities, Medical Schools, &c., of the United Kingdom, where Chemistry and Physical Science form a part of the education, who have not yet forwarded the necessary information to our Office for publication in that Number, will confer a favour by sending it with the least possible delay.

Advertisements for this Number should reach the Office not later than Wednesday, the 17th instant.

Just published, 8vo., cloth, 5s.

UNIVERSITY COLLEGE, BRISTOL.
CHEMICAL DEPARTMENT.PROFESSOR—W. RAMSAY, Ph.D.
LECTURER—SYDNEY YOUNG, D.Sc.

The SESSION 1884-85 begins on 7th OCTOBER. Lectures on Inorganic, Organic, Advanced, and Technical Chemistry will be delivered during the Session. The Laboratories are fitted with the most recent improvements for the study of Practical Chemistry in all its branches. In the evening, Lectures on Inorganic Chemistry at reduced fees are delivered; and a Special Course of Lectures on Technical Chemistry is also given, with the co-operation of the Worshipful Company of Clothworkers. A Correspondence Class especially adapted for those engaged in the Clothworking and Dyeing Industries will begin in October. Several Scholarships are tenable at the College. Calendar, containing full information, price 1s. (by post 1s. 3d.) For prospectus and further information apply to the Registrar.

ST. PAUL'S SCHOOL.—An Examination for filling up about 20 Vacancies on the Foundation will be held on the 10th September.—For information apply to the Bursar, St. Paul's School, West Kensington, S.W.

LEATHER-GLUE, of highest strength, guaranteed free from acid and grease, for prompt delivery at any time on best terms.—**JULIUS HEROLD**, Glue Manufacturer, MONZINGEN ON THE NAHE, RHEINISH-PRUSSIA.

UNIVERSITY COLLEGE, LONDON.

FACULTY OF SCIENCE, including the Departments of ENGINEERING and CHEMICAL and MECHANICAL TECHNOLOGY.

The Session will open on October 2nd.

For detailed Prospectuses of the Courses of Instruction, Exhibitions, Scholarships, &c., apply to the College, Gower Street, W.C.

TALFOURD ELY, M.A., Secretary.

UNIVERSITY COLLEGE, LONDON.

TUFNELL SCHOLARSHIPS IN CHEMISTRY.

A SCHOLARSHIP of £100 per annum, tenable for two years, will be open for Competition in June, 1885, by Students in Analytical Chemistry. Candidates must attend the Laboratory during the previous Session, and must have Matriculated at the University of London within three years.

For further information apply to the Secretary of the College.

TALFOURD ELY, M.A., Secretary.

OWENS COLLEGE (VICTORIA UNIVERSITY), MANCHESTER.

SESSION 1884-5.

I. DEPARTMENT of ARTS and LAW.

II. DEPARTMENT of SCIENCE and ENGINEERING.

Candidates for Admission in these Departments must not be under 14 years of age, and those under 16 will be required to pass an Entrance Examination in English, Arithmetic, and Elementary Latin, to be held on the 3rd OCTOBER.

III. DEPARTMENT of MEDICINE and SURGERY and of DENTAL SURGERY.

Students are required, before entering, to have passed either the Entrance Examination in Arts, or the Preliminary Examination in the Victoria University, or some other of the Preliminary Examinations prescribed by the General Medical Council.

IV. DEPARTMENT for WOMEN (223, Brunswick-street).

The SESSION in Departments I., II., and IV., will commence on the 7th, and in III., on the 1st OCTOBER.

V. EVENING CLASSES.

The SESSION will commence on the 13th OCTOBER. New Students will be admitted on the 8th, 9th, and 10th October, between 6.30 and 9 p.m.

ENTRANCE EXHIBITIONS and SCHOLARSHIPS are offered to be Competed for by Male Students in Classics, Greek, Testament, Mathematics, English, and History; and also a DAUNTESKY MEDICAL SCHOLARSHIP, value £100. FOUR SCHOLARSHIPS of the value of £20 per annum, tenable for three years, in the Department for Women, have also been founded, of which two are open to general competition, and two may be competed for only by Pupils in the Manchester High School for Girls.

Prospectuses of the several Departments may be obtained at Mr. CORNISH'S, Piccadilly, Manchester, and they will be forwarded from the College on application.

J. HOLME NICHOLSON, Registrar.

THE MASON COLLEGE, BIRMINGHAM.

SESSION 1884-85.

FACULTIES OF SCIENCE AND ARTS.

The SESSION will commence on FRIDAY, the 3rd of OCTOBER NEXT.

All departments of the College are open to both sexes on the same terms. Special arrangements are made for the convenience of ladies. Syllabuses containing full information as to Admission of Students, Courses of instruction, Fees, Entrance and other Scholarships, &c., may be had from Cornish Bros., Birmingham, or from the undersigned. Price 6d.; by post, 7½d.

GEO. H. MORLEY, Secretary.

THE MASON COLLEGE, BIRMINGHAM.

SCHOLARSHIPS IN CHEMISTRY OF £30 PER ANNUM.

An Examination in Theoretical and Practical Chemistry for this Scholarship will be held on Tuesday and Wednesday, 7th and 8th October, 1884. Candidates must either have studied Chemistry two years in the College, or they may be B.Sc. of London, or Associates of the Institute of Chemistry.

Application to be made before 1st October to

GEO. H. MORLEY, Secretary.

E. J. DAVEY

(Printer of THE CHEMICAL NEWS).

F.R.S. L. & E., F.R.A.S., President of the Section.

Steps towards a Kinetic Theory of Matter.

THE now well-known kinetic theory of gases is a step so important in the way of explaining seemingly static properties of matter by motion, that it is scarcely possible to help anticipating in idea the arrival at a complete theory of matter, in which all its properties will be seen to be merely attributes of motion. If we are to look for the origin of this idea, we must go back to Democritus, Epicurus, and Lucretius. We may then, I believe, without missing a single step, skip 1800 years. Early last century we find in Malebranche's "*Recherche de la Verité*," the statement that "*La dureté des corps*" depends on "*petits tourbillons*."* These words, embedded in a hopeless mass of unintelligible statements of the physical, metaphysical, and theological philosophies of the day, and unsupported by any explanation, elucidation, or illustration throughout the rest of the three volumes, and only marred by any other single sentence or word to be found in the great book, still do express a distinct conception, which forms a most remarkable step towards the kinetic theory of matter. A little later we have Daniel Bernoulli's promulgation of what we now accept as a surest article of scientific faith—the kinetic theory of gases. He, so far as I know, thought only of the Boyle's and Mariotte's law of the "spring of air," as Boyle called it, without reference to change of temperature or the augmentation of its pressure if not allowed to expand for elevation of temperature, a phenomenon which perhaps he scarcely knew, still less the elevation of temperature produced by compression, and the lowering of temperature by dilation, and the consequent necessity of waiting for a fraction of a second or a few seconds of time (with apparatus of ordinary experimental magnitude), to see a subsidence from a larger change of pressure, down to the amount of change that verifies Boyle's law. The consideration of these phenomena forty years ago by Joule, in connection with Bernoulli's original conception, formed the foundation of the kinetic theory of gases as we now have it. But what a splendid and useful building has been placed on this foundation by Clausius and Maxwell, and what a beautiful ornament we see on the top of it in the radiometer of Crookes, securely attached to it by the happy discovery of Tait and Dewar,† that the length of the free path of the residual molecules of air in a good modern vacuum may amount to several inches. Clausius's and Maxwell's explanations of the diffusion of gases, and of thermal conduction in gases, their charmingly intelligible conclusion that in gases the diffusion of heat is just a little more rapid than the diffusion of molecules, because of the interchange of energy in collisions between molecules,‡ while the

chief transference of heat is by actual transport of the molecules themselves; and Maxwell's explanation of the viscosity of gases, with the absolute numerical relations which the work of those two great discoverers found among the three properties of diffusion, thermal conduction, and viscosity, have annexed to the domain of science a vast and ever-growing province.

Rich as it is in practical results, the kinetic theory of gases, as hitherto developed, stops absolutely short at the atom or molecule, and gives not even a suggestion towards explaining the properties in virtue of which the atoms or molecules mutually influence one another. For some guidance towards a deeper and more comprehensive theory of matter, we may look back with advantage to the end of last century and the beginning of this century, and find Rumford's conclusion regarding the heat generated in boring a brass gun: "It appears to me to be extremely difficult, if not quite impossible, to form any distinct idea of anything capable of being excited and communicated in the manner the heat was excited and communicated in these experiments, except it be MOTION," and Davy's still more suggestive statement: "The phenomena of repulsion are not dependent on a peculiar elastic fluid for their existence. . . ." "Heat may be defined a peculiar motion, probably a vibration, of the corpuscles of bodies, tending to separate them. . . ." "To distinguish this motion from others, and to signify the causes of our sensations of heat, &c., the name *repulsive* motion has been adopted." Here we have a most important idea. It would be somewhat a bold figure of speech to say the earth and moon are kept apart by a repulsive motion; and yet, after all, what is centrifugal force but a repulsive motion, and may it not be that there is no such thing as repulsion, and that it is solely by inertia that what seems to be repulsion is produced? Two bodies fly together, and, accelerated by mutual attraction, if they do not precisely hit one another, they cannot but separate in virtue of the inertia of their masses. So, after dashing past one another in sharply concave curves round their common centre of gravity, they fly asunder again. A careless onlooker might imagine they had repelled one another, and might not notice the difference between what he actually sees and what he would see if the two bodies had been projected with great velocity towards one another, and either colliding and rebounding, or repelling one another into sharply convex continuous curves, fly asunder again.

Joule, Clausius, and Maxwell, and no doubt Daniel Bernoulli himself, and I believe every one who has hitherto written or done anything very explicit in the kinetic theory of gases, has taken the mutual action of molecules in collision as repulsive. May it not after all be attractive? This idea has never left my mind since I first read Davy's "*Repulsive Motion*," about thirty-five years ago, but I never made anything of it, at all events have not done so until to-day (June 16, 1884), (if this can be said to be making anything of it), when in endeavouring to prepare the present address I notice that Joule's and my own old experiments* on the thermal effect of gases expanding from a high pressure vessel through a porous plug, proves the less dense gas to have greater intrinsic *potential* energy than the denser gas, if we assume the ordinary hypothesis regarding the temperature of a gas, according to which

themselves, and this again ought to be much less rapid than either the material or thermal diffusivities of gases. Thus the diffusivity of common salt through water was found by Fick to be as small as 0.000012 square centimetres per second: nearly 200 times as great as this is the diffusivity of heat through water, which was found by J. T. Bottomley to be about 0.002 square centimetres per second. The material diffusivities of gases, according to Loschmidt's experiments, range from 0.008 (the interdiffusivity of carbonic acid and nitrous oxide) to 0.642 (the interdiffusivity of carbonic oxide and hydrogen); while the thermal diffusivities of gases, calculated according to Clausius's and Maxwell's kinetic theory of gases, are 0.089 for carbonic acid, 0.16 for common air or other gases of nearly the same density, and 1.12 for hydrogen (all, both material and thermal, being reckoned in square centimetres per second).

* "*Preuve de la supposition que j'ay faite : Que la matière subtile ou étherée est nécessairement composée de PETITS TOURBILLONS ; et qu'ils sont les causes naturelles de tous les changements qui arrivent à la matière ; ce que je confirme par l'explication des effets les plus généraux de la Physique, tels que sont la dureté des corps, leur fluidité, leur pesanteur, leur légèreté, la lumière et la réfraction et réflexion de ses rayons.*"—Malebranche, *Recherche de la Verité*, 1712.

† *Proc. R. S. E.* March 2, 1874, and July 5, 1875.

‡ On the other hand in liquids, on account of the crowdedness of the molecules, the diffusion of heat must be chiefly by interchange of energies between the molecules, and should be, as experiment proves it is, enormously more rapid than the diffusion of the molecules them-

two gases are of equal temperatures* when the kinetic energies of their constituent molecules are of equal average amounts per molecule.

Think of the thing thus. Imagine a great multitude of particles enclosed by a boundary which may be pushed inwards in any part all round at pleasure. Now station an engineer corps of Maxwell's army of sorting demons all round the enclosure, with orders to push in the boundary diligently everywhere, when none of the besieged troops are near, and to do nothing when any of them are seen approaching, and until after they have turned again inwards. The result will be that with exactly the same sum of kinetic and potential energies of the same enclosed multitude of particles, the throng has been caused to be denser. Now Joule's and my own old experiments on the efflux of air prove that if the crowd be common air, or oxygen, or nitrogen, or carbonic acid, the temperature is a little higher in the denser than in the rarer condition when the energies are the same. By the hypothesis, equality of temperature between two different gases or two portions of the same gas at different densities means equality of kinetic energies in the same number of molecules of the two. From our observations proving the temperature to be higher, it therefore follows that the potential energy is smaller in the condensed crowd. This—always, however, under protest as to the temperature hypothesis—proves some degree of attraction among the molecules, but it does not prove ultimate attraction between two molecules in collision, or at distances much less than the average mutual distance of nearest neighbours in the multitude. The collisional force might be repulsive, as generally supposed hitherto, and yet attraction might predominate in the whole reckoning of difference between the intrinsic potential energies of the more dense and less dense multitudes. It is, however, remarkable that the explanation of the propagation of sound through gases, and even of the positive fluid pressure of a gas against the sides of the containing vessel, according to the kinetic theory of gases, is quite independent of the question whether the ultimate collisional force is attractive or repulsive. Of course it must be understood that if it is attractive, the particles must be so small that they hardly ever meet—they would have to be infinitely small to *never* meet—that, in fact, they meet so seldom, in comparison with the number of times their courses are turned through large angles by attraction, that the influence of these purely attractive collisions is preponderant over that of the comparatively very rare impacts from actual contact. Thus, after all, the train of speculation suggested by Davy's "Repulsive Motion" does not allow us to escape from the idea of true repulsion, does not do more than let us say it is of no consequence, nor even say this with truth, because, if there are impacts at all, the nature of the force during the impact, and the effects of the mutual impacts, however rare, cannot be evaded in any attempt to realise a conception of the kinetic theory of gases. And in fact, unless we are satisfied to imagine the atoms of a gas as mathematical points endowed with inertia, and, as according to Boscovich, endowed with forces of mutual positive and negative attraction, varying according to some definite function of the distance, we cannot avoid the question of impacts, and of vibrations and rotations of the molecules resulting from impacts, and we must look distinctly on each molecule as being either a little elastic solid, or a configuration of motion in a continuous all-pervading liquid. I do not myself see how we can ever permanently rest anywhere short of this last view; but it would be a very

pleasant temporary resting-place on the way to it, if we could, as it were, make a mechanical model of a gas out of little pieces of round, perfectly elastic solid matter, flying about through the space occupied by the gas, and colliding with one another and against the sides of the containing vessel. This is, in fact, all we have of the kinetic theory of gases up to the present time, and this has done for us, in the hands of Clausius and Maxwell, the great things which constitute our first step towards a molecular theory of matter. Of course from it we should have to go on to find an explanation of the elasticity and all the other properties of the molecules themselves, a subject vastly more complex and difficult than the gaseous properties, for the explanation of which we assume the elastic molecule; but without any explanation of the properties of the molecule itself, with merely the assumption that the molecule has the requisite properties, we might rest happy for awhile in the contemplation of the kinetic theory of gases, and its explanation of the gaseous properties, which is not only stupendously important as a step towards a more thorough-going theory of matter, but is undoubtedly the expression of a perfectly intelligible and definite set of facts in nature. But alas for our mechanical model consisting of the cloud of little elastic solids flying about amongst one another. Though each particle have absolutely perfect elasticity, the end must be pretty much the same as if it were but imperfectly elastic. The average effect of repeated and repeated mutual collisions must be to gradually convert all the translational energy into energy of shriller and shriller vibrations of the molecule. It seems certain that each collision must have something more of energy in vibrations of very finely divided nodal parts than there was of energy of such vibrations before the impact. The more minute this nodal subdivision, the less must be the tendency to give up part of the vibrational energy into the shape of translational energy in the course of a collision, and I think it is rigorously demonstrable that the whole translational energy must ultimately become transformed into vibrational energy of higher and higher nodal subdivisions if each molecule is a continuous elastic solid. Let us, then, leave the kinetic theory of gases for a time with this difficulty unsolved, in the hope that we or others after us may return to it, armed with more knowledge of the properties of matter, and with sharper mathematical weapons to cut through the barrier which at present hides from us any view of the molecule itself, and of the effects other than mere change of translational motion which it experiences in collision.

To explain the elasticity of a gas was the primary object of the kinetic theory of gases. This object is only attainable by the assumption of an elasticity more complex in character, and more difficult of explanation, than the elasticity of gases—the elasticity of a solid. Thus, even if the fatal fault in the theory, to which I have alluded, did not exist, and if we could be perfectly satisfied with the kinetic theory of gases founded on the collisions of elastic solid molecules, there would still be beyond it a grander theory which need not be considered a chimerical object of scientific ambition—to explain the elasticity of solids. But we may be stopped when we commence to look in the direction of such a theory with the cynical question: What do you mean by explaining a property of matter? As to being stopped by any such question, all I can say is that if engineering were to be all and to end all physical science, we should perforce be content with merely finding properties of matter by observation, and using them for practical purposes. But I am sure very few, if any, engineers are practically satisfied with so narrow a view of their noble profession. They must and do patiently observe, and discover by observation, properties of matter, and results of material combinations. But deeper questions are always present, and always fraught with interest to the true engineer, and he will be the last to give weight to any other objection to any attempt to see below the surface of things than the

* That this is a mere hypothesis has been scarcely remarked by the founders themselves, nor by almost any writer on the kinetic theory of gases. No one has yet examined the question: what is the condition as regards average distribution of kinetic energy, which is ultimately fulfilled by two portions of gaseous matter, separated by a thin elastic septum which absolutely prevents interdiffusion of matter, while it allows interchange of kinetic energy by collisions against itself? Indeed I do not know but that the present is the very first statement which has ever been published of this condition of the problem of equal temperatures between two gaseous masses.

practical question: Is it likely to prove wholly futile? But now instead of imagining the question: What do you mean by explaining a property of matter? to be put cynically, and letting ourselves be irritated by it, suppose we give to the questioner credit for being sympathetic, and condescend to try and answer his question. We find it not very easy to do so. All the properties of matter are so connected that we can scarcely imagine one *thoroughly explained* without our seeing its relation to all the others, without in fact having the explanation of all, and till we have this we cannot tell what we mean by "explaining a property," or "explaining the properties" of matter. But though this consummation may never be reached by man, the progress of science may be, I believe will be, step by step towards it, on many different roads converging towards it from all sides. The kinetic theory of gases is, as I have said, a true step on one of the roads. On the very distinct road of chemical science, Ste.-Claire Deville arrived at his grand theory of dissociation without the slightest aid from the kinetic theory of gases. The fact that he worked it out solely from chemical observation

will lead to a kinetic theory of matter. Now this, as I have already shown,* we can do in several ways. In the case of the last of the communications referred to, of which only the title has hitherto been published, I showed that, from the mathematical investigation of a gyrostatically dominated combination contained in the passage of Thomson and Tait's "Natural Philosophy" referred to, it follows that any ideal system of material particles, acting on one another mutually through massless connecting springs, may be perfectly imitated in a model consisting of rigid links jointed together, and having rapidly rotating fly-wheels pivoted on some or on all of the links. The imitation is not confined to cases of equilibrium. It holds also for vibration produced by disturbing the system infinitesimally from a position of stable equilibrium and leaving it to itself. Thus we may make a gyrostatic system such that it is in equilibrium under the influence of certain positive forces applied to different points of this system; all the forces being precisely the same as, and the points of application similarly situated to, those of the stable system with springs. Then, provided proper masses (that

FIG. 1.

FIG. 2.

and experiment, and expounded it to the world without any hypothesis whatever, and seemingly even without consciousness of the beautiful explanation it has in the kinetic theory of gases, secured for it immediately an independent solidity and importance as a chemical theory when he first promulgated it, to which it might even by this time scarcely have attained if it had first been suggested as a probability indicated by the kinetic theory of gases, and been only afterwards confirmed by observation. Now, however, guided by the views which Clausius and Williamson have given us of the continuous interchange of partners between compound molecules constituting chemical compounds in the gaseous state, we see in Deville's theory of dissociation a point of contact of the most transcendent interest between the chemical and physical lines of scientific progress.

To return to elasticity: if we could make out of matter devoid of elasticity a combined system of relatively moving parts which, in virtue of motion, has the essential characteristics of an elastic body, this would surely be, if not positively a step in the kinetic theory of matter, at least a finger-post pointing a way which we may hope

is to say, proper amounts and distributions of inertia) be attributed to the links, we may remove the external forces from each system, and the consequent vibration of the points of application of the forces will be identical. Or we may act upon the systems of material points and springs with any given forces for any given time, and leave it to itself, and do the same thing for the gyrostatic system; the consequent motion will be the same in the two cases. If in the one case the springs are made more and more stiff, and in the other case the angular velocities of the fly-wheels are made greater and greater, the periods of the vibrational constituents of the motion will become shorter and shorter, and the amplitudes smaller and smaller, and the motions will approach more and more nearly those of two perfectly rigid groups of material points, moving through space and rotating according to the well-known mode of rotation of a rigid body having

* Paper on "Vortex Atoms," *Proc. R. S. E.*, Feb., 1867; abstract of Lecture before Royal Institution of Great Britain, March 4, 1881, on "Elasticity viewed as possibly a Mode of Motion", Thomson and Tait's "Natural Philosophy," second edition, Part I., §§ 345 viii. to 345 xxvii.; "On Oscillation and Waves in an Adynamic Gyrostatic System" (title only), *Proc. R. S. E.*, March, 1883.

unequal moments of inertia about its three principal axes. In one case the ideal nearly rigid connection between the particles is produced by massless exceedingly stiff springs; in the other case it is produced by the exceedingly rapid rotation of the fly-wheels in a system which, when the fly-wheels are deprived of their rotation, is perfectly limp.

The drawings (Figs. 1 and 2) before you illustrate two such material systems.* The directions of rotation of the fly-wheels in the gyrostatic system (Fig. 2) are indicated by directional ellipses, which show in perspective the direction of rotation of the fly-wheel of each gyrost. The gyrostatic system (Fig. 2) might have been constituted of two gyrostatic members, but four are shown for symmetry. The enclosing circle represents in each case in section an enclosing spherical shell to prevent the interior from being seen. In the inside of one there are fly-wheels, in the inside of the other a massless spring. The projecting hooked rods seem as if they are connected by a spring in each case. If we hang any one of the systems up by the hook on one of its projecting rods, and hang a weight to the hook of the other projecting rod, the weight when first put on will oscillate up and down, and will go on doing so for ever if the system be absolutely unfrictional. If we check the vibration by hand, the weight will hang down at rest, the pin drawn out to a certain degree; and the distance drawn out will be simply proportional to the weight hung on, as in an ordinary spring balance.

Here, then, out of matter possessing rigidity, but absolutely devoid of elasticity, we have made a perfect model of a spring in the form of a spring balance. Connect millions and millions of particles by pairs of rods such as these of this spring balance, and we have a group of particles constituting an elastic solid; exactly fulfilling the mathematical ideal worked out by Navier, Poisson, and Cauchy, and many other mathematicians who, following their example, have endeavoured to found a theory of elasticity of solids on mutual attraction and repulsion between a group of material particles. All that can possibly be done by this theory, with its assumption of forces acting according to any assumed law of relation to distance, is done by the gyrostatic system. But the gyrostatic system does, besides, what the system of naturally acting material particles cannot do: it constitutes an elastic solid which can have the Faraday magneto-optic rotation of the plane of polarisation of light; supposing the application of our solid to be a model of the luminiferous ether for illustrating the undulatory theory of light. The gyrostatic model spring balance is arranged to have zero moment of momentum as a whole, and therefore to contribute nothing to the Faraday rotation; with this arrangement the model illustrates the luminiferous ether in a field unaffected by magnetic force. But now let there be a different rotational velocity imparted to the jointed square round the axis of the two projecting hooked rods, such as to give a resultant moment of momentum round any given line through the centre of inertia of the system, and let pairs of the hooked rods in the model thus altered, which is no longer a model of a mere spring-balance, be applied as connections between millions of pairs of particles as before: with the lines of resultant moment of momentum all similarly directed. We now have a model elastic solid which will have the property that the direction of vibration in waves of rectilinear vibrations propagated through it shall turn round the line of propagation of the waves; just as Faraday's observation proves to be done by the line of vibration of light in a dense medium between the

poles of a powerful magnet. The case of wave front perpendicular to the lines of resultant moment of momentum (that is to say, the direction of propagation being parallel to these lines) corresponds, in our mechanical model, to the case of light travelling in the direction of the lines of force in a magnetic field.

In these illustrations and models we have different portions of ideal rigid matter acting upon one another, by normal pressure at mathematical points of contact—of course no forces of friction are supposed. It is exceedingly interested to see how thus, with no other postulates than inertia, rigidity, and mutual impenetrability, we can thoroughly model not only an elastic solid, and any combination of elastic solids, but so complex and recondit a phenomenon as the passage of polarised light through a magnetic field. But now, with the view of ultimately discarding the postulate of rigidity from all our materials, let us suppose some to be absolutely destitute of rigidity, and to possess merely inertia and incompressibility, and mutual impenetrability with reference to the still remaining rigid matter. With these postulates we can produce a perfect model of mutual action at a distance between solid particles, fulfilling the condition, so keenly desired by Newton and Faraday, of being explained by continuous action through an intervening medium. The law of the mutual force in our model, however, is not the simple Newtonian law, but the much more complex law of the mutual action between two electromagnets—with this difference, that in the hydrokinetic model in every case the force is opposite in direction to the corresponding force in the electro-magnetic analogue. Imagine a solid bored through with a hole and placed in our ideal perfect liquid. For a moment let the hole be stopped by a diaphragm, and let an impulsive pressure be applied for an instant uniformly over the whole membrane, and then instantly let the membrane be dissolved into liquid. This action originates a motion of the liquid relatively to the solid, of a kind to which I have given the name of "irrotational circulation," which remains absolutely constant however the solid be moved through the liquid. Thus, at any time the actual motion of the liquid at any point in the neighbourhood of the solid will be the resultant of the motion it would have in virtue of the circulation alone were the solid at rest, and the motion it would have in virtue of the motion of the solid itself, had there been no circulation established through the aperture. It is interesting and important to remark: passing that the whole kinetic energy of the liquid is the sum of the kinetic energies which it would have in the two cases separately. Now, imagine the whole liquid to be enclosed in an infinitely large rigid containing vessel, and in the liquid, at an infinite distance from any part of the containing vessel, let two perforated solids, with irrotational circulation through each, be placed at rest near one another. The resultant fluid motion due to the two circulations will give rise to fluid pressure on the two bodies, which if unbalanced will cause them to move. The force systems—force-and-torques, or pairs of forces—required to prevent them from moving will be mutual and opposite, and will be the same as, but opposite in direction to, the mutual force systems required to hold at rest two electro-magnets fulfilling the following specification. The two electro-magnets are to be of the same shape and size as the two bodies, and to be placed in the same relative positions, and to consist of infinitely thin layers of electric currents in the surfaces of solids possessing extreme diamagnetic quality—in other words, infinitely small permeability. The distribution of electric current on each body may be any whatever which fulfils the condition that the total current across any closed line drawn on the surface once through the aperture is equal to $1/4\pi$ of the circulation* through the aperture in the hydrokinetic analogue.

* In Fig. 1 the two hooked rods seen projecting from the sphere are connected by an elastic coach spring. In Fig. 2 the hooked rods are connected one to each of two opposite corners of a four-sided jointed frame, each member of which carries a gyrost. so that the axis of rotation of the fly-wheel is in the axis of the member of the frame which bears it. Each of the hooked rods in Fig. 2 is connected to the framework through a swivel joint, so that the whole gyrostatic framework may be rotated about the axis of the hooked rods in order to annul the moment of momentum of the framework about this axis due to rotation of the fly-wheels in the gyrostatics.

* The integral of tangential component velocity all round any closed curve, passing once through the aperture, is defined as the "Cyclic constant," or the "circulation" ("Vortex Motion," § 60 (a) *Treatise*).

It might be imagined that the action at a distance thus provided for by fluid motion could serve as a foundation for a theory of the equilibrium, and the vibrations, of elastic solids, and the transmission of waves like those of light through an extended quasi-elastic solid medium. But unfortunately for this idea the equilibrium is essentially unstable, both in the case of magnets and, notwithstanding the fact that the forces are oppositely directed, in the hydrokinetic analogue also, when the several movable bodies (two or any greater number) are so placed relatively as to be in equilibrium. If, however, we connect the perforated bodies with circulation through them in the hydrokinetic system, by jointed rigid connecting links, we may arrange for configurations of stable equilibrium. Thus without fly-wheels, but with fluid circulations through apertures, we may make a model spring balance, or a model luminiferous ether, either without or with the rotational quality corresponding to that of the true luminiferous ether in the magnetic fluid—in short, do all by the perforated solids with circulations through them that we saw we could do by means of linked gyrostats. But something that we cannot do by linked gyrostats we can do by the perforated bodies with fluid circulation. We can make a model gas. The mutual action at a distance, repulsive or attractive according to the mutual aspect of the two bodies when passing within collisional distance* of one another, suffices to produce the change of direction of motion in collision, which essentially constitutes the foundation of the kinetic theory of gases; and which, as we have seen before, may as well be due to attraction as to repulsion, so far as we know from any investigation hitherto made in this theory.

There remains, however, as we have seen before, the difficulty of providing for the case of actual impacts between the solids; which must be done by giving them massless spring buffers, or, which amounts to the same thing, attributing to them repulsive forces sufficiently powerful at very short distances to absolutely prevent impacts between solid and solid; unless we adopt the equally repugnant idea of infinitely small perforated solids, with infinitely great fluid circulations through them. Were it not for this fundamental difficulty, the hydrokinetic model gas would be exceedingly interesting; and, though we could scarcely adopt it as conceivably a true representation of what gases really are, it might still have some importance as a model configuration of solid and liquid matter, by which without elasticity the elasticity of a true gas might be represented.

But lastly, since the hydrokinetic model gas with perforated solids and fluid circulations through them fails because of the impacts between the solids, let us annul the solids and leave the liquid performing irrotational circulation round vacancy,† in the place of the solid cores which we have hitherto supposed; or let us annul the rigidity of the solid cores of the rings and give them molecular rotation according to Helmholtz's theory of vortex motion. For stability the molecular rotation must be such as to give the same velocity at the boundary of the rotational fluid core as that of the irrotationally circulating liquid in contact with it, because, as I have proved, frictional slip between two portions of liquid in contact is inconsistent with stability. There is a further condition,

upon which I cannot enter in detail just now, but which may be understood in a general way when I say that it is a condition of either uniform or of increasing molecular rotation from the surface inwards, analogous to the condition that the density of a liquid, resting for example under the influence of gravity, must either be uniform or must be greater below than above for stability of equilibrium. All that I have said in favour of the model vortex gas composed of perforated solids with fluid circulations through them holds without modification for the purely hydrokinetic model, composed of either Helmholtz cored vortex rings or of coreless vortices, and we are now troubled with no such difficulty as that of the impacts between solids. Whether, however, when the vortex theory of gases is thoroughly worked out, it will or will not be found to fail in a manner analogous to the failure which I have already pointed out in connection with the kinetic theory of gases composed of little elastic solid molecules, I cannot at present undertake to speak with certainty. It seems to me most probable that the vortex theory cannot fail in any such way, because all I have been able to find out hitherto regarding the vibrations of vortices,* whether cored or coreless, does not seem to imply the liability of translational or impulsive energies of the individual vortices becoming lost in energy of smaller and smaller vibrations.

As a step towards kinetic theory of matter it is certainly most interesting to remark that in the quasi-elasticity, elasticity looking like that of an india-rubber band, which we see in a vibrating smoke-ring launched from an elliptic aperture, or in two smoke-rings which were circular, but which have become deformed from circularity by mutual collision, we have in reality a virtual elasticity in matter devoid of elasticity, and even devoid of rigidity, the virtual elasticity being due to motion, and generated by the generation of motion.

DETERMINATION OF WOOL, SILK, AND COTTON IN TISSUES.

By A. REMONT.

THE author takes four portions, weighing each 2 grms., puts one of them aside, and boils the remainder for a quarter of an hour in hydrochloric acid at 3 per cent. If after the lapse of this time the liquid is deeply coloured it is decanted, and fresh acid is added, in which the swatches are boiled for half-an-hour longer. Finally, they are washed in water, and wrung out in a linen cloth. This removes the dressing. The ebullition with dilute acid removes the dyes readily from cotton, less readily from wool, and very imperfectly from silk. Dark coloured silks are most heavily weighted. The iron compounds used for this purpose are completely removed by the process above described, if they do not exceed one-quarter of the total weight of the fibre, which has then a chestnut-brown colour. If the weighting is very heavy the material is only partially decolourised. In this case a few threads, after boiling, are incinerated; the weight of the residual ferric oxide is determined and taken into account if it exceeds 5 per cent.

One of the boiled swatches is laid aside, and the other two are plunged for one or two minutes into a boiling solution of basic zinc chloride at 60° B. (This reagent is prepared, according to Morin, by mixing together 1000 parts melted zinc chloride, 850 parts of distilled water, and 40 parts of zinc oxide, heating until the last-mentioned article is dissolved.) The swatches are allowed to drain, thrown into water, and thoroughly washed, first with acidulated water, and then with pure water. This opera-

R. S. E., April 29, 1867). It has the same value for all closed curves passing just once through the aperture, and it remains constant through all time whether the solid body be in motion or at rest.

* According to this view there is no precise distance, or definite condition respecting the distance, between two molecules at which apparently they come to be in collision, or when receding from one another they cease to be in collision. It is convenient, however, in the kinetic theory of gases, to adopt arbitrarily a precise definition of collision, according to which two bodies or particles mutually acting at a distance may be said to be in collision when their mutual action exceeds some definite arbitrarily assigned limit, as, for example, when the radius of curvature of the path of either body is less than a stated fraction ($1/100$, for instance) of the distance between them.

† Investigations respecting coreless vortices will be found in a paper by the author, "Vibrations of a Columnar Vortex," *Proc. R.S.E.*, March 1, 1880; and a paper by Hicks, recently read before the Royal Society.

* See papers by the author "On Vortex Motion," *Trans. R. S. E.*, April, 1867, and "Vortex Statics," *Proc. R. S. E.*, December, 1875; also a paper by J. J. Thomson, B.A., "On the Vibrations of Vortex Ring," *Trans. R. S.*, December, 1881, and his valuable book on Vortex Motion.

tion is accelerated by wringing out the swatches each time in a linen cloth. This operation removes the silk.

One of the two swatches from which the silk has thus been removed is put aside. The other is gently boiled for a quarter of an hour in 60 to 80 c.c. soda-lye at sp. gr. 1.020. If the boiling is too strong the lye may become so far concentrated as to attack vegetable fibre considerably. The swatch is washed as above, avoiding friction, as the fibres have been rendered brittle by the treatment which they have undergone.

All four swatches are then heated for fifteen minutes in distilled water, pressed, and allowed to lie in the same room in which they had been previously kept. The next day they are weighed. The swatch first laid aside should weigh 2 grms.; a difference of less than 5 milligrams may be neglected, but a greater difference must be taken into account. The difference between the weight of this swatch and that of the second represents the dressing; that between the second and third gives the silk. The weight of the fourth swatch represents approximately the vegetable fibre present (cotton, phormium, flax, hemp), but it is somewhat attacked by the soda-lye. In cotton this loss has been found in a series of experiments to amount to 5 per cent. On multiplying the figures obtained by 50 we obtain the percentage of dressing silk and vegetable fibre. The remainder is the wool.—*Zeitschrift für Analytische Chemie*.

ON THE CONNECTION BETWEEN PSEUDO SOLUTION AND TRUE SOLUTION.

By W. W. J. NICOL, M.A., B.Sc., F.R.S.E., F.C.S.,
Lecturer on Chemistry, Mason College, Birmingham.

It is well known that very finely divided solids are capable of remaining suspended in water for days, or weeks, or even months without any appreciable precipitation taking place. So long ago as 1827 Brown* observed that such fine particles exhibit a quivering or jumping motion—the so-called "Brownian" or "pedetic motion." By the exhaustive researches of Weber† and Wiener‡ it has been shown that this motion is *not* caused—

- (a) By infusoria;
- (b) By mechanical agitation communicated to the liquid;
- (c) By the mutual attraction or repulsion of the particles themselves;
- (d) By alterations of temperature;
- (e) By evaporation.

And it is now very generally admitted that the motion of the particles is due to the impact of the molecules of the liquid on them, and that such motion is exhibited only by particles less than 0.0005 m.m. in diameter.

Still more recently it has been found|| that the amount and rapidity of this motion increases with the temperature of the liquid; and that the influence of the impact of the molecules of the liquid is sufficient to overcome the action of gravity even in the case of particles of heavy bodies in a specifically light liquid. For instance, particles of mercuric sulphide, of sufficiently small size, suspended in water, not only do not sink to the bottom of the vessel, but actually diffuse uniformly throughout the liquid. Small bubbles of various gases in soap solution also exhibit similar motions; and drops of oil or small particles of fat are known to remain long suspended in water, and to possess a motion in an inverse ratio to their size. Finally, when a solid body, in a fine state of division, remains suspended for an indefinite time in water, it is possible to

bring about almost immediate precipitation by the addition of soluble substances to the water; thus, alum is well known to have a clearing effect on turbid water. The precipitate thus produced is found to consist of amorphous aggregations of particles which are destitute of motion.*

I wish briefly to point out the agreement of the observed facts with regard to pseudo solution with what may be called the molecular theory of solution† in contradistinction to the hydrate theory. According to this theory, solution of a salt in water is a consequence of the attraction of the water molecules for a single salt molecule, exceeding the attraction of the molecules of salt for one another. Thus the solubility or insolubility of a salt is conditioned largely by its cohesion; if the cohesion be great the solubility is small, and *vice versa*. Thus, in the case of barium sulphate the cohesion is very great, and the solubility almost *nil*; but if by mechanical or other means the cohesion be destroyed for a time—that is, if it be finely divided—then it will remain suspended in water for a very long time. Thus, although the water molecules of themselves are not able to overcome the cohesion of the salt, yet, when that is overcome by other means, they are able to retain the salt in pseudo solution, which differs from true solution only in the degree of division of the solid. If, therefore, it were possible to divide an insoluble body into its molecules, it would also be possible to dissolve it in water to a great extent, and separation from such a solution would go on exceedingly slowly, for only seldom would a sufficient number of the molecules of the solid be in contact at one time, so that their mutual attraction might exceed that of the water for them. Cases similar to this are very common: I may instance the extremely slow precipitation of many insoluble compounds from cold dilute solutions.

In conclusion, I have already pointed out,‡ in a paper on saturation, that if there be two salts, one very soluble in water and the other less so,—e.g., CaCl_2 and NaCl —then if CaCl_2 be added to a solution of NaCl , this last salt is precipitated owing to the more soluble salt having a greater attraction for the molecules of water, a case analogous, I think, to the precipitation of fine mud from water on the addition of a soluble body. Colloidal silica and ferric hydrate are also precipitated on the addition of salt, but such cases are intermediate between pseudo and true solution.

CHEMICAL ACTIONS WITH CARBON AND ITS COMPOUNDS.||

By G. GORE, LL.D., F.R.S.

THE following experiments were made partly with the object of finding some new reactions in which carbon was set free in the elementary state, and also to discover new facts respecting carbon and some of its compounds:—

1. White phosphorus was added in very small fragments at a time to potassic cyanide in a state of fusion; strong effervescence occurred. On dissolving the cooled mass in water a small quantity of black matter was left. The black matter was insoluble in a hot mixture of nitric and hydrofluoric acids; it burned with a glow, without flame, and left hardly a trace of residue; it was therefore carbon, and may have been derived from potassic carbonate contained in the cyanide. (Compare experiments 2 and 3).

2. Red phosphorus in a state of powder, added to potassic cyanide in a state of fusion, produced strong action, and caused the cyanide to become black; and upon dissolving the cooled salt in water much black powder of low specific gravity separated. Powdered arsenic also caused the separation of a small amount of black

|| Read before the Birmingham Philosophical Society, June, 1884.

matter from the fused salt. Powdered antimony had a similar effect.

3. A mixture of pure potassic and sodic carbonates in a fused state was not visibly decomposed by metallic arsenic or antimony; but by aluminium carbon was separated.

4. When carbonate of sodium at a low red-heat was decomposed by vapour of phosphorus, if the residue was not finally heated so as to expel all free phosphorus, on subsequently dissolving it in water a dark brown liquid was obtained, the blackness of which could not be entirely removed even by a large number of successive filtrations. The black matter in the filter required extreme washing in order to obtain a colourless filtrate.

5. By adding phosphide of sodium to a fused mixture of the pure carbonates of sodium and potassium a little incandescence occurred, and a black coaly-looking substance was obtained. The cooled substance, on being thrown into water, evolved a very small amount of spontaneously inflammable gas. The experiment was repeated with the previous addition of zinc to the salt. In each case, on treating the residue with water, a black powder was obtained which burned readily and left no residue.

6. By projecting small portions of a mixture of red phosphorus and ammoniac carbonate, each in a state of powder, into a red-hot porcelain crucible, fused phosphoric acid of a blackish colour was obtained.

7. No carbon was set free by adding ammoniac carbonate to fused sodium in a wrought-iron cup; scintillation only took place when the carbonate touched the melted metal.

8. Metallic sodium was added to melted potassic cyanide; it floated, burned, and disappeared. On treating the cooled mass with water a minute quantity only of black matter separated.

9. A piece of potassium and a small quantity of bisulphide of carbon were highly heated in a lightly closed glass tube, and shaken. The glass became filled with green vapour of potassium, portions of the contents became red-hot, and the tube burst with a loud report.

10. Coal-gas was passed over red-hot peroxide of iron in a state of fine powder; it set free metallic iron and carbon as a fine black powder.

11. By passing coal-gas over fused argentic fluoride in a platinum boat at an incipient red-heat all the silver salt was reduced to metal, hydrofluoric acid was formed, and a little carbon was separated as a black powder mixed with the unfused silver.

12. Coal-gas was passed over argentic chloride just below its fusion-point, also over chloride of lead in a state of fusion, until the salts were quite reduced to metal. In each case, but most with the silver salt, carbon in the state of a fine black powder was set free, and was obtained on dissolving the residue in dilute nitric acid. The chlorides of copper and cadmium were similarly treated; the former was slowly reduced and some carbon liberated; the latter was not decomposed.

13. By passing coal-gas, during several hours, over fused iodide of silver in a glass retort, at a red-heat, only a comparatively small portion of the salt was reduced to the metallic state; no carbon was detected.

14. A mixture of tetrafluoride of silicon and carbonic anhydride was passed through a red-hot glass tube. No silica was produced nor carbon set free. By passing also a mixture of carbonic anhydride, phosphuretted hydrogen, and vapour of carbonate of ammonium through a similarly heated tube, no carbon was liberated.

15. Mixtures of carbonic anhydride and hydrogen, carbonic oxide and hydrogen, and of all three of these gases, were passed through red-hot glass tubes, and also over red-hot platinum-foil, but in no case was either vapour of water formed or carbon eliminated. By passing a mixture of carbonic anhydride and hydrogen through a red-hot iron tube containing iron turnings, no decomposition occurred.

16. No carbon was liberated by long-continued contact

of carbonic anhydride gas with a solution of white phosphorus in carbonic bisulphide. Pieces of white phosphorus in water exposed to an atmosphere of carbonic anhydride in a dark place, during nine weeks, showed no signs of change.

17. Silicon in contact with pure gold in water exposed to carbonic anhydride showed no visible change in six weeks. With vapour of CCl_4 , instead of carbonic anhydride, the results were the same. With magnesium in absolute alcohol exposed to carbonic anhydride gas, no carbon was liberated.

18. By condensing carbonic anhydride in the liquid state at 60°F . into contact with potassium and sodium, no carbon was set free.

19. By passing vapour of selenium slowly over a layer of charcoal powder, 8 inches long, in a thick refractory glass tube, at a full red-heat during one hour and a half, about three drops of a liquid were obtained. Several experiments of this kind were made, and in one of them the liquid dissolved some of the selenium, and formed a thick oil, of a red-brown colour.

20. Potassium which had been kept immersed in excess of liquid C_2Cl_4 in a closely stoppered bottle during four years, became wholly converted into a soluble white salt of strongly alkaline reaction. No carbon was separated.

21. By bringing into contact either of the four chlorides of carbon, bromide of carbon, carbonic bisulphide, pure anhydrous carbonate, or formate of sodium, or ammoniac oxalate, with a deep blue solution of potassium or sodium in anhydrous liquid ammonia under pressure at 60°F ., chemical changes occurred: the liquid was decolourised, soluble salts were formed, but no carbon was liberated in either of the instances.

22. By passing dry ammonia gas through liquid C_2Cl_4 containing potassium, gas was caused to evolve from the surface of the metal, and a red powder was precipitated. By using Persian naphtha instead of the chloride of carbon some ammonia was dissolved, and the potassium only became red on its surface. Potassium in amylene evolved gas freely.

23. Lampblack, also well-burned wood charcoal, was insoluble in anhydrous liquefied cyanogen, but the chlorides and sulphide of carbon were freely soluble. Lampblack was also insoluble in liquid chloride of sulphur, terchloride of phosphorus, or boiling penta-chloride of antimony.

24. Carbon was not consumed by being heated to redness in contact with argentic fluoride; if, however, chlorine was present, the carbon disappeared.

25. By experiment I found that carbon was insoluble in anhydrous hydrofluoric acid at 32°F .; also in anhydrous hydrochloric acid, or carbonic acid, each in the liquefied state under great pressure at 60°F . Carbon which had been reduced from vaporous carbonic bisulphide by means of red-hot potassium or sodium, dissolved slightly in boiling nitric acid, and formed a brownish liquid.

26. Neither carbonic bisulphide nor either of the chlorides of carbon would dissolve in, or unite with, liquefied anhydrous hydrofluoric acid, nor was either of the four chlorides of carbon perceptibly soluble in concentrated hydrochloric acid.

27. A vessel filled with carbonic anhydride was inverted over strong aqueous hydrofluoric acid at 60°F ., during thirty-six hours; scarcely any of the gas was absorbed.

28. A saturated solution of sulphur in bisulphide of carbon, also one of phosphorus in that liquid, were each enclosed in separate glass globes filled with carbonic anhydride, and kept in the dark during two months. No signs of any chemical change took place.

29. A thin wire of platinum was twisted round a thick one of pure tin, and immersed in purified carbonic bisulphide during nine weeks. No visible change occurred. This is a process which some one had published as an artificial one for producing diamonds.

30. In carbonic bisulphide, silver in contact with platinum

became quite black in three weeks. Magnesium in contact with that metal was unaffected in ten weeks. Lead in contact with mercury during two years formed a black powder which was entirely soluble in dilute nitric acid.

31. Bisulphide of carbon was not decomposed by a current of gaseous terfluoride of boron. Tetrachloride of tin, also bichloride of titanium and cyanogen gas, was found to be freely soluble in carbonic bisulphide. A solution of iodine in the same liquid was decolourised by a stream of hydrogen.

32. By contact of potassium with platinum in a solution of sulphur in bisulphide of carbon, during a long period, the platinum received no carbon deposit; zinc remained bright.

33. Bright metallic thallium rapidly became black in pure carbonic bisulphide which had been re-distilled twice from lead carbonate and porous chloride of calcium. After a period of two years no carbon was separated.

34. Carbon bisulphide instantly precipitated a solution of mercuric chloride in ether.

35. Aluminium became dull, but did not corrode or form crystals, in a solution of phosphorus in carbonic bisulphide, during two years; magnesium behaved similarly.

36. Platinum alone was partly immersed in aqueous solution of argentic nitrate in contact with vapour of carbonic bisulphide. Slow decomposition occurred. In seven weeks the silver was apparently all precipitated as an abundant black powder. No deposit formed upon the platinum wire except just beneath the surface of the liquid.

37. Magnesium, aluminium, or silver, partly immersed in water exposed to vapour of carbonic bisulphide, showed no change in seven weeks, but with silver in contact with platinum, under the same condition, the liquid became dark in colour, and the silver above it blackish, during that time. The same metals, similarly prepared, but with vapour of CCl_4 instead of the sulphide, showed no change during the same period.

38. Magnesium in contact with gold, in water exposed to coal-gas during seven weeks, yielded no deposit except magnesia.

39. Magnesium alone was immersed in amylene; in amylene mixed with some glacial acetic acid in a mixture of absolute alcohol, with acetone, with valerianic acid, with oxalic and acetic acid, with crude vegetable naphtha, with the crude distillate from wood after neutralisation by lime; also in a mixture of glacial acetic acid with sulphuric ether, with benzene, and with toluol, each during several days: no carbon was liberated.

40. An alloy of magnesium and thallium was immersed in liquefied glacial acetic acid, and in a mixture of absolute alcohol and acetic acid; an amalgam of mercury and a little sodium was also immersed in semi-glacial acetic acid; each during several days, without separation of carbon.

41. Magnesium in contact with platinum was immersed in mesitylene (five weeks); in mesitylene and vegetable naphtha (four days); in heavy wine oil (seven weeks); in an aqueous solution of sulphovinate of potassium (nine days); in a solution of naphthalene in vegetable naphtha (four days): it was also immersed (and so also was aluminium), in contact with platinum, in a mixture of absolute alcohol and glacial acetic acid (three days); both in absolute alcohol and with spirit of wine with xylol (two days each); in a solution of dry malic acid in absolute alcohol (two days); and in each case the result was similar to the above.

42. Crystals of silicon and of boron were immersed in a moderately strong solution of carbonate of rubidium at 60°F. , in a glass bottle, during two months. No visible chemical effect occurred.

43. Crystals of silicon in contact with platinum dissolved slowly in a mixture of solution of sodic carbonate and hydrate during two years, and left a skeleton of impurity. They also, and aluminium, dissolved slowly in a solution of potassic cyanide; selenium dissolved less slowly, whilst

magnesium and boron were unaffected, and white phosphorus became very slowly blackened. White phosphorus, when in contact with platinum, in a solution of potassic carbonate, in a flint-glass bottle, caused the glass to become black on its surface in two years.

44. Numerous experiments were also made of immersing white phosphorus, magnesium, aluminium, silicon, and boron, in contact with platinum, palladium, gold, silver, iron, &c., in solutions of the carbonates and bicarbonates of potassium and sodium, the formiates and oxalates of these metals, during various periods of time, extending in many instances to two years; also in water, glycerin, solutions of sodic hydrate and potassic chloride, exposed to coal-gas, carbonic oxide, carbonic anhydride, carbonic bisulphide, vapour of CCl_4 , and in water containing solid chloride of carbon; but in no case was carbon separated.

ACTION OF HYDROCHLORIC ACID ON LEAD.

By S. P. SHARPLES.

MOST authors state that lead is but slightly acted upon by hydrochloric acid. In some recent experiments made with a view to destroying cotton fibre by means of the hot acid, it was found that lead-lined vessels were very rapidly destroyed by it, and that even the cold acid could not be kept in wooden tanks lined with lead. These tanks stood sulphuric acid perfectly well.

NOTICES OF BOOKS.

Notes on the Literature of Explosives. By Professor C. E. MUNROE, U.S.N.A.

THESE Notes seem to be the sixth issue of a series. The author first gives a summary of Berthelot's theory of explosions induced by some adjacent explosion. He remarks that formerly the only methods of transmitting an explosion recognised were the direct application of fire or of a violent shock to the substance in question. Now, however, attention has been drawn to explosions by influence, such as are propagated either through the air or through solids which do not participate in the chemical change.

That explosion is so propagated is beyond all doubt. Instances have occurred where detached buildings explode in succession, as in powder-mills, where it may be regarded as certain that no burning materials can have been projected from the first store to the second. In an experiment performed by Captain Muntz a charge of 5 kilos. of dynamite, under water, induced the explosion of another charge of 4 kilos. situate at the distance of three metres. Professor Abel finds that the explosion of a torpedo charged with gun-cotton causes the detonation of other torpedoes within a certain radius.

Berthelot considers that this phenomenon depends on the production of two series of waves; the one representing the explosive waves, properly speaking, developed in the midst of the detonating matter, and consisting of a continuous transformation of chemical action into thermal and mechanical action. The other series is purely mechanical and physical, and transmits the sudden pressure all around the centre of the concussion to the adjoining bodies.

Prof. Abel, on the contrary, brings forward the theory of synchronous vibrations. He holds that the originating cause of the detonation of an explosive substance lies in the synchronism between the vibrations in the first exploding body and those of which the other explosive bodies are capable, just as a violin string vibrates in unison with another vibrating chord. In support of his theory he brings forward the experimental fact that one kind of ex-

plosive cannot by influence determine the detonation of an explosive of a different kind. Thus, nitrogen iodide cannot cause the explosion of compressed gun-cotton. Prof. Munroe, however, seems to lean to the theory of M. Berthelot.

Next follows an account of the so-called "Panclasticite" of E. Turpin, formed by mixing liquid nitrogen tetroxide, N_2O_4 , with carbon disulphide. It is said to be more powerful than dynamite, not sensitive to blows, whilst the manufacture may be easily controlled by Government, as the tetroxide is not an article of commerce.

What will be of more interest to lovers of piece is that this mixture is capable of other applications. The heat developed is so great that platinum melts instantly, and that even graphite begins to fuse.

Prof. Munroe next quotes from a work by W. N. Hill, now out of print, some particulars on the manufacture of nitro-glycerin. Here we learn that the mixture of nitric and sulphuric acid is now "largely sold," we presume in America. The number of names under which are sold mixtures of nitro-glycerin with other bodies is almost perplexing.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 7, August 18, 1884.

Discourses Pronounced at the Funeral of M. Paul Thenard.—MM. Bouley and Fremy.—M. Bouley referred to the deceased as the fourth eminent French chemist whom the Academy has lost within a comparatively short time, and gave a summary of his researches, especially in agricultural chemistry.

Freezing-point of Saline Solutions.—F. M. Raoult.—The author infers that the molecular lowering of the congelation of salts formed by the monobasic and bibasic acids is the sum of the partial molecular lowering of their electro-positive and electro-negative radicles. Contrary to the author's earlier opinion, the general law of congelation does not apply to salts dissolved in water. The facts, however, tend to show that it is applicable to the constituent radicles of salts, almost as if such radicles were merely mixed in the solutions.

Combinations of Tellurous Acid with Acids.—D. Klein.—To avoid confusion the author calls these compounds salts of tellurium dioxide. He describes the basic nitrate and basic sulphate.

No. 8, August 25, 1884.

Researches on Vegetation: Studies on the Formation of the Nitrates; Methods of Analysis.—MM. Berthelot and G. André.—The presence of nitrates in the vegetable world is, practically speaking, universal, and it is the result of a special function, seated principally in the stem. The authors have found it necessary to analyse separately the roots, the stem, the leaves, flowers, &c., of the plants under examination, separating them from the plant immediately when it was pulled up, and weighing each separately. They determine moisture at 110° , fixed matter, total ash, soluble and insoluble mineral matters, and nitrogen present as ammonia. A portion of the air-dried material was then treated with alcohol at 60 per cent, which dissolves out the nitrates and coagulates the albumenoids. The dissolved portion was evaporated in the water-bath, and the authors determined the weight of the soluble matter (dried at 110°), which they call the hydro-alcoholic extract, and they measured the volume, and consequently ascertained the weight of the nitrogen

dioxide yielded by this extract, making use of Schloesing's process. The portion insoluble in aqueous alcohol was dried, and its nitrogen was determined as ammonia by the soda-lime process. The weight of this nitrogen multiplied by 6 gives, approximately, the weight of the albumenoids, which is less than the weight of the nitrogenised principles contained in the plant, such as the alkaloids in the case of tobacco, and of the Solanaceæ, or the peptones, dissolved by aqueous alcohol. They have found no exact and general method for the determination of these latter principles.

A Thermo-regulator of a Simple Construction, serving also as a Registering Thermometer.—E. H. von Baumhauer.—This instrument cannot be described without the two accompanying figures.

The Ultra-red Emission-Spectra of Metallic Vapours.—H. Becquerel.—The author gives in a table the wave-lengths of the principal emission rays of the incandescent vapours of potassium, sodium, strontium, calcium, magnesium, aluminium, zinc, cadmium, lead, thallium, bismuth, silver, and tin. Nickel gave several very feeble bands or groups of rays; iron, under the conditions of the author's experiments, gave no band sufficiently intense.

Quality of Flours obtained by Different Methods of Grinding.—Aimé Girard.—The author gives his results in the form of tables.

Loss of Nitrogen during the Fermentation of Farmyard Manure.—C. Brame.—The author shows that in papers inserted in the *Comptes Rendus* for 1876 and 1878 he has already replied to the question suggested by M. H. Joulie (*Comptes Rendus*, June 9, 1884), that it is necessary to find means for avoiding their losses. He proposes pits in stables, cow-houses, &c., 1 or 1.5 metre in depth, with cemented sides. In the bottom of these he deposits 0.30 to 0.40 metre of light, very dry earth, above which are placed 0.06 to 0.10 metre of straw, &c. As a convenient "ammonia-scope" he recommends a small stoppered bottle filled with asbestos saturated with glacial acetic acid. Such a bottle, if unstopped only when examining manure heaps, will remain fit for use for five years. He maintains that farmyard manure can never be superseded by chemical manures and the powdery manures of commerce. These latter, save in certain limited cases, will never become more than adjuncts, and often require substances of the former kind to render them assimilable.

Moniteur Scientifique, Quesneville.

Vol. xiv., Sept., 1884.

Discourse delivered at the Third Annual Meeting of the Society of Chemical Industry.—Mr. Walter Weldon.—This discourse, delivered at the Newcastle meeting of the Society of Chemical Industry on July 8, is of course well known to our readers.

A great part of the present issue is taken up with reports of the Proceedings of the Academy of Sciences and with Patent-literature, comprising patents connected with the chemical arts taken in France during the months of June and July last; a selection of French chemical patents issued during June and July; an industrial review of foreign patents, and a special review of patents, chiefly German, connected with the manufacture of artificial colours.

Industrial Society of Mulhouse, June 11, 1884.—M. Schaeffer read a letter from M. de Portheim, calling attention to phenyl-hydrazine, a compound which has much analogy with hydroxylamine. M. Schaeffer has made some attempts to discharge manganese-bronze with this base.

The Secretary read a paper by Dr. Werner on a recent case of poisoning at Thann, under the influence of the benzole used for dissolving caoutchouc. At the Thann

works are used the first portions of the distillation of crude benzol, called light benzol. This substance contains, along with carbon disulphide, ethylic alcohol, carbides of the series of the olefines, amylen, hexylen, &c., benzol, methyl cyanide, or aceto-nitrile, a small quantity of an isocyanide. The experiments undertaken by Werner in conjunction with Noelting prove that the poisonous properties of ordinary benzol are due to a small quantity of this isocyanide. Rabbits poisoned with the benzol of Thann, and others poisoned with ethyl isocyanide, displayed the same pathological phenomena as did the workman who fell a victim, and the benzol from Thann, when freed from this constituent, had no poisonous action.

M. Noelting communicated the sequel of his researches on the xylidins.

MM. Noelting and Weingaertner are engaged with the study of a violet colouring matter formed by the action of sulphuretted hydrogen and ferric chloride upon paramidophenol.

Economical Procedures applicable in the Textile Industry.—Dr. W. Ramsay.—From the *Journal of the Society of Arts*.

Review of Organic Chemistry.—G. de Becchi.—A series of abstracts from the *Berichte der Deutschen Chemischen Gesellschaft*.

Cosmos les Mondes.

No. 12, July 19, 1884.

This issue contains a notice of the death of the Abbé Moigno, who terminated his long career of intense scientific activity on July 13th.

No. 13, July 26, 1884.

Influence of Temperature upon the Characters of the Spectral Rays.—Ch. Fievez.—The author pronounces that the modifications in the appearance of the rays are identical in the spectra of flame and in the electric spectra, whence it may be concluded that an increase of complexity in the constitution of a spectral ray is a certain sign of an increase of the temperature of the emissive ray. Hence it may be inferred that the temperature of the sun-spots is higher than that of the disc, because the spectral rays of the spots have a greater breadth than those of the disc.

The Biological Part of Iron in the Animal Economy.—M. E. Vial.—There exists in the blood-globules a definite compound of potassium and iron, which is originally in the ferrous state in the leucocytes, and is peroxidised in the blood under the influence of the air.

Studies on Potable Waters and Lead.—A. Hamon.—It is proved beyond all doubt that waters which circulate or stand in leaden pipes or vessels, besides the mechanical action due to friction, attack the metal in consequence of the affinity of several of their constituents, the compound produced being generally lead carbonate. Minute quantities of lead introduced into the system must rank among the factors of anæmia and defective nutrition in large towns. Pipes, cisterns, and cooking utensils of lead ought entirely to disappear.

Presence of Bacteria on Money.—Dr. Heinsch, of Frankfurt, has detected upon half-mark pieces which have been long in circulation the presence of bacteria and fungoid growths.

No. 14, August 2, 1884.

A New Proof of the Non-existence of Ammonium Hydrate.—Dr. D. Tommasi.—The author's opinion has been confirmed by the recent researches of M. Bouty on the conductivity of saline solutions. This *savant* has shown that the solution of an anhydrous alkali does not conduct electricity, but that, on the other hand, the solution of a hydrated alkali conducts as do salts. He has

also found experimentally that liquid ammonia conducts 110 times more feebly than does a salt of the same molecular weight. This result is quite in harmony with Dr. Tommasi's conclusion that ammonium hydrate is non-existent.

Physical Analysis of Milk.—Dr. C. Brame.—The author declares that his method anticipates by thirty years that of Dr. Georges Quesneville. The points which Dr. Brame determines are the density of the milk, skimmed and unskimmed, the degree of the creamometer, the degree of Downé's lactoscope, the weight of the solid residue at 120°, and, if needful, the absolute quantity of fatty matter. (How if foreign fats have been introduced so as to form a spurious cream?)

THE CHEMICAL NEWS.

VOL. L. No. 1295.

A HINT TO STUDENTS.

An examination of our students' number must convince everyone that the facilities for the study of chemistry have been greatly multiplied. But in addition to the colleges and institutions here particularised there are many classes for the study of the science of which we have not been able to glean any exact information, and which are consequently not mentioned. Further, our literature is exceedingly rich,—richer, indeed, probably than that of any other nation—in chemical hand-books, manuals, "manual-ettes," and other elementary treatises.

The question then naturally occurs—and we think it deserves the attention of all students—what is the outcome of all these multiplied appliances?

May we not answer, inverting a saying of old, "the labourers are many but the harvest is scanty." As a nation we must confess that in chemistry at least our theoretical discoveries and our practical inventions bear no satisfactory proportion to the number of chemical schools and laboratories or the totality of students who attend them. It may then be seriously asked what is the use of so much teaching and learning if it leads to so little successful investigation into the many unexplored secrets of nature? We are quite unable to say how many out of every hundred students who attend the laboratories which we have enumerated ever try to add even the smallest crumb to the existing sum of human knowledge. We fear that the percentage, could it be ascertained, would not prove a large one. More than the half, probably, when they have acquired a certain knowledge of chemistry, which is officially required as a portion of the qualifications for a degree, or for a profession, dismiss the subject from their minds, and religiously abstain alike from further research and from applying what they have already learnt.

Of such students it is very easy to have too many, and to such it is difficult, if it at all possible or justifiable, to address any words of welcome or of encouragement. But we may legitimately ask why are such barren fig-trees so abundant in our midst? Not, surely, from any defect in our national intellect. Is not the root of the evil to be sought for in the quality of the teaching given. Professor Tilden, in an address reported in the "Mason College Magazine," stated that, as far as chemistry is concerned, "England is now in a fair way to retrieve her fallen fortunes. Abundance of good work is being done. In the matter of instruction we are very little behind the Germans, and we are very rapidly gaining upon them." To the question, "what more do we want?" he replies:—"We want more money for materials and appliances, more students (?), more leisure for the professors, more sympathy from the governing bodies in our work alike of teaching and research, more intelligent recognition of the usefulness of chemical knowledge by our chemical manufacturers." True, we want these things, and something more. Professor Tilden draws a most truthful picture of the state of things in our chemical manufactories. He

writes:—"If we go into the iron and steel works of the North of England, into the dye-houses and print-works of Yorkshire and Lancashire, into the alkali-works of St. Helens and the Tyne, we find the laboratories literary swarming with Germans who are holding the situations which ought to be occupied by Englishmen. How long this state of things is to exist is a question which is entirely within the power of young English chemists to determine."

Our fallen fortunes then are as yet not quite retrieved. Nay, it may even be asked whether the number of foreign chemists employed in this country is not increasing, instead of diminishing, a significant comment on the recent revival of technical science among us.

As to what young English chemists can do in the matter we must remember that they and their instructions are alike hampered by the haunting necessity of preparing for examinations. As a matter of course they have less original and suggestive minds than their foreign rivals who have been trained to research.

What more do we want? We want abolition of "payment by results," and of the examination system altogether. If the higher powers will grant these two points "this state of things" will not exist much longer.

UNIVERSITIES AND COLLEGES.

UNIVERSITY OF LONDON.

CANDIDATES for any Degree granted by this University are required to have passed the Matriculation Examination, to which no candidate is admitted unless he has produced a certificate showing that he has completed his sixteenth year.

The Fee for this examination is £2.

The Examination will be held on Monday, January 12th, 1885. It is conducted by means of Printed Papers; but the Examiners are not precluded from putting, for the purpose of ascertaining the competence of the Candidates to pass, *viva voce* questions to any Candidate in the subjects in which they are appointed to examine.

Candidates are not approved by the Examiners unless they have shown a competent knowledge in each of the following subjects:—Latin. Any two of the following Languages:—Greek, French, German, and either Sanskrit or Arabic. The English Language, English History, and Modern Geography. Mathematics. Natural Philosophy. Chemistry.

The Examination in Chemistry is—Chemistry of the Non-metallic Elements; including their compounds—their chief physical and chemical characters—their preparation—and their characteristic tests.

A Pass Certificate, signed by the Registrar, will be delivered to each Candidate who applies for it, after the Report of the Examiners has been approved by the Senate.

If in the opinion of the Examiners any Candidates in the Honours Division of not more than Twenty years of age at the commencement of the Examination possess sufficient merit, the first among such Candidates will receive an Exhibition of thirty pounds per annum for the next two years; the second among such Candidates will receive an Exhibition of twenty pounds per annum for the next two years; and the third will receive an Exhibition of fifteen pounds per annum for the next two years; such exhibitions are payable in quarterly instalments, provided that on receiving each instalment the Exhibitioner declares his intention of presenting himself either at the two Examinations for B.A., or at the two Examina-

tions for B.Sc., or at the Intermediate Examination in Laws, or at the Preliminary Scientific M.B. Examination, and Intermediate Examination in Medicine, within three academical years from the time of his passing the Matriculation Examination.

Under the same circumstances, the fourth among such Candidates will receive a prize to the value of ten pounds in books, philosophical instruments, or money; and the fifth and sixth will each receive a prize to the value of five pounds in books, philosophical instruments, or money.

Any Candidate who may obtain a place in the Honours Division at the Matriculation Examination in January is admissible to the Intermediate Examination either in Arts or in Science in the following July.

INTERMEDIATE EXAMINATION IN SCIENCE.

The Intermediate Examination in Science will be held in July, 1885.

No Candidate (with the exception of such as have obtained Honours at the Matriculation Examination in the preceding January) is admitted to this Examination within one academical year of the time of his passing the Matriculation Examination.

The Fee for this Examination is £5.

Candidates will be examined as follows:—For a Pass or for Honours in (1) Inorganic Chemistry, (2) Experimental Physics, (3) Mathematics; and for a Pass only in (4) General Biology. Candidates may also be examined for Honours in Botany and in Zoology.

Every Candidate, on sending in his name for the Examination, must state whether he intends to compete for Honours in any subject or subjects; and if he does so intend, must specify the subject or subjects.

No Candidate will be allowed to take both the Pass and the Honours Papers in the same subject, but every Candidate must take the Pass Papers in those subjects in which he does not offer himself for Honours.

A Candidate who enters for, but fails to obtain, Honours in Inorganic Chemistry, Experimental Physics, and Mathematics, may be recommended by the Examiners for a Pass in these subjects respectively, if they are satisfied that he has shown such a competent knowledge thereof as is required by the Regulations for the Pass Examination.

The Examiners will make no report upon the Examination for Honours of a Candidate who has failed in any part of his Pass Examination.

Examination for Honours.

Any Candidate who presents himself at the Intermediate Examination in Science for examination in all its subjects may be examined for Honours in (1) Chemistry, (2) Experimental Physics, (3) Mathematics, (4) Botany, and (5) Zoology; unless he has previously obtained the Exhibition in Mathematics at the Intermediate Examination in Arts, in which case he will not be admissible to the Examination for Honours in that subject; or unless he has previously obtained an Exhibition at the Preliminary Scientific (M.B.) Examination in any of the subjects which are common to it with the Intermediate Examination in Science, in which case he will not be admissible to the Examination for Honours in that subject.

Candidates for Honours in Chemistry will be examined in Inorganic Chemistry, treated more fully than in the Pass Examination. In addition, they will be examined practically in Simple Qualitative Analysis. This Examination, will consist of six hours' examination by two printed papers and of six hours' practical work.

In the Examination for Honours, the Candidate, not being more than 22 years of age at the commencement of the Pass Examination, who most distinguishes himself will receive an Exhibition of £40 per annum for the next two years.

B.Sc. EXAMINATION.

The B.Sc. Examination will be held in October.

Candidates for this Examination are required to have

passed the Intermediate Examination in Science at least one academical year previously.

The Fee for this Examination is £5.

The regulations are framed with the view of allowing the candidate to select any three of the following nine subjects:—

1. Pure Mathematics.
2. Mixed Mathematics.
3. Experimental Physics.
4. Chemistry.
5. Botany, including Vegetable Physiology.
6. Zoology.
7. Animal Physiology.
8. Physical Geography and Geology.
9. Mental and Moral Science.

Examination for Honours.

Any Candidate who has passed the B.Sc. Examination, and has not previously passed the B.A. Examination, may be examined at the Honours Examination next following the B.Sc. Examination at which he has passed, for Honours in (1) Mathematics, (2) Mental and Moral Science, (3) Experimental Physics, (4) Chemistry, (5) Botany, (6) Zoology, (7) Physiology, (8) Physical Geography and Geology; provided that he shall have gone through the Pass Examination in the corresponding subject or subjects immediately before. And any Bachelor of Arts who has passed the B.Sc. Examination may under the same conditions be examined for Honours in one or more of the above mentioned subjects, unless he have previously obtained a Scholarship at the B.A. Examination in either of the first two of those subjects, in which case he shall not be admissible to the Examination for Honours in that subject.

The examination for Honours in Chemistry will take place on Monday and Tuesday in the week following the Examination for Honours in Mathematics; on Monday by printed papers (chiefly on Organic Chemistry), and on Tuesday by practical exercises in Simple Qualitative and Quantitative Analysis.

The candidate, being not more than 23 years of age, who most distinguishes himself in Chemistry, will receive £50 per annum for the next two years, with the style of University Scholar.

DOCTOR OF SCIENCE.

The examination for the Degree of Doctor of Science takes place annually within the first twenty-one days of June, and the examination in each branch occupies four days.

No candidate is admitted to the examination for the Degree of D.Sc. until after the expiration of two Academical Years from the time of his obtaining the Degree of B.Sc. in this University, unless he shall have passed the B.Sc. Examination in the First Division at least two Academical years subsequently to having passed the Intermediate Examination in Science, in which case he shall be admitted to the examination for the Degree of Doctor of Science at the expiration of one Academical Year from the time of obtaining his B.Sc. Degree.

The Fee for this Examination is £10.

Every candidate for the degree of D.Sc. is examined in some one or more of the various branches of Physical, Biological, Geological and Palæontological, or Mental Science, to be selected by himself; and no candidate is approved by the examiners unless he has shown a thorough practical knowledge of the principal subject and a general acquaintance with the subsidiary subject or subjects, specified as belonging to the branch so selected. He is expected to be so fully conversant with the principal subject he may select as to be able to go through any examinational test (whether theoretical or practical) of his acquirements in it that can be fairly applied. Candidates, when giving notice, must specify the branch or branches in which they desire to be ex-

aminated. The following are the requirements in Chemistry:—

BRANCH IV. OF PHYSICAL SCIENCE.

INORGANIC CHEMISTRY.

Principal Subject—Inorganic Chemistry.

Subsidiary Subjects—Either Organic Chemistry; or Mineralogy, Crystallography, and Chemical Technology in its relations to Inorganic Chemistry.

BRANCH V., ORGANIC CHEMISTRY.

Principal Subject—Organic Chemistry.

Subsidiary Subjects—Either Inorganic Chemistry; or Chemical Technology in its relations to Organic Chemistry, and the Chemistry of Animal and Vegetable Life.

PRELIMINARY SCIENTIFIC (M.B.) EXAMINATION.

This examination will be held in July, 1885.

No Candidate is admitted to this examination until he has passed the Matriculation Examination,* and notice must be given to the Registrar at least 14 days before the commencement of the examination. The fee for this examination is five pounds.

Candidates for the degree of M.B. are required by the Senate to pass the Preliminary Scientific Examination before commencing their regular medical studies; and are recommended to devote a preliminary year to preparation for it according to the following programme:—Winter Session: Experimental Physics; Chemistry (especially Inorganic); Zoology. Summer Session: Practical Chemistry (Inorganic); Botany.

Any candidate who presents himself at the Preliminary Scientific (M.B.) Examination may be examined for Honours unless he has previously obtained an Exhibition in any one of the subjects at the Intermediate Examination in Science, in which case he is not admissible to the Examination for Honours in that subject.

Candidates for Honours in Chemistry are examined in Inorganic Chemistry, treated more fully than in the Pass Examination. In addition they are examined practically in Simple Qualitative Analysis.

EXAMINATION IN SUBJECTS RELATING TO PUBLIC HEALTH.

A Special Examination will be held in December in subjects relating to public health.

No candidate is admitted to this Examination unless he has passed the Second Examination for the Degree of Bachelor of Medicine in this University at least one year previously; nor unless he shall have given notice of his intention to the Registrar at least two calendar months before the commencement of the Examination.

The Fee for this Examination is £5.

SCHOLARSHIPS.

A Scholarship of the value of Fifty Pounds per annum is biennially offered to Candidates intending to pursue, at Owens College, Manchester, their studies for Graduation in one of the Faculties of the University of London; a single Scholarship of Fifty Pounds per annum for three years being awarded to the highest of those Candidates at the June Matriculation Examination who shall have been previously approved by the Principal of Owens College, provided that he pass in the Honours Division; or, in case no Candidate should so pass, two Scholarships, each of Twenty-five Pounds per annum, being awarded to the two Candidates as aforesaid who shall stand highest in the First Division.—Particulars may be obtained on application to the Principal of Owens College, Manchester.

A Scholarship of Fifty Pounds per annum, tenable for three years, is also annually awarded to that Candidate in the Honours Division at the June Matriculation

* Candidates who pass in all the subjects of the Preliminary Scientific (M.B.) Examination, and also pass at the same time in the Pure Mathematics of the Intermediate Examination in Science, or who have previously passed the Intermediate Examination in Arts, are admissible to the B.Sc. Examination.—One Fee of £5, paid on entering for the Preliminary Scientific Examination also admits a Candidate to the Mathematics of the Intermediate Examination in Science, if taken at the same time.

Examination who shall stand highest of the Candidates previously approved by the Principal of University College, Bristol; and who intends to study at that College with a view to graduation in one of the Faculties of the University of London. (N.B.—This Scholarship is open to Women.) Further particulars may be obtained on application to the Principal of University College, Bristol.

Particulars of the Colonial and Indian Scholarships may be obtained on application to the Secretary of the Gilchrist Educational Trust, 4, Broad Sanctuary, Westminster, S.W.

UNIVERSITY OF OXFORD.

Waynflete Professor of Chemistry.—W. Odling, M.A., F.R.S.

Professor of Mineralogy.—N. S. Maskelyne, M.A., F.R.S.

Every Student must reside in one or other of the Colleges or Halls, or in licensed lodgings, for a period of three years, passing at least two examinations in Arts, and one in either Mathematics, Natural Science, Law, Modern History, or Theology, when, if he obtain a first, second, or third class, he can take his B.A. Degree; if he do not gain such honour he has to pass a third examination in *Literis Humanioribus*.

The fee for students working in the Laboratory for three days in the week during the Term is £3; for students working every day, £5.

Scholarships of about the value of £75 are obtainable at Christ Church, Magdalen, and other colleges, by competitive examination in Natural Science.

More detailed information may be obtained from the University Calendar; from the professors; from E. Chapman, Esq., M.A., Frewin Hall; and from the Sub-Librarian in the Radcliffe Library or the Museum.

UNIVERSITY OF CAMBRIDGE.

Professor of Chemistry.—G. D. Liveing, M.A., F.R.S.
Jacksonian Professor of Natural and Experimental Philosophy.—J. Dewar, M.A., F.R.S.

The Student must enter at one of the Colleges, or as a Non-collegiate Student, and keep terms for three years by residence in the University. He must pass the previous examination in Classics and Mathematics, which may be done in the first or second term of residence, or through the Oxford and Cambridge Schools Examination Board, or through the Senior Local Examinations, before commencing residence. He may then proceed to take a Degree in Arts, either continuing mathematical and classical study, and passing the ordinary examinations for B.A., or going out in one of the Honour Triposes.

The scholarships, ranging in value from £20 to £80 a year, are chiefly given for mathematical and classical proficiency. Scholarships are given for Natural Science in Trinity, St. John's, St. Peter's, Clare, Christ's, Sidney, Pembroke, Caius, and Downing Colleges; the examinations being at Easter, and in June and October.

The Chemical Laboratory of the University is open daily for the use of the Students. The Demonstrators attend daily to give instructions.

Non-collegiate Students are allowed to attend certain of the College Lectures and all the Professors' Lectures, and have the same University status and privileges as the other Students. They are under the superintendence of the Rev. R. B. Somerset, Orford House, Cambridge, from whom further information may be obtained.

The following are the Lectures on Chemistry for the ensuing Academic Year:

MICHAELMAS TERM, 1885.

General Course, by the Professor of Chemistry, on Tuesdays, Thursdays, and Saturdays, at 12 noon. Begin Oct. 14.

Physical Chemistry (Advanced), by the Jacksonian Professor, on Mondays, Wednesdays, and Fridays, at 12 noon. Begin Oct. 15.

Elementary Organic Chemistry, by Mr. Main, at St. John's College, on Tuesdays, Thursdays, and Saturdays, at 10 a.m. Begin Oct. 14.

General Principles (advanced), by Mr. Pattison Muir, Caius College, Monday, Wednesday, and Friday, at 10 a.m. Begin Oct. 13.

Elementary Chemistry (especially Metals), by Mr. Pattison Muir, Caius College, Tuesdays, Thursdays, and Saturdays, at 10 a.m. Begin Oct. 14.

Elementary Physical Chemistry, by the Assistant to the Jacksonian Professor, on Mondays, Wednesdays, and Fridays, at 1 p.m. Begin Oct. 15.

General Principles (Non-metals) for Natural Science Tripos, by Mr. Heycock, at King's College, on Mondays, Wednesdays, and Fridays, at 10 a.m. Begin Oct. 15.

Spectroscopic Analysis, by the Professor of Chemistry, on Tuesdays, Thursdays, and Saturdays, at 1.30 p.m. Begin Oct. 16.

Practical Chemistry, by the Demonstrators of Chemistry. University Laboratory. Also at St. John's, Caius, and Sidney Colleges. Daily. Begin Oct. 13.

LENT TERM, 1885.

General Course continued, by the Professor of Chemistry, on Tuesdays, Thursdays, and Saturdays, at 12 noon. Begin Jan. 22.

Organic Chemistry, by the Jacksonian Professor, on Mondays, Wednesdays, and Fridays, at 12 noon. Begin Jan. 23.

General Course of Chemistry, by Mr. Main, at St. John's College, on Tuesdays, Thursdays, and Saturdays, at 10 a.m. Begin Jan. 22.

General Principles (continued) by Mr. Pattison Muir, at Caius College, on Mondays, Wednesdays, and Fridays, at 10 a.m. Begin Jan. 23.

Elementary Course (especially Non-metals) by Mr. Pattison Muir, Caius College, on Tuesdays, Thursdays, and Saturdays, at 10 a.m. Begin Jan. 22.

Elementary Organic Chemistry, by the Assistant to the Jacksonian Professor, on Mondays, Wednesdays, and Fridays, at 1 p.m. Begin Jan. 23.

Chemical Philosophy, by Mr. Heycock, King's College, on Mondays, Wednesdays, and Fridays, at 10 a.m. Begin Jan. 23.

Chemistry practically applied to Agriculture, by Mr. Robinson, on Mondays, Wednesdays, and Fridays, at 11 a.m. Begin Jan. 23.

Practical Chemistry, at the University Laboratory, and at St. John's, Caius, and Sidney Colleges, daily. Begin Jan. 22.

EASTER TERM, 1885.

Elementary Chemistry, by a Demonstrator, on Mondays, Wednesdays, and Fridays, at 12 noon. Begin April 24.

General Course continued, by Mr. Main, at St. John's College, on Tuesdays, Thursdays, and Saturdays, at 10. Begin April 24.

Elementary Course for first M.B. (continued) including Carbon Compounds, by Mr. Pattison Muir, at Caius Laboratory, on Tuesdays, Thursdays, and Saturdays, at 10 a.m. Begin April 23.

Gas Analysis, by the Assistant to the Jacksonian Professor, on Mondays, Wednesdays, and Fridays, at 10 a.m. Begin April 24.

Elementary and Advanced Demonstrations in Practical Chemistry, on Mondays, Wednesdays, and Fridays, at 9.15 a.m. Begin April 24.

Practical Chemistry, at the University Laboratory, at St. John's College, at Caius College, and at Sidney College, daily. Begin April 23.

KING'S COLLEGE.

(DEPARTMENT OF ENGINEERING AND APPLIED SCIENCE.)

Professor of Chemistry.—C. L. Bloxam, F.C.S.

Demonstrator of Practical Chemistry.—J. M. Thomson, F.C.S.

Assistant Demonstrator.—G. S. Johnson, F.C.S.

On Tuesday and Friday at 10.20 a.m. Students of the First Year are admitted to the Course of Theoretical and Applied Chemistry. The Course commences with a View of the Forces which concur to the production of Chemical Phenomena, after which the laws of Chemical Attraction are discussed, and the Non-metallic elements and their principal Compounds are described.

The Metals and their principal compounds are next examined, care being taken to point out the applications of the Science to the Arts; and the processes of the different Manufactures, of Metallurgy, and of Domestic Economy, are explained and illustrated.

Examinations of the Class, both *visd voce* and by written papers, are held at intervals during the course at the usual Lecture hour.

Second Year.—Students attend in the Laboratory twice a week, on Tuesday and Friday, at 10.20, and they go through a course of Manipulation in the most important operations of Chemistry, including the first steps of Analysis.

Any Student of this Department may be admitted to this Class at any period of his study on payment of an extra fee.

Experimental and Analytical Chemistry in the Laboratory.—The object of this Class is to afford to Students who are desirous of acquiring a knowledge of analysis, or of prosecuting original research, an opportunity of doing so under the superintendence of the Professor and Demonstrator; Students may enter, upon payment of extra Fees, at any time except during the vacation, and for a period of one, three, six, or nine months, as may best suit their convenience. The laboratory hours are from ten till four daily, except Saturday, on which day the hours are from ten till one.

In addition to the Laboratory Fee, each Student defrays the expenses of his own Experiments. The amount of this expense, which is comparatively trifling, is entirely under his own control.

Special hours and fees are arranged for the convenience of such Third Year Students as wish to study Analytical Chemistry.

Fees.—Chemistry per term, £3 3s. od.; per ann., £8 8s. od.; Practical Chemistry per term, £4 4s. od.; per ann., £10 10s. od.; Experimental and Analytical Chemistry.—One Month (daily attendance), £4 4s. od.; Three Months (daily attendance), £10 10s. od.; Six Months (daily attendance), £18 18s. od.; Nine Months (daily attendance), £26 5s. od. A student taking a month's ticket may attend daily during 1 month, or 3 days a week during 2 months, or 2 days a week during 3 months.

Rules as to Admission of Students.

I. The Academical Year consists of Three terms: Michaelmas Term, from beginning of October to the week before Christmas; Lent Term, from the middle of January to the week before Easter; Easter Term, from Easter to the beginning of July.

II. The days fixed for the Admission of New Students in the Academical Year 1884-85, are Tuesday, September 30, Wednesday, January 14, and April 15.

METALLURGY.

Professor.—A. K. Huntington, F.I.C., F.C.S., &c.

The following subjects are treated of in the Lectures: The Selection and Economic Preparation of Fuel and of Refractory Materials; the Methods by which Metals are obtained from their ores, and the means by which they are rendered suitable for the various requirements of the Arts.

Particular attention is made to the study of the Nature and Properties of Metals and Alloys available for Constructive Purposes.

In the Metallurgical Laboratory, which is always open during College hours, the relation between the Chemical Composition of Metals and their Mechanical Properties may be studied by the aid of Testing Machinery. Th:

study of the other subjects above referred to, and also of Assaying, is carried on under the direction of the Professor.

Fees.—Lectures only, £3 3s. Practice (including Lectures), for one month, £6 6s.; two, £11 11s.; three, £15 15s.; six, £27 6s.; nine, £37 16s.

EVENING CLASSES.

Classes for Evening Instruction in various subjects are held during the months from October to March, inclusive, and during the months of April, May, and June. The next Winter Course will begin on Monday, October 6th, and will terminate on Friday, March 27th, 1885, the last fortnight being devoted to examinations. Many of these classes have special reference to the B.A. and Matriculation Examinations of the University of London.

Agriculture.—A Course of Lectures on this subject will be given during the ensuing Winter by Mr. Frederick James Lloyd, F.C.S., of the Royal Agricultural Society of England. The Lectures will be given on Monday Evenings at 8 p.m., beginning October 6th, 1884.

UNIVERSITY COLLEGE.

FACULTY OF SCIENCE.

Professor.—Alex. W. Williamson, Ph.D., LL.D., F.R.S. *Lecturers.*—Henry Forster Morley, M.A., D.Sc.; R. T. Plimpton, Ph.D.

The Session is divided into three Terms, as follows, all the dates being inclusive:—

First Term, from Friday, October 3rd, until Thursday, December 18th;

Second Term, from Tuesday, January 6th, 1885, till Saturday, March 21st;

Third Term, for Lectures, from Tuesday, April 14th, till Tuesday, June 16th. Class Examinations occupy about ten days, beginning on Wednesday, June 17th.

Students preparing for the Preliminary Scientific Examination who enter in January are recommended to attend the Laboratory, and to supplement the instruction received there with private study of the theoretical part of their work.

Introductory or Matriculation Course.

Third Term: Tuesday, Wednesday, and Friday, at 11. Fee:—£4 4s.

The Course will consist of about thirty lessons, partly theoretical and partly practical, on the non-metallic elements. Frequent exercises will be given.

General Course of Chemistry and Chemical Physics.

First and Second Terms: Inorganic.—The Class meets five times a week: Mondays, Wednesdays, and Fridays, at 11, for Lectures or Examinations; and on Tuesdays and Thursdays, at 9, for Exercises.

Third Term: Elementary Organic.—Lectures or Exercises, Tuesdays, Wednesdays, and Fridays, at 11.

Fee:—For the Course, £7 7s.; Perpetual, £9 9s.; for the First or Second Terms, £3 3s.; for the Third Term, £3 3s.

The subjects treated in the First Terms of the Course include those required in Chemistry at the Matriculation Examination of the University of London.

For the Preliminary Scientific Examination Students attend during the First and Second Terms.

Arrangements will be made to give Candidates for the Preliminary Scientific and Intermediate B.Sc. Examinations, who have attended during the First and Second Terms, opportunities for revising some parts of their work during the Summer Term.

The Third Term provides instruction in the preparation, composition, and fundamental properties of the most common important organic substances. The subjects dealt with include those required by Candidates for the First Examination of the College of Physicians. The last three Meetings will be devoted to recapitulation; and Students who postpone the above examination for a twelve-month will find it advantageous to attend these meetings in their second year.

Organic Chemistry.

Monday, Wednesday, and Friday, at 9, in the First and Second Terms; and Tuesday and Thursday, at 9, in the Third Term, beginning Wednesday, October 8th. The hour of meeting will be altered should the Class desire it.

This Course of Organic Chemistry is intended for those who in studying the subject have not a Medical Examination chiefly in view. Candidates for Honours at the Int. M.B. are, however, recommended to attend this Course during the First and Second Terms, instead of the Special Summer Course.

The Course includes the subjects required at the B.Sc. Examination, Pass and Honours; but no previous acquaintance with Organic Chemistry will be expected of those joining the Class.

Fee:—For the Course, £6 6s.; for a Term, £2 12s. 6d.

Practical Class.

First and Second Terms, on Tuesday and Thursday, at 11 or 10. Each Student will attend twice a week, at the hour allotted to him, on arrangement with the Professor.

Fee, including cost of materials, £5 5s.; for a Second Course, £3 3s.

The Course includes the Practical Chemistry required at the Preliminary, Scientific, and Intermediate B.Sc. Examinations of the University of London.

Senior Practical Class.

Mondays and Saturdays from 10 to 12 during the Third Term.

Fee:—(Including cost of materials) £5 5s.; for a Second Course, £3 3s.

Elementary Chemistry. (Women.)

Lectures: Wednesday and Friday, from 4 to 5.

A Class of Elementary Chemistry, including the subjects required for Matriculation, will be given during the Second and Third Terms, commencing Wednesday, January 7th.

The common gases and acids will be prepared and examined by the Students themselves.

A few minutes during each Lecture will be devoted to *viva voce* examination on the subject of the preceding Lecture.

One or two questions, to be worked out at home, will be set at each meeting.

Fee:—for the Course, including the cost of apparatus and materials, £4 4s.

Quantitative Analysis.

A Course of Ten Lectures on the newer methods of Quantitative Analysis will be given during the Second Term, on Mondays, at 5. Fee, £1 1s. Some of the more important operations and methods of Quantitative Analysis will be described, including some of the best methods which are of too recent introduction to have found a place in the ordinary text-books.

Analytical and Practical Chemistry.

The Laboratory is open daily from 9 a.m. to 4 p.m., Saturdays, 9 a.m. to 2 p.m., from October until the middle of July, with a short recess at Christmas and at Easter.

Fees: for the Session, £26 5s.; six months, £18 18s.; three months, £10 10s.; one month, £4 4s.

Three specified days a week:—for the Session, £15 15s.; six months, £11 11s.; three months, £6 6s.; one month, £2 12s. 6d., exclusive of expense of materials. Students may enter at any period of the Session.

The Laboratory Course includes the Practical Chemistry required at the following Examinations of the University of London:—Prel. Sci. (M.B.), Intermediate M.B., Intermediate B.Sc., B.Sc., D.Sc.

Students who wish to attend the Laboratory and Classes of Technical Chemistry may acquire here the requisite preliminary knowledge of Practical Chemistry and Analysis.

When accompanied by, or preceded by, attendance on the Lectures on Chemistry and Organic Chemistry, the Laboratory Course qualifies Students in the application of Chemistry to Manufactures, Metallurgy, Medicine, or Agriculture, &c.

There is also a Chemical Library containing the chief Journals and Standard Works on Chemistry.

A Gold Medal and Certificates of Honour are competed for by Students entered for the Session.

Chemical Technology.

Professor CHARLES GRAHAM, D.Sc., F.I.C.

Assistants.—C. J. Wilson, F.C.S., and T. W. Lovibond, F.C.S.

The Course of instruction in this Department is designed to afford to Students who propose to devote themselves to industrial pursuits in which Chemistry plays an important part, or to prepare themselves for the profession of Consulting Chemist, the instruction essential for their success in their future line of work. It will also be found of great value in two of the branches (Organic and Inorganic Chemistry) in which the Degree of Doctor of Science can be taken at the University of London.

In the Session 1884-85, it is proposed to treat of the following subjects:—

Heating and Lighting.

Metallurgy.

The Chemistry of the Alkali trade.

Chemistry of Brewing.

Agricultural Chemistry.

Fees—for each Course, £2 2s.; for two Courses, £3 3s.; for the five Courses, £5 5s.

Laboratory of Chemical Technology.

The instruction in the Laboratory of Chemical Technology will consist of the examination and valuation of raw materials used, and of the final products obtained in various manufacturing industries, and of experimental examination of the processes employed in the arts and manufactures.

The Laboratories are open daily from 9 a.m. to 4 p.m., from the 6th of October until the middle of July, with a short recess at Christmas and at Easter.

Fees—for the Session, 25 guineas; six months, 18 guineas; three months, 10 guineas; one month, 4 guineas; exclusive of the expense of materials.

NORMAL SCHOOL OF SCIENCE AND ROYAL SCHOOL OF MINES.

Professor.—E. Frankland, Ph.D., D.C.L., F.R.S.

Assistant Professor.—F. R. Japp, M.A., Ph.D.

Demonstrators.—W. R. Hodgkinson, Ph.D., and P. F. Frankland, Ph.D., B.Sc.

Assistants.—G. S. Newth and H. Chapman Jones.

The Normal School of Science at South Kensington is intended, primarily, for the instruction of teachers, and of students of the industrial classes selected by competition in the examinations of the Science and Art Department. The Royal School of Mines is affiliated to the Normal School. Students entering for the Associateship of the School of Mines obtain their general scientific training in the Normal School. The instruction in the Normal School is arranged in such a manner as to give the Students a thorough training in the general principles of Science, followed by advanced instruction in one or more special branches of Science. The Associateship is granted in certain divisions or lines of study. Students who go through any one of the prescribed courses of instruction and pass the necessary Examinations receive a Certificate of Associateship of the Normal School, or of the Royal School of Mines. But students who are not candidates for the Associateship are permitted to take up the course of instruction in one or more special branches of science, and on passing the examination receive a Certificate to that effect. The

Associateship of the Normal School of Science is given in one or more of the following divisions:—Mechanics, Physics, Chemistry, Biology, Geology, and Agriculture, and the Associateship of the Royal School of Mines in Metallurgy and Mining.

The course of instruction is the same for all the divisions during the first two years, after which it is specialised in accordance with the Scheme detailed in the Prospectus of the School.

The Session is divided into two Terms. The first Term begins about the 1st of October and ends about the middle of February. The second Term begins in the middle of February and ends about the middle of June.

Examinations are held at the end of each course of instruction and at such other periods as may be found necessary. On the results of these examinations the successful candidates are arranged in two classes, first and second. There are also "Honours" examinations for the subjects of the third and fourth years, the successful candidates being placed in order of merit. A student obtains the Associateship who passes in all the subjects of the first two years and of the special division he selects for his Associateship. A student who goes through the prescribed course of instruction in any subject and passes the final examination in it receives a certificate to that effect.

Students who do not wish to attend the lectures are admitted for short periods to the laboratories, at the discretion of the Professors. The fees for the laboratories are £4 per month.

Admission is granted to persons desirous of attending certain courses of the lectures without the laboratory instruction, on payment of the lecture fees.

The fees which are shown in the following table must be paid to the Registrar of the School before the commencement of each course.

	Part I. Part II. Part III. Part IV.				
	Lecs.	Lab.	Lecs.	Lecs. & Lab.	Lecs. & Lab.
Chemistry	4	13	15	15	1
Physics	5	12	12	12	
Biology with Botany	5	12	12	12	8
Geology with Mineralogy	4	8	8		8
Mechanics	4	6	8	8	
Metallurgy	2	13	15		
Assaying for Mining Students		10			
Mining	4	6			
Agriculture	4	10			
Astronomy	2				

Mathematics £3 per term. Practical Geometry and Mechanical Drawing £3 per term. Freehand Drawing £1 per term.

Thus the fees for the first two years amount to about £75, and for the remainder of the course for the Associateship they vary from £30 to about £40.

Both the private and the State-aided students are required to furnish themselves with certain instruments and apparatus before the commencement of the courses. These are enumerated in the syllabuses of the several subjects.

Officers of the Army, Navy, and Civil Service, recommended by their respective Departments, are admitted to the Lectures and Laboratories at half the foregoing charges.

Associates of the Normal School of Science and of the Royal School of Mines have the privilege of free admission to the Library and to all the courses of lectures.

Science teachers actually engaged in teaching who are registered by the Science and Art Department as qualified to earn payments for teaching Science may attend any course of lectures on the payment of £1.

Several valuable Exhibitions, Scholarships, and Prizes are attached to the studentship.

Summer Courses for Teachers.—Short courses of instruction are given annually, about July, in different branches of science for the benefit of teachers of science

schools in the country. The courses last three weeks. About 200 teachers are admitted to them, and they receive 2d class railway fare to and from South Kensington, and a bonus towards their incidental expenses of £2 each. (See Science Directory.)

Working Men's Lectures.—Three courses of evening lectures for working men will be given during the session by Professors Judd, Chandler Roberts, and Guthrie. The admission to each course of six lectures will be 6d. The number of tickets is limited by the size of the lecture theatre.

UNIVERSITY COLLEGE OF WALES, ABERYSTWYTH.

Professor of Chemistry and Experimental Physics.—T. S. Humpidge, Ph.D., B.Sc. (Lond.)

The Session begins on Wednesday, September 17th, 1884.

The College is open to male and female students not under the age of 15 years.

The Fee for the whole Session, paid in advance, is £10; if paid by single Terms, for the first Term of attendance in each Session £4; for the second Term, £3 10s.; for the third Term £3. The Fee for Practical Chemistry, or Practical Physics, is 5s. per Term extra. Any person wishing to attend single classes may do so on payment of the sum of £1 per Term for each class.

Several valuable Scholarships and Exhibitions are attached to the Studentship.

Fee for all subjects extending over the whole Session, £10. Practical Chemistry, 5s. per term extra.

UNIVERSITY COLLEGE, BRISTOL.

Professor of Chemistry.—W. Ramsay, Ph.D.

Lecturer.—Sydney Young, B.Sc.

DAY LECTURES.

Inorganic Chemistry.

This Course treats of the principles of Chemistry, and of the Chemistry of the Non-Metals and Metals.

Lectures will be given at 9 o'clock on Mondays, Wednesdays, Fridays, and Saturdays during the First and Second Terms.

The lectures will be illustrated with experiments and diagrams.

Examinations will be held from time to time during the course.

Fee, £4 4s. for two Terms, £3 3s. for one Term.

Special Laboratory Course.

Special instruction will be given on Tuesdays and Thursdays from 3 to 5. The Course is designed for Students entering for elementary examinations in Chemistry, and others to whom the hour may prove convenient.

Fees, £3 3s. for two Terms; £2 2s. for one Term.

Organic Chemistry.

This Course will relate to the more important groups of the Compounds of Carbon.

Lectures will be given during the Second Term on Tuesdays and Thursdays at 10 o'clock; during the Third Term on Tuesdays, Thursdays, and Saturdays at 10 o'clock. Special Lectures will also be given.

Fee, £3 3s.

Advanced Course.

This Course will be given on Saturdays at 9 o'clock during the first and second Terms, and will be devoted to a more minute consideration of Chemical Theory, as shown in recent researches. First Term.—Volume Relation of Solids, Liquids, and Gases; relations between Constitutive and Refractive Index for Light, &c. Second and Third Terms.—Thermal Chemistry.

Fee for the course, £3 3s.; for a single Term, £1 1s.

Practical Chemistry.—Laboratory Instruction.

The Laboratory will be open daily from 10 a.m. to 5 p.m., except on Saturdays, when it will close at 1 p.m. Instruction will be given in the Laboratory in all branches of Practical Chemistry, including Qualitative and Quantitative Inorganic and Organic Analysis, the preparation of Chemical Products, and Inorganic and Organic Research. Special facilities will be afforded to those who desire to study Practical Chemistry as applied to the different processes employed in the Arts and Manufactures, and to Scouring, Bleaching, and Dyeing. The Laboratory is under the immediate supervision of the Professor and the Lecturer.

Fees in Guineas—

	6 Days a Week.	5 Days a Week.	4 Days a Week.	3 Days a Week.	2 Days a Week.
Per Session ..	17	15	13	10	7½
„ Two Terms ..	13	11	9	7½	5½
„ One Term ..	7	6	5	4	3
„ Month ..	3	3	2	2	1½

Students may arrange to divide their days of laboratory work into half-days.

In order that Students may have an opportunity of acquiring some knowledge of Applied Chemistry, excursions to some of the Mines and Manufactories of the neighbourhood will be occasionally made. They will be conducted by the Professor or by the Lecturer.

Correspondence Classes are held for the purpose of giving instruction in chemical processes important to those engaged in the manufacture of woollen goods.

EVENING LECTURES.

Inorganic Chemistry.

Lecturer.—Sydney Young, B.Sc.

Wednesday and Friday, 8 to 9.

This course will consist of Two Lectures a week during the First and Second Terms; they will be devoted to the consideration of the Principles of Chemistry and Chemical Physics and the Chemistry of the Non-Metallic Elements. A few Lectures at the end of the Course will be devoted to the consideration of the Chemistry of the Metals. Special attention will be paid throughout to those products which have a practical application in the Arts and Manufactures.

Fee, 10s. 6d. for Two Terms; 7s. for One Term.

Technical Chemistry.—Special Courses.

Professor.—W. Ramsay, Ph.D.

First and Second Terms.—A Course of Lectures will be delivered on Tuesday evenings at 8 o'clock, on the Scouring, Bleaching, and Dyeing of Wool, Silk, Cotton, Linen, and Jute. This course is designed to afford information to those engaged in the manufacture and sale of articles made of the above materials. It will imply no previous knowledge of chemistry; but those who purpose to attend it are recommended to enter the Evening Chemistry Classes during the first Term.

Fee, 15s. for two Terms; 10s. for one Term.

Chemical Scholarship.—Among others, a Chemical Scholarship of £25 is offered for competition.

With the approval of the Council of the Institute of Chemistry students desiring to qualify as Associates may pass through the requisite amount of study at this College, which has also been approved as a centre for the Practical Examination of the Institute.

ROYAL AGRICULTURAL COLLEGE, CIRENCESTER.

CHEMICAL DEPARTMENT.

Professor.—Prof. E. Kinch, F.C.S., F.I.C.

Systematic courses of Lectures are given on Inorganic, Organic, and Agricultural Chemistry, illustrated by experiments, and by the collections in the College Museum. They comprise, as preliminary, the laws of Chemical Combination and the general Chemistry of mineral

bodies, and of the more frequently occurring bodies of organic origin, with the relationship of their leading groups; and, finally, the Chemistry of the atmosphere, of soils and manures, of vegetation and animal nutrition, and of Agricultural economy.

In the Laboratory practical instruction is given in the construction and use of apparatus and in Chemical manipulation and analysis, both qualitative and quantitative. After studying the simple operations and the properties of the commonly occurring substances, the Students are taught to analyse a series of compounds, and apply the knowledge thus obtained to the analysis of manures, soils, waters, foods and feeding stuffs, and other substances met with in the ordinary course of Agricultural practice. Chemico-agricultural researches are undertaken by the senior Students under the direction of the Professor and his Assistants.

THE YORKSHIRE COLLEGE, LEEDS.

Professor of Chemistry.—T. E. Thorpe, Ph.D., F.R.S., F.C.S.

Assistant Lecturers.—C. H. Bothamley, F.C.S., and Herbert Ingle.

The Session begins October 7, 1884.

Students of the Leeds School of Medicine are admitted to any of the classes on payment of the class fees, and are not charged with the College entrance fee.

Lecture Courses.

1. General Course on Systematic Chemistry—Monday, Tuesday, Thursday, and Friday, at 4 p.m., from October to the end of the second term. Fee for the Course, £5 5s.

2. Lectures on Laboratory Practice and Chemical Calculation—Monday, at 12.30 during the First and Second Terms. Fee, £1 1s.

3. Chemistry as Applied to Coal Mining—Wednesday, during the First Term, at 4 p.m.

4. Organic Chemistry—Tuesday and Thursday at 12.30 p.m., during the Second and Third Terms. Fee £2 12s. 6d.

5. Lectures on Chemical Technology—Will be varied from session to session. During Session 1884-5 a Course of Twenty Lectures "On the Destructive Distillation of Coal" will be given on Wednesdays, at 4 p.m., during the Second and Third Terms. Fee £2 2s.

6. A Class on Elementary Chemistry, consisting of about Twenty Lessons, on the Non-metals, will be held on Saturdays, at 12.30 p.m., during the First and Second Terms. Fee for the Lecture Class, 10s. 6d.

7. Photographic Manipulation—A Course of Ten Lessons will be given on Saturdays, during the Third Term, from 10 to 1, with special reference to dry plate processes and silver and platinum printing. Fee, £1 1s.

Laboratory Courses.

The College Laboratory will be open daily from 9 a.m. to 1 p.m., and from 2 to 5 p.m., except on Saturdays, when it will close at 1 p.m.

Fees for the Session—Students working six days per week, £18 18s.; five, £16 16s.; four, £14 14s.; three, £12 12s.

Class in Practical Chemistry, Saturday mornings, from 9.30 to 12.30. Fee £1 11s. 6d.

Practical Chemistry for Medical Students.—On Tuesday and Thursday, from 10 to 12 a.m., from May to July.

Evening Classes.

A Course of twenty Lectures by Mr. C. H. Bothamley, on the Elements of Inorganic Chemistry (the Non-metals) will begin during the first and second Terms, on Wednesdays, at 7.30 p.m., beginning October 15. Fee, 10s. 6d.

Dyeing Department.

Instructor.—J. J. Hummel, F.C.S.

Lecture Course, with practical work in the Dye-house,

for Students who wish to receive, on leaving the College, a certificate of proficiency in Dyeing; such certificate to be obtained by special examination in the several subjects of the Course, the latter extending over a period of two years. Fee, £3 3s.

Several valuable Scholarships are at the disposal of the College, viz., the Cavendish, Salt, Akroyd, Brown, and Clothworkers' Scholarships, and the Leighton Trustees' Exhibition.

MASON SCIENCE COLLEGE, BIRMINGHAM.

Professor.—W. A. Tilden, D.Sc., Lond., F.R.S.

Assistant Lecturer.—W. W. J. Nicol, M.A., B.Sc., Edin.

Demonstrator.—Thomas Turner, F.C.S.

The Session will be opened on Friday, October 3rd, 1884.

Elementary Course.

Twenty Elementary Lectures adapted to the requirements of beginners will be given in the Winter Term, and will be repeated after Christmas, on Mondays and Fridays at 12.30. The Second Course will begin on the first Monday in March.

Persons entirely unacquainted with Chemistry are recommended to attend these Lectures before entering for the General Course, which commences in October. Candidates for the Matriculation Examination of the University of London may obtain the instruction they require for that Examination by attending this Course.

General Course.

The General Course of Lectures on Chemistry will be found useful by Students who are afterwards to become Engineers, Architects, Builders, Brewers, or Manufacturers (such as Metallurgists, Alkali, Soap, Manure, Glass, or Cement Makers, Bleachers and Dyers, &c.)

Students preparing for the Intermediate Examination in Science and Preliminary Scientific (M.B.) Examination of the University of London, should attend the Lectures on *Inorganic Chemistry* (Winter and Spring Terms).

Candidates for B.Sc. and Intermediate Examinations in Medicine will in general require only that part of the course (Summer Term) which relates to *Organic Chemistry*.

The full course, extending over three terms, will also satisfy the requirements of Students preparing for the Associateship of the Institute of Chemistry, so far as attendance at lectures on General and Theoretical Chemistry is concerned.

1. From October to March (Winter and Spring Terms). About one hundred lectures on *Inorganic Chemistry* and *Chemical Philosophy* will be given on Mondays, Tuesdays, Wednesdays, Thursdays, and Fridays, at 10 a.m., commencing Wednesday, October 8th, 1884. Fee, £3 3s. for a single term, or £5 5s. for the course from October to March.

2. April to June (Summer Term). About forty lectures will be given on *Organic Chemistry*, or the chemistry of the most important series of carbon compounds. This course will include all the subjects required for the Intermediate Examination in Medicine of the University of London. Lecture Days.—Monday, Tuesday, Wednesday, and Thursday, at 9.30 a.m. Fee, £2 2s.

In both these courses the instruction at least once a week will take the form of class teaching, and exercises will be set which students will be expected to work at home.

Laboratory Practice.

The College Laboratory will be open daily from 9.30 to 5, except on Saturdays, when it will be closed at 1 p.m.

Candidates for Intermediate Examination in Science, Preliminary Scientific (M.B.), B.Sc., and Intermediate Examination in Medicine of the University of London, may obtain in the Laboratory of the College the instruction necessary. The three months Course of Practical

Chemistry for the B.Sc., Edinburgh, in the department of Public Health may be taken in the Mason College Laboratory.

The Ordinary Course for Medical Students is given on Tuesdays and Thursdays from 2 to 4 p.m. throughout the Summer Term.

Fees:—

	All day.	Three hours per day.
One Term	7 guineas	4½ guineas.
Two Terms	13 „	8½ „
Three Terms	18 „	12 „

A Course of short demonstrations and exercises will be given by the Professor or one of his Assistants once a week. All first-year Students will be required to attend, unless exempted for special reasons by the Professor. No Fee.

Metallurgy.—Two Courses of about Ten Lectures each will be given in the Winter and Spring Terms (October to March), on Tuesday Afternoons at 2.30, on the Principles and Practice of Metallurgy. Fee for each Course, 10s. 6d.

Arrangements will be made in the Chemical Laboratory or giving instruction in Practical Metallurgy.

Excursions.

During previous Sessions permission has been obtained to visit some of the great factories in or near Birmingham, in which chemical and metallurgical industries are carried on. Students have thus had most valuable opportunities of gaining a practical acquaintance with some branches of Applied Science. The privilege thus courteously granted by several manufacturers will, it is hoped, be enjoyed in every future Session. The excursions will be conducted by the Professor.

UNIVERSITY COLLEGE, LIVERPOOL.

Professor.—Campbell Brown, D.Sc.

Assistant.—H. Ll. Snape.

The Session commences October 1st. The Chemical Laboratories have been enlarged so as to accommodate 70 Lecture Students and 48 Working Students; the contemplated further large extensions have already been commenced.

Students desirous of having a thorough theoretical and practical acquaintance with Technical Chemistry, or who intend to adopt Chemistry as a profession, must devote at least three years to special study. They ought to have an ordinary school acquaintance with English Composition and Latin, and must be proficient in Arithmetic and the elements of Algebra.

They are recommended to adopt the following curriculum:—

First Year.—Chemistry—Course of Lectures on Theoretical Chemistry during the Autumn and Lent Terms; Chemical Laboratory, two or three days a week, during the Lent and Summer Terms; and the Practical Chemistry Class during the Summer Term. Mathematics, Pure and Applied, Physics or Geology, French or German.

Second Year.—Chemistry—Second Attendance on General Lecture Course, if necessary; Lectures on Organic Chemistry in the Summer Term. Chemical Laboratory, three days per week. Physics, Mathematics, German or French.

Third Year.—Any of the above-mentioned lectures which have not been attended. Lectures on Organic Chemistry. Chemical Laboratory, four or five days per week. Physical Laboratory, one day per week.

Special Certificates will be granted to those Students who pass through the above or a similar curriculum, and who perform their work and pass the periodical examinations to the satisfaction of the Professors; but these Certificates of Proficiency will only be given to such as can perform Practical Work in a reliable manner. Remunerated appointments are occasionally offered to efficient Students of the third year.

The Laboratory is opened for Students from 10 a.m. to 4.30 p.m. daily, on Saturdays from 10 to 1 only.

The Prospectus containing full particulars may be obtained from Adam Holden, 48, Church St., Liverpool, price 6d.; or from the Registrar, University College, Liverpool.

LIVERPOOL COLLEGE OF CHEMISTRY.

Principal.—George Tate, Ph.D., F.G.S., F.C.S.

The Laboratories are open daily from 10 to 5. Fee for a course of two years' instruction in General and Applied Chemistry, Sixty Guineas. Evening Courses are held during the Winter Session on Chemistry, Metallurgy, and Physics. A course of lectures specially adapted for those engaged in Engineering and Iron and Steel Works will be held on Tuesdays. Prospectuses containing full particulars of the laboratory and lecture courses may be had on application at the College.

UNIVERSITY OF DURHAM.

COLLEGE OF PHYSICAL SCIENCE, NEWCASTLE.

Professor of Chemistry.—P. Phillips Bedson, D.Sc., F.C.S.

Demonstrator.—Saville Shaw.

The Session will commence on September 29th, 1884.

Junior Division.—General Principles of Chemistry. History of the Non-Metallic Elements. History of the Metals and their more important Native and Artificial Compounds. Principles of Qualitative Analysis. Mondays, Wednesdays, and Fridays, at 12.5 p.m. **Senior Division.**—Organic Chemistry. Elements of Applied Chemistry. Tuesdays and Thursdays, at 11. Fee, £5 5s.

Practical Chemistry.—The Laboratory is open from 10 a.m. to 1 p.m., and from 2 to 5 p.m., except on Saturdays, when it closes at 1 p.m. **Laboratory Fees.**—Students working six days per week, £5 5s. per term; alternate days, £3 3s.; one day per week, £1 1s.

Courses of Study.—Students will be divided into two classes:—(1) Regular, or Matriculated Students; and (2) Non-Matriculated Students. Regular Students will be required to follow such a course of study in the subjects professed in the College as will enable them to pass the Examinations for the title of Associate in Physical Science. Non-Matriculated Students will attend such classes as they may select. Every candidate for admission as a regular student must pass an examination on entrance, in reading, writing from dictation, English or Latin Grammar, arithmetic (including decimals), and geography. Registered students in medicine are exempted from this examination, or students who produce a certificate of having passed either of the two following examinations:—

1. Durham Examination for certificate of proficiency in General Education, held in March and September.

2. Durham Examination for Students in Arts in their first year, or any examination of a similar nature that may be accepted by the Council.

Associateship in Physical Science.—Every candidate for the Associateship in Physical Science will be required to satisfy the examiners in three, at least, of the four subjects,—Mathematics, Physics, Chemistry, and Geology,—in an examination, to be held at the beginning of his second year.

The examination in Chemistry comprises:—General Principles of Chemistry. Elements of Inorganic Chemistry. Elements of Qualitative Analysis, including a Practical Examination.

The examination in Chemistry for Candidates at the end of their second year comprises:—Elements of Organic Chemistry and Applied Chemistry. Advanced Qualitative Analysis, including a Practical Examination. Elements of Quantitative Analysis.

Exhibitions.—Three Exhibitions of the value of £25, £15, and £10 respectively will be awarded in October next

to Candidates desirous of attending the first year course of study in the College.

Candidates must send their names to the Secretary, on or before the 22nd of September, and specify, at the same time, the special subject in which they desire to be examined.

The examination will be held at the College, and will commence on Monday, September 29th.

Two Exhibitions of £15 each will be awarded at the next examination of "Persons not members of the University," which will be held at Durham in March next.

Scholarships.

T. Y. Hall Scholarship.—This Scholarship, of the yearly value of £20, tenable for three years by students attending two or more of the classes, will be awarded on the result of the first examination for the Associateship in Science.

Charles Mather Scholarship.—This Scholarship, of the yearly value of about £40, will be awarded on the result of the Final Examination for the Associateship in Science, and is tenable for one year from the time of obtaining the Associateship in Science, provided the Scholar continues his studies in the College to the satisfaction of the Professors.

Nathaniel Clark Scholarship.—This Scholarship, of the value of £15 for one year, will be awarded in October to that student who shall pass the First Examination for the Associateship in Science, and who shall be most distinguished in Chemistry and Geology. The Scholar will be required to attend the classes of Chemistry and Geology, so as to be qualified to take those subjects for the Final Examination for the Associateship in June next.

VICTORIA UNIVERSITY.

OWENS COLLEGE, MANCHESTER.

Professor and Director of the Chemical and Metallurgical Laboratories.—H. E. Roscoe, LL.D., Ph.D., F.R.S., F.C.S.

Professor of Organic Chemistry.—C. Schorlemmer, F.R.S.

Demonstrators and Assistant Lecturers.—Watson Smith, F.C.S., Harry Baker, F.C.S., Arthur Smithells, B.Sc., and W. Bott, Ph.D.

The Session begins on October 7, 1884, and ends on June 26, 1885.

The instruction is given by means of Experimental Lectures and Tutorial Classes. The Chemical Classes form part of the Courses for Chemistry in the University.

Technological Chemistry.

Persons desiring to attend this course will be required to enter the College under the ordinary conditions of studentship.

The object of this course is to offer to students intending to devote themselves more especially to Applied Chemistry as complete a training as the College can provide in those branches of instruction which form the scientific foundation of the subject.

The complete course of instruction extends over four years, and embraces the following subjects:—

First Year.—Chemistry Lectures, Junior. Preparatory:—Chemical Laboratory, two days per week, and Analytical Chemistry Lectures class. Mathematical class, Section I. Experimental Mechanics. Geology (Physiography). French or German. Geometrical Drawing Lectures (evening class). Mechanical Drawing, Practical (evening class).

Second Year.—Chemistry Lectures, Junior* and Senior, classes. Chemical Laboratory, three days per week. Technological Chemistry Lectures. Experimental Physics or Mineralogy Lectures and Practical Courses. German or French. Geometrical Drawing Lectures (evening class). Mechanical Drawing, Practical (evening class).

* Students who gain a place in the First or Second class in the annual examinations will be excused a second attendance on these classes.

Third Year.—Chemistry Lectures, Senior* classes. Organic Chemistry Lectures. Chemical Philosophy. Chemical Laboratory, three days per week. Technological Chemistry Lectures (second course). Physical Laboratory, 1 day per week, or Advanced Mineralogy Lectures and Practical Course. Mechanical Drawing, Practical (evening class).

Fourth Year.—Organic Chemistry Lectures.* Technological Chemistry Lectures (third and fourth courses). Chemical Laboratory, 4 days per week. Mechanical Drawing, Practical (evening class).

Fees.—Every student is required to pay on admission an entrance fee of £1 1s. and a library fee of 5s., and the fees for the classes for which he enters. As alternative courses are in some instances open to a student offering himself for the Victoria University Examinations, it is not practicable to give tabular statements of the fees for every combination of classes. Special prospectuses may be obtained at the office of the College.

The aggregate of the fees in each year will vary slightly according to the particular class selected in French or German, or to the choice made in respect of the other alternatives proposed.

When a student is excused a second attendance on any of the Chemistry Lecture Courses the fee will be reduced accordingly.

Certificates will be granted to students on the successful completion of this course. Attendance on the full course of four years is expected of candidates for the Certificate, but students may obtain exemption (on cause shown) from the first or first and second year's course. Students so excused will nevertheless be required to undergo examination in all the subjects specified.

The Certificate will state in which subjects the candidate has gained Honours, and in which he has merely satisfied the Examiners.

The following are some of the more important Exhibitions, &c., available to students:—

Entrance Exhibitions.

Wellington Exhibition (Greek Testament), £15.

Dalton Mathematical Exhibition, £15. Renewable for a second year.

Grammar School Scholarship, £18 10s. per annum, tenable for three years; open to scholars of the Manchester Grammar School only.

Gilchrist Scholarships, three of £50 per annum, tenable for three years; awarded on the results of the Matriculation Examination of the University of London.

Rumney Scholarship, £45 per annum, tenable for three years.

Ramsbottom Scholarship, £40 per annum, tenable for two years.

Crace-Calvert Scholarship, £25 per annum, tenable for two years. The next competition will take place in June, 1886. This scholarship is open only to duly qualified members of the Evening Chemistry Classes.

Dauntsey Medical Scholarship, £100.

Fellowship.

The Langton Fellowship, £150 per annum, tenable for three years. Candidates must have been students in the College for not less than three sessions, and must during their studentship or within one year after the close of the same have obtained a degree of some University of the United Kingdom, or been elected to the Associateship of the College.

Scholarships.

The following (except the Shakspeare Scholarship) are open to the competition of students of the College only.

Victoria Scholarship (Classics), £40 per annum, tenable for two years.

Wellington Scholarship (Greek Testament), £20 per annum, tenable for two years.

Shuttleworth Scholarship (Political Economy), £50, tenable for one year.

Shakspere Scholarship (English Language and Literature), £40 per annum, tenable for two years.

Bradford History Scholarship, £45 per annum, tenable for one year, and renewable for a second year.

Dalton Chemical Scholarships, £50 per annum, tenable for two years.

Dalton Mathematical Scholarships, one Senior and one Junior Scholarship, of the value of £25 each, tenable for one year.

Platt Scholarships (Physiology), two, one offered annually, £50 per annum, tenable for two years.

Heginbottom Physical Scholarship, £30 per annum, tenable for two years.

Ashbury Scholarships (Engineering), two, each of £25 per annum, tenable for two years.

Prizes.

Lee Greek Testament Prizes, one of £25 and one of £12 10s. value.

Classical Prizes.—Essay, value £5. Junior Class Prizes, value £5 and £2 10s.

Shuttleworth History Prize, value £5.

English Essay and Poem Prizes, each of the value of £5.

Early English Text Society's Prizes.—A selection of the Society's publications offered to the competition of students in the Day and in the Evening Classes respectively.

New Shakspere Society's Book Prizes.

Cobden Club Book Prizes (Political Economy).

Dalton Natural History Prize, value £15.

Engineering Essay Prize, value £5.

UNIVERSITY COLLEGE, NOTTINGHAM.

Professor of Chemistry—Frank Clowes, D.Sc. Lond., F.I.C., F.C.S.

Demonstrator—Mr. J. B. Coleman, F.C.S.

Lecture Courses.—A systematic course of day lectures is delivered on Tuesday and Thursday afternoons at 4.30: the non-metals are treated of in the Autumn Term (October 6th to December 20th), the metals in the Spring Term (January 19th to April 4th), and the carbon compounds in the Summer Term (April 27th to July 13th).

A course of evening lectures runs parallel with the day course, being delivered on Wednesday evenings at 8 o'clock.

A lecture class in connection with both courses meets on Wednesday evenings at 7 o'clock.

Excursions are conducted by the Professor to works where the technical applications of chemistry may be seen by the students.

Students may qualify themselves by attendance at these lectures and classes for the Examinations of the Universities of London, Cambridge, or Oxford: they may also obtain instruction in Chemistry for technical or other purposes.

Fees.—For the day lectures, £2 10s. for the session, and one guinea for a term; for evening lectures, 2s. 6d. per term; or 5s. for lectures and classes.

Practical Chemistry.—The chemical laboratory is open every day except Saturday from 10 to 1 and from 2.30 to 5.30, also on Tuesday and Thursday evenings from 7 to 9. Each Student works independently of other Students at a course recommended by the Professor. Instruction is given in Chemical Analysis, and in Experimental and Applied Chemistry. A set of ordinary apparatus and reagents and a private locker are supplied free of charge, for the safe keeping of which the Student is held responsible; no extra charge is made for the use of gas and water, and of the cheaper chemicals.

Fees.—Inclusive fee £15 per session, or £6 6s. per term; terminal fee for day students for three hours weekly 20s., for six hours 35s., for nine hours 50s., and 10s. extra for each additional three hours per week; for evening students 10s. for one evening per week, and 20s. for two evenings per week.

Government Classes.—Under the direction of the Demonstrator.

Lecture Courses.—Inorganic Chemistry, Monday evening; Organic Chemistry, Friday evening. Fee, 2s. 6d. for the Session.

Practical Chemistry.—On Tuesday and Thursday evenings from 7 to 9. Fees, one evening per week, 5s.; two evenings per week, 10s., for session.

All classes of Students are eligible to attend without distinction of sex. In virtue of the affiliation of the University College to Cambridge University a suitable course of study is recognised in lieu of part of the ordinary residence at Cambridge. For other information Students are referred to the College Calendar.

FIRTH COLLEGE, SHEFFIELD.

Professor of Chemistry.—W. Carleton Williams, B.Sc., F.C.S.

Demonstrator and Assistant Lecturer.—L. T. O'Shea, F.C.S.

The Session will commence on Tuesday, October 7, 1884.

First Year's Course.—Chemistry of the Non-Metallic Elements. Monday, Wednesday, Friday, from 10 to 11 a.m. Fee, £3 13s. 6d.

Second Year's Course.—Chemistry of Metals. Tuesday and Thursday, from 10 to 11 a.m. £2 2s.

Third Year's Course.—Organic Chemistry, on Tuesday, Thursday, and Saturday, from 10 to 11. Fee, £1 11s. 6d. Chemical Philosophy, on Saturday at 10. Fee, £1 1s.

Analytical Chemistry.—Lecture course by Mr. O'Shea. Friday, 11 to 12. Sessional fee, £1 11s. 6d.

Laboratory.—Working hours to be arranged between Professor and Students.

Sessional Fees for Day Students:—Six hours per week, £4 10s.; Nine, £6 10s.; Twelve, £8; Eighteen, £11 4s.; Twenty-four, £14; Thirty, £16 16s.; Thirty-six, £19.

Day Students may not enter for less than six hours a week. Students joining the Laboratory at Christmas will be charged two-thirds and at Easter one-third of the Fees for the whole Session.

Fees for short periods (working thirty-six hours per week):—For one month, £3 13s. 6d.; two months, £6 6s.

An arrangement has been entered into with the Science and Art Department, South Kensington, which will enable Science Teachers to work in the Chemical Laboratory for two days a week on payment of one-quarter of the usual fee, the Department being willing to pay the remainder under certain conditions, of which full information may be obtained on application to the Registrar.

Evening Classes.—Lectures, Tuesday and Friday, 7 to 8. Laboratory instruction, Monday and Wednesday, 6 to 9. Sessional Fee, three hours per week, £2 5s.; six, £4 8s.

UNIVERSITY COLLEGE, DUNDEE.

Professor.—T. Carnelley, D.Sc., F.C.S.

Lecture Assistant.—John Foggie.

The second session of the College will be opened on October 8th, 1884.

The Lectures and Laboratory practice in Chemistry are recognised by the Royal College of Physicians, London, and for degrees in Science and Medicine by the University of Edinburgh.

The courses are suitable for the Degrees of the London University and for the Civil Service appointments, and will also satisfy the requirements of students in Pharmacy, and of students who intend to become candidates for the Associateship of the Institute of Chemistry, so far as attendance at lectures on General and Theoretical Chemistry is concerned.

Lecture Courses.

The object of these courses will be (1) to give systematic instruction in the general principles of the science, and information regarding the elements and their more impor-

tant compounds; (2) to show how this knowledge may be usefully applied in the Arts and Manufactures.

A course of instruction in Practical Chemistry in the Laboratory is recommended to all who wish to obtain a sound knowledge of the science, and the methods of applying it to useful purposes—the duration of such course depending upon the special wants of the student.—The Professor will be glad to give any information to intending students.

First year's lecture course: Monday, Wednesday, and Friday, from 10 to 11 a.m.; fee, £2 2s.

Second year's lecture course: Tuesday, Thursday, and Saturday, from 9 to 10 a.m.; fee, £2 2s.

Practical Chemistry (Laboratory).

The aim of the Laboratory Courses is to make the student practically acquainted with the science, so that he may conduct chemical analysis and original research, and generally to fit him for applying the science to the Arts, Manufactures, and Agriculture. The courses are also suitable for students preparing for their medical and pharmaceutical examinations. A three months' course of Practical Chemistry for the B.Sc., Edinburgh, in the Department of Public Health, may be taken in the College Laboratory.

The Laboratory will be open for students daily from 9 a.m. to 4 p.m., except on Saturdays, when it will be closed at 1 p.m. Each student on entering will be allowed to arrange his working hours to suit his own convenience, but will be required to keep the hours when once fixed.

Sessional Fees for Day Students:—The fees for both sessions are—for six hours per week, £3 3s.; each additional hour per week, 10s. 6d. Day students may not enter for less than six hours a week. Students joining the Laboratory during the second term will be charged two-thirds, and during the third term one-third of the above fees. Students may also enter for short periods, working every day in the week at the following fees:—For one month, £2 12s. 6d.; for two months, £5; for three months, £7 7s.

Evening Classes.—Courses of Lectures and Practical Laboratory instruction.

UNIVERSITY OF EDINBURGH.

Professor.—A. Crum Brown, F.R.S.E.

The Session will commence on October 28, 1884.

Two degrees in Science are conferred by the University of Edinburgh, viz., Bachelor of Science (B.Sc.) and Doctor of Science (D.Sc.). Both these degrees are conferred in Physical and Natural Science, in Public Health, and in Engineering.

Candidates for degrees in Physical and Natural Science must pass a preliminary examination in English, Latin, Arithmetic, the Elements of Mathematics, and the Elements of Mechanics, and in at least two of the following subjects:—Greek, French, German, Higher Mathematics, Natural Philosophy, Logic, and Moral Philosophy.

The First B.Sc. Examination embraces Mathematics, Natural Philosophy, Chemistry, Zoology, including Comparative Anatomy, and Botany. The Second B.Sc. Examination the Higher Higher Mathematics, Natural Philosophy, Experimental Physics, Chemistry, Zoology, Botany, Physiology, and Geology.

The D.Sc. Examination embraces Mathematics, Applied Mathematics, Experimental Physics, Practical Astronomy, Chemistry, Zoology and Comparative Anatomy, Animal Physiology, Botany, and Geology, including Palæontology and Mineralogy.

ANDERSON'S COLLEGE, GLASGOW.

Professor of Chemistry.—William Dittmar, F.R.S.E.

Chief Assistant.—John M'Arthur.

Laboratory Assistants.—James B. M'Arthur and Robert Anderson.

Junior Assistants.—Archibald Kling and Alex. Lamb.

A Course of 100 Experimental Lectures on Chemistry: Daily, Saturdays excepted, from 10.15 to 11.15, commencing on Wednesday, Oct. 29th. The Lectures up to the end of the year are devoted to an Elementary Exposition of the Philosophy and the Methods of the Science, as illustrated by the History of the Non-metallic Elements. The rest of the Session is divided between the Chemistry of the Metals and Organic Chemistry, select chapters. In addition to occasional extemporised examinations during class hours, five written examinations are held during the Session, on Saturdays from 10 to 1.

The Laboratory is open daily (Saturdays excepted) during the Winter Session from 10 to 5, during Summer from 9.30 to 5. Advanced students may obtain permission to work privately on Saturdays also until 1 p.m. The teaching is conducted on the tutorial system, each student working by himself, at a separate place, and on his own subject. Hence students of any grade of advancement may enter at any time, and the courses of instruction can be adapted to the special requirements of the individual. Original research is not forgotten, but Mr. Dittmar makes it a strict rule not to use his students as his private assistants in connection with his own investigations, and to rather discourage original research with students who have not yet obtained a sufficient mastery of all the practically important methods of chemical analysis and of preparative chemistry. Fee per month, £2 2s.; due in advance. For any period of six months or more, if paid in advance, at the rate of £1 15s. per month. The fees include the use of all the ordinary reagents, and of the resources of the laboratory generally; but the student has to find his own small apparatus (test-tubes, beakers, &c.), and also a few of the more expensive reagents—e.g., chloride of platinum, nitrate of silver, molybdate of ammonia.

Of the several duties which the prestige and traditions of this Chair impose upon its occupant, the first and foremost is to offer to young men, of even limited means, the opportunity of receiving a training in chemistry sufficient to prepare them fully for positions in chemical works, or as professional chemists.

A special Practical Class for Medical Students, meeting twice a week for two hours each time, is conducted during the Summer Session. Fee, including all expenses, £2 2s.

The Evening Department opens on the 3rd of October.

THE

"YOUNG" CHAIR OF TECHNICAL CHEMISTRY, ANDERSON'S COLLEGE.

Professor.—Edmund J. Mills, D.Sc. (Lond.), F.R.S.

Assistant.—Mr. C. Ellis.

This Chair has for its object the instruction of Students in Chemistry as applied to the various branches of industry in Chemical and other works, Metallurgy, Agriculture, &c.

LECTURES.—*Principal Course.*—A Course of Twenty-five Lectures will be delivered on Mondays, Tuesdays, and Wednesdays, at 10 a.m., commencing on November 3rd. The Lectures will be illustrated with Experiments, Diagrams, and Models, as well as by the actual inspection of Manufacturing Processes; and the progress of the Students will be tested by periodical Examinations. The earlier Lectures will have reference to units of weight and measure, to the calculations necessitated by Chemical operations, and to the nature and laws both of the Chemical process and its results, as illustrated in Chemical Technology.

Fee for the Course, One Guinea.

Subsidiary Course.—A subsequent Course of Thirty Lectures will be delivered on Mondays, Tuesdays, and Wednesdays, at 10 a.m. These Lectures are more particularly intended for Dyers, Colour Manufacturers, Brewers and Distillers, Tar Refiners, Drysalter, and others interested in a knowledge of Technical Organic Chemistry.

Fee for the Course, Two Guineas.

Evening Courses.—There will be special Evening course of twenty-five lectures on Oils, Paints, and Varnishes. Other Courses of Lectures and Practical Courses will be arranged.

Laboratories.—The Laboratories are open daily from 10 to 4, and on Saturday from 10 to 1 o'clock for practical working by the Students, under the superintendence of the Professor and his Assistants.

The Fee for attending the Laboratories is £20 per Session of Nine Months, £14 10s. for Six Months, £7 10s. for Three Months, or £2 10s. per month.

Students must have a fair acquaintance with elementary Chemistry.

The New Laboratory Buildings comprise four stories, with a lecture room in the rear, and are exclusively devoted to the purposes of this Chair.

The Trustees, having had under consideration the requirements of Inventors, Patentees, and others whose investigations require isolation and privacy, as well as professional advice, have included in the arrangements Five Private Laboratories. Electric Cable has been laid to these laboratories for the supply, if required, of adequate power.

Library.—A Students' Library Society was founded in 1875. Its objects are to provide a collection of standard chemical works, and to maintain a regular supply of chemical journals. A large number of works have already been purchased or bestowed, and nine journals are received. Annual subscription, Half-a-crown.

QUEEN'S COLLEGE, BELFAST.

Professor.—E. A. Letts, Ph.D., F.R.S.E., F.C.S.
The Session begins October 21st.

I.—Chemistry.—The lectures are delivered at 3 p.m., on the first five days of each week until the beginning of April, and on two days of each week after May 1st. The course is divided into three parts:—(1) Chemical Philosophy; (2) Inorganic Chemistry; (3) Organic Chemistry.

II.—Advanced and Organic Chemistry.—Lectures on these subjects are given from the beginning of the Session, on Tuesdays and Thursdays, at 10 a.m., until the beginning of April, and on the same days at 3 p.m., after May 1st.

III.—Practical Chemistry.—In this course the Students are instructed in the general methods of conducting Chemical Analyses.

IV.—Laboratory Pupils.—The Chemical Laboratory is open from November until the beginning of April, and from May 1st until the middle of July, on the first five days of the week, from 10 a.m. until 4 p.m. The course of instruction is under the direction of the Professor of Chemistry, and of the Chemical Assistant. Students are admitted as working pupils on payment of a fee of £5 for the first period, or of £3 10s. for the second period (or for a single term).

QUEEN'S COLLEGE, CORK.

Professor.—Maxwell Simpson, D.Sc., M.D., F.R.S., &c.
The Session begins October 21st. The Chemistry Classes are held on Mondays, Wednesdays, and Fridays.

The Course is divided into Inorganic and Organic Chemistry.

In the first part are discussed the Laws of Combination and Affinity, Molecular Chemistry and Crystallography, and the History of the Non-Metallic and Metallic substances.

In the Organic portion of the Course will be considered the subjects of Organic Analysis, Organic Series, Compound Radicals and Types, Metamorphosis of Organic Bodies, History of Special Animal and Vegetable Bodies.

In treating of the Laws of Chemistry, and the History of Inorganic and Organic Bodies those points will be chiefly dwelt upon which have a practical bearing in the Arts, Medicine, Engineering, and Agriculture. Thence,

during the Course, attention will be directed to the application of Chemistry to Medicine and Physiology, to Metallurgical Operations, Chemical Manufactures, Building Materials, Soils, and Manures.

Fee.—For each Sessional Course, £2. Each subsequent Course in Medicine, £1.

The Chemical Laboratory is open daily except on Saturdays, from 10 to 4 o'clock, under the Superintendence of the Professor, to Students desirous of prosecuting an extended course of qualitative and quantitative analysis, and for the purpose of original investigation in connection with the Arts, or in the higher departments of Scientific Chemistry.

UNIVERSITY OF DUBLIN.

TRINITY COLLEGE.

Professor of Chemistry.—J. Emerson Reynolds, M.D., F.R.S.

Senior Assistant and Demonstrator.—William Early, F.I.C.

The professor of chemistry lectures on Elementary Chemistry during the whole of Michaelmas and Hilary Terms, on the Non-Metals and Metals; and the students repeat in the Laboratories many of the experiments shown at lecture.

The advanced course consists chiefly of Laboratory instruction in qualitative analysis (including spectrum analysis) commencing in Michaelmas Term, about November 1st. Volumetric and gravimetric analysis, commencing in Hilary Term. Organic preparations and analysis, commencing in Trinity Term.

Professor Reynolds lectures on Organic Chemistry during Trinity Term. In the main Laboratory facilities are afforded for the prosecution of experimental researches.

ROYAL COLLEGE OF SCIENCE FOR IRELAND, STEPHEN'S GREEN, DUBLIN.

Professor of Practical and Theoretical Chemistry.—W. Noel Hartley, F.C.S.

The Session commences on Monday, October 6, 1884.

The instruction comprises courses of Lectures on General, Applied, and Analytical Chemistry, and also a course of Lectures on Metallurgy.

The Chemical and Metallurgical Laboratories, under the direction of Mr. Hartley, are open every week-day during the Session, except Saturday. Instruction is given in the different branches of Analytical Chemistry, including Assaying, and in the methods for performing Chemical Research. Fee, for the Session of nine months, £12; or for three months, £5; or for one month, £2.

There are four Royal Scholarships of the value of £50 each yearly, with Free Education, including Laboratory Instruction, tenable for two years; two become vacant each year; they are given to Students who have been a year in the College. There are also nine Exhibitions attached to the College, of the yearly value of £50 each, with Free Education, including Laboratory Instruction, tenable for three years; three become vacant each year.

A Diploma of Associate of the College is granted at the end of the three years' course.

Evening Classes.—Systematic Courses of Evening Lectures are given by most of the Professors throughout the Session.

CHEMICAL LECTURES, CLASSES, AND LABORATORY INSTRUCTION.

CITY AND GUILDS OF LONDON INSTITUTE FOR THE ADVANCEMENT OF TECHNICAL EDUCATION, TECHNICAL COLLEGE, FINSBURY.—Professor, H. E. Armstrong, Ph.D., F.R.S. The College fulfils the functions of a finishing technical school for those entering industrial life at a

comparatively early age; of a supplementary school for those already engaged in the factory or workshop; and of a preparatory school for the Central Institution. It is under the general direction of the Principal or Superintendent of Studies. At the head of each Department is a Professor, who is assisted by one or more Demonstrators; and besides these there are Lecturers and Teachers for instruction in special subjects: Skilled Artizans are employed in the Workshops for the guidance of the Students. The Session is divided into three terms:—The Winter term commences on Monday, October 6th, and ends on December 19th; the Spring term commences on the second Monday in January, and ends about the 21st of March; the Summer term commences about the 15th of April and ends about July 16th, the evening classes terminating in June. An examination for the admission of Students will be held at the College at 10 o'clock on Thursday, October 2nd, 1884, and the work of the Session will commence on Monday, October 6th. The instruction consists of Day and Evening Classes and Laboratory Instruction.

CITY OF LONDON COLLEGE.—Professor, Dr. A. B. Griffiths, F.C.S., &c. A course of about 35 Lectures on Metallurgy, Metallurgical Chemistry, and Assaying, will be delivered every Friday evening from 7 to 8, commencing on October 3rd. The lectures will comprise the following subjects:—Processes used in the Extraction (by dry and wet methods) of all the important Metals. Materials used in the construction of Furnaces, Crucibles, Retorts, &c. Fuel, Calorific Power, Coking and Coking-Ovens. Assaying of Metals and Alloys. Machinery and appliances used in Metallurgical operations. Composition of Slags. Hot and Cold Blast, &c. This course will meet the requirements of those students competing for Whitworth Scholarships, Science Department and other examinations. It is a course most useful for students desirous of following the Chemical Profession. Prospectuses and further details on application to the Secretary of the College. White Street, Moorfields, E.C., or to Dr. Griffiths, The Heath, Bromsgrove.

BIRKBECK LITERARY AND SCIENTIFIC INSTITUTION, BREAM'S BUILDINGS, CHANCERY LANE.—*Organic Chemistry*: A course of 30 Lectures, beginning on October 7th, at 7 p.m., by Mr. H. Chapman Jones. Also a class for Practical Work, conducted by Mr. Chapman Jones, will meet in the Laboratory of the Institution at 8 p.m. on October 7th. *Photography*: A course of 30 Lectures, with Demonstrations on the Theory and Practice of Photography, by Mr. H. Chapman Jones, beginning at 7 p.m., on October 1st. *Inorganic Chemistry*: A course of 30 lectures to Elementary Students, beginning on October 7th, and a similar course to Advanced Students, beginning on October 12th, by Mr. George Chaloner. Classes for Practical Chemistry and Analysis on Tuesday and Saturday evenings, beginning on October 7th, conducted by Mr. George Chaloner.

CRYSTAL PALACE COMPANY'S SCHOOL OF ART, SCIENCE, AND LITERATURE. SCHOOL OF PRACTICAL ENGINEERING. *Principal*—Mr. J. W. Wilson, Memb. Inst. C.E.—This school was established with the purpose of affording to Students of Civil or of Mechanical Engineering the advantage of thorough practical instruction in the rudiments of either profession, and in the manipulation of materials. The leading object is to prepare Students, by systematic practical instruction, for professional articles, so that on entering an Engineer's office or works the pupil may at once be useful to his Principal, and enabled to take advantage of the opportunities for learning open to him, because he has mastered the elementary details of the profession. The school is also available for Students already articulated, who desire instruction in either the offices or shops. The Colonial Section is designed particularly for gentlemen who are going to the Colonies or abroad, as explorers or settlers. The object proposed is to afford them so much practical knowledge of scientific and mechanical work and expedients as shall enable them best

to utilise the means at their disposal, especially when entirely dependent on their own resources.

Ladies' Division.—The School was established to utilise the valuable Courts and Collections of the Crystal Palace for the purposes of instruction in Art, Science, Literature, &c., so that education of the highest class might be afforded under most advantageous conditions. The system of tuition is, for some subjects, in the manner of private tutorial instruction by the best masters, but other subjects are taught on the University method, in accordance with the regulations laid down by the Syndicate of the University of Cambridge, by whom some of the lectures and classes are conducted. A student may take lessons in one or several studies at option. The School is a centre for both the University of Oxford and the University of Cambridge Local Examinations, the Oxford Ex-

amination for Women, and for the Cambridge Higher Local Examination. The following examinations will be held in the Ladies' Division during 1883-84:—Cambridge Local, December, 1884; Oxford Local and Oxford Examination for Women, June, 1885; Cambridge Higher Examination, June, 1885. The session opens on October 1.

DENTAL HOSPITAL, London.—Prof. A. K. Huntington. Course of Lectures on Metallurgy in its Application to Dental Purposes.

NEW CENTRAL SCHOOL OF CHEMISTRY AND PHARMACY, 173, Marylebone Road, London.—Mr. A. P. Luff, F.I.C., F.C.S., and Mr. J. Woodland, F.C.S., M.P.S. In addition to the usual Chemical studies, Special Instruction Classes are held for Students of Medicine.

SOUTH LONDON SCHOOL OF CHEMISTRY, 325, Kennington Road.—Dr. John Muter, F.C.S. Daily, at 10 a.m. Lectures on Theoretical Chemistry, and Junior and Senior Course of Practical Chemistry.

ST. JOHN'S TRAINING COLLEGE, Battersea.—Both Theoretical and Practical Chemistry form part of the curriculum of the College. Lecturer and Director of the Laboratory, Alfred Senior, M.D., F.I.C., F.C.S.

THE WESTMINSTER COLLEGE OF CHEMISTRY AND PHARMACY, Trinity Square, S.E.—Messrs. Wills and Wootton. Daily, at 9 a.m. Theoretical and Practical Chemistry. Also Evening Classes, at 7.

SCHOOL OF PHARMACY OF THE PHARMACEUTICAL SOCIETY OF GREAT BRITAIN, 17, Bloomsbury Square.—The school opens on Wednesday, the 1st of October. Lectures on Chemistry and Pharmacy, by Professor Redwood, assisted by Mr. Wyndham R. Dunstan, F.C.S., on Monday, Tuesday, and Wednesday mornings, at 9 a.m. The Laboratories for Practical Instruction in Chemistry as applied to Pharmacy, &c., under the direction of Prof. Attfield, assisted by Mr. F. W. Short, and Mr. Eastes, will be open daily at 10 a.m. throughout the Session. They are fitted up with every convenience for the study of the principles of Chemistry by personal experiment. They are specially designed for the student of Pharmacy, but are equally well adapted for the acquirement of a knowledge of Chemistry in its application to Medicine, Manufactures, Analysis, or Original Research. There is no general class for simultaneous instruction, each student following an independent course of study always determined by his previous knowledge; pupils can therefore enter for any period at any date. Fees for the Lectures, One Course, £3 3s.; an entire Session—Two Courses, £4 4s.; Perpetual Admission, £5 5s.; for Practical Chemistry, 10 months, 12 to 25 guineas, according to hours of attendance. *Council Prizes*.—At the end of each of the five months Courses of Lectures on Chemistry and Pharmacy, and Botany and Materia Medica, a Bronze Medal and Certificates of Merit, and at the close of the Session (ten months) a Silver Medal and Certificates of Honour and Merit, are offered for competition by the Council. In the Class of Practical Chemistry, a Silver Medal, two Bronze Medals, and Certificates of Honour and Merit, offered by the Council, are competed for at the end of the Session.

ONSLOW COLLEGE OF SCIENCE, 183, Kings Road, Chelsea, S.W.—Lectures and Laboratory instruction in Chemistry and Pharmacy. Special Evening Classes in Inorganic and Organic Chemistry, &c. The Chemical and Metallurgical Laboratories are open every day and evening for practical work. Principal, Mr. W. H. Martin.

BIRMINGHAM.—QUEEN'S COLLEGE.—In connection with this College the Chemistry Lectures are given at Mason Science College, by Prof. W. A. Tilden.

BRISTOL MEDICAL SCHOOL.—Mr. T. Coomber, F.C.S. DERBY CENTRAL SCHOOL OF SCIENCE.—Evening Lectures and Practical Laboratory Instruction, commencing September 29. Physics and Mathematics—H. Barfield, D.Sc. Chemistry—L. Archbutt, F.C.S.

INSTITUTE OF CHEMICAL TECHNOLOGY, Hackins Hey, Liverpool.—Principal, Mr. A. Norman Tate, F.I.C. The course of instruction is intended more especially for

students who wish to gain a knowledge of chemistry and the allied sciences in their relation to industrial and commercial pursuits, and embraces a thorough preliminary course of theoretical chemistry and practical laboratory work, followed by instruction in chemical technology fitted to the requirements of each pupil. In addition to these chemical studies, students who desire it can enter upon a special course calculated to afford them knowledge useful in the erection and arrangement of manufactories and plant, and construction of apparatus. Fee: Fifty guineas per annum, with extra fee according to circumstances for the special course.

LEEDS SCHOOL OF MEDICINE.—Prof. T. E. Thorpe, Ph.D., F.R.S.

QUEENWOOD COLLEGE, near Stockbridge, Hants.—Dr. H. Wilson Hake, F.C.S., F.I.C. Lectures on Inorganic Chemistry and Physics and Laboratory Instruction.

SALFORD WORKING MEN'S COLLEGE, EVENING CLASSES.—Teacher of Chemistry, Mr. G. H. Hurst. Lectures on Organic and Inorganic Chemistry and practical laboratory instruction.

SHEFFIELD BOROUGH ANALYSTS' LABORATORY, 1, Surrey Street.—Mr. A. H. Allen, F.C.S. Day and Evening Classes.

UNIVERSITY OF ABERDEEN.—Mr. J. S. Brazier, F.C.S. SCHOOL OF MEDICINE, SURGEON'S HALL, EDINBURGH.—Dr. Stevenson Macadam, F.R.S.E., Mr. Falconer King, Mr. Ivison Macadam, and Mr. Drinkwater.

EDINBURGH SCHOOL OF PHARMACY AND CHEMISTRY.—The instruction qualifies for graduation in Medicine and Science in the University of Edinburgh and other Examining Boards. Dr. Stewart gives instruction to Pharmaceutical Students in the B. P. tests. Day and Evening Classes.

EDINBURGH SCHOOL OF MEDICINE, 41, Chambers St.—Dr. Drinkwater, F.C.S.—The instruction here qualifies for all Medical Boards, Edinburgh University, London University, &c. Day and Evening Classes.

MINTO HOUSE MEDICAL SCHOOL, CHAMBERS STREET, EDINBURGH.—Mr. J. Falconer King, F.I.C., F.C.S. Lectures and Classes.

NEW VETERINARY COLLEGE, LEITH WALK, EDINBURGH.—Dr. Stevenson Macadam.

SCIENCE SCHOOLS, FALKIRK.—Mr. Andrew Wilson and Assistants. Day and Evening Classes in Theoretical and Practical Chemistry and Metallurgy.

GLASGOW UNIVERSITY.—Prof. J. Ferguson.

GLASGOW VETERINARY COLLEGE.—Professor Cooke. COLLEGE OF SCIENCE AND ARTS, GLASGOW.—Mr. A. Humboldt Sexton. Day and Evening Classes.

SCHOOL OF CHEMISTRY, 138, Bath Street, Glasgow.—Dr. Wallace, Mr. Tatlock, and Dr. Clark. Day and Evening Classes.

CHEMICAL LABORATORY, 180, West Regent Street, Glasgow.—Dr. Milne. Day and Evening Classes.

QUEEN'S COLLEGE, GALWAY.—Dr. T. H. Rowney.

ROYAL COLLEGE OF SURGEONS IN IRELAND.—Dr. C. A. Cameron, F.I.C. The Laboratories of the College are provided with every appliance for the study of Chemistry, especially in its application to Medicine, Hygiene, and Pharmacy.

DUBLIN, CARMICHAEL COLLEGE OF MEDICINE.—Dr. C. R. C. Tichborne.

DUBLIN, CATHOLIC UNIVERSITY.—Dr. Campbell.

DUBLIN, DR. STEVENS'S HOSPITAL AND MEDICAL COLLEGE.—Mr. McHugh.

MECHANICS' INSTITUTE, Abbey Street, Dublin.—Mr. Clement J. Leaper.

Electrolysis Applied to the Analysis of Red Wine.—L. Monrad Krohn.—The electrolysis of a red wine, joined to the microscopic examination of the deposit formed is, according to the author, a certain means of detecting if the colouration of the sample is natural.—*Journ. de Phar. et de Chimie*.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Cosmos les Mondes.
No. 16, August 16, 1884.

What is to be done during Epidemics of Cholera?—Thomasi Crudeli.—The author pronounces it practically impossible to guard against the invasions of epidemics by cordons, quarantines, and fumigations, and recommends sanitary reform. He proposes that the clothing of the sick should be disinfected by steeping in water containing 0.2 per cent of mercuric chloride,—a precaution which he found satisfactory at Palermo during the epidemic of 1866.

No. 17, August 23, 1884.

Petroleum Industry in the Caucasus.—Translated from *Engineering*.

Determination of Nitric Acid as Cinchonamine Nitrate.—M. Arnaud.—Already inserted.

Journal de Pharmacie et de Chimie.
Series 5, Vol. ix., March, 1884.

Researches on the Alkaline Sulphites.—M. Berthelot.
Pyrogenous Decomposition of Potassium Sulphite.—M. Berthelot.

On the Metasulphites.—M. Berthelot.

Examination and Analysis of Two Samples of Wine from Cochinchina.—M. Sambuc.—These wines are obtained from the fruit of a tuberous-rooted vine, the stem of which dies down annually in November and shoots out again in March. The acidity of the wines is high, and the proportion of alcohol low.

The Danger of the Use of Badly Vulcanised Caoutchouc Tubes in Certain Chemical Operations.—M. Limousin.—The presence of sulphur and of antimony sulphide is especially dangerous in the preparation of oxygen gas.

On Meat-Powders.—M. Yvon.—This paper does not admit of useful abstraction.

OWENS COLLEGE (VICTORIA UNIVERSITY), MANCHESTER.

SESSION 1884-5.

I. DEPARTMENT OF ARTS AND LAW.

II. DEPARTMENT OF SCIENCE AND ENGINEERING.

Candidates for Admission in these Departments must not be under 14 years of age, and those under 16 will be required to pass an Entrance Examination in English, Arithmetic, and Elementary Latin, to be held on the 3rd OCTOBER.

III. DEPARTMENT OF MEDICINE and SURGERY and of DENTAL SURGERY.

Students are required, before entering, to have passed either the Entrance Examination in Arts, or the Preliminary Examination in the Victoria University, or some other of the Preliminary Examinations prescribed by the General Medical Council.

IV. DEPARTMENT FOR WOMEN (223, Brunswick-street).

The SESSION in Departments I., II., and IV., will commence on the 7th, and in III., on the 1st OCTOBER.

V. EVENING CLASSES.

The SESSION will commence on the 13th OCTOBER. New Students will be admitted on the 8th, 9th, and 10th October, between 6.30 and 9 p.m.

ENTRANCE EXHIBITIONS and SCHOLARSHIPS are offered to be competed for by Male Students in Classics, Greek, Testament, Mathematics, English, and History; and also a DAUNTESSEY MEDICAL SCHOLARSHIP, value £100. FOUR SCHOLARSHIPS of the value of £20 per annum, tenable for three years, in the Department for Women, have also been founded, of which two are open to general competition, and two may be competed for only by Pupils in the Manchester High School for Girls.

Prospectuses of the several Departments may be obtained at Mr. CORNISH'S, Piccadilly, Manchester, and they will be forwarded from the College on application.

J. HOLME NICHOLSON, Registrar.

CARBONATE OF AMMONIA from Ammoniacal Liquor,—Dr. Siedler's Patent process. For Royalty and particulars apply to J. Berger Spence and Co., Manchester.

THE MASON COLLEGE, BIRMINGHAM.
SESSION 1884-85.

FACULTIES OF SCIENCE AND ARTS.

The SESSION will commence on FRIDAY, the 3rd of OCTOBER NEXT.

All departments of the College are open to both sexes on the same terms. Special arrangements are made for the convenience of ladies.

Syllabuses containing full information as to Admission of Students, Courses of Instruction, Fees, Entrance and other Scholarships, &c., will be forwarded on application to

GEO. H. MORLEY, Secretary.

UNIVERSITY COLLEGE, LIVERPOOL.

The SESSION will commence on Wednesday, October 1st. EVENING CLASSES on October 6th.

Full Courses of Lectures for all London University Examinations in Arts or Science. Physical, Chemical, and Biological Laboratories. All Classes (except the Medical) open to both sexes on the same terms.

For full details of Classes, Fees, &c., see "Calendar" (price 2s.), published by ADAM HOLDEN, 48, Church Street, Liverpool.

INSTITUTE OF CHEMICAL TECHNOLOGY
AND

ANALYTICAL LABORATORY,

5, 9, and 11, PHILADELPHIA CHAMBERS, HACKINS HEY,
and 3 and 12 A, ASHTON CHAMBERS, HACKINS HEY,
LIVERPOOL.

PRINCIPAL—A. NORMAN TATE, F.I.C.

Designed for the examination, for scientific, commercial, and industrial purposes, of substances used and produced in the Arts and Manufactures, and found in Commerce; and for the instruction of Students in Chemistry and the allied sciences in their relation to industrial and commercial pursuits.

The Laboratories have lately been entirely re-arranged and considerably extended, and are provided with all appliances necessary for analytical investigations, special technical examinations, and Students' work.

Students' fees, fifty guineas per annum.

In addition to their chemical studies, Students who desire it can enter upon a course of instruction calculated to afford them knowledge useful in the erection and arrangement of manufacturing buildings and plant, and construction of apparatus. Special fees are charged for this course.

All communications should be addressed to Mr. A. Norman Tate, 9, Hackins Hey, Liverpool, as, owing to similarity of surname with that of the principal of another chemical establishment in Liverpool, misconception and mistakes have arisen.

LIVERPOOL COLLEGE OF CHEMISTRY,
DUKE STREET, LIVERPOOL.

Founded by Dr. SHERIDAN MUSPRATT.

PRINCIPAL—Dr. GEORGE TATE, F.C.S., F.G.S.

The design of the College is to give a thorough knowledge of Chemistry in all its relations and applications to Medicine, Agriculture, and the Chemical Arts generally.

Every accommodation is afforded in the Laboratories of the College for original research and analytical investigation.

Fee for the two years' course of study, 60 guineas.

Prospectuses of the Day and Evening Classes, commencing in October, may be had on application.

THE YORKSHIRE COLLEGE,
LEEDS.

The Eleventh Session of the Department of Science, Technology, and Arts will begin, in the new buildings, College Road, Leeds, on the 7th October. The Classes prepare for the examinations of the University of London, Scholarships at Oxford and Cambridge, and for various professions. They include Mathematics, Physics, Chemistry, Geology, Biology, Latin, Greek, English, French, German, and Oriental Languages and Literatures, History, Metal and Coal Mining; Civil, Mechanical, and Electrical Engineering; Weaving, Designing and Dyeing Textile Fabrics, &c.

The Fifty-fourth Session of the Medical Department (formerly the Leeds School of Medicine) begins October 1st.

The Chemistry Classes and Chemical Laboratories, under Dr. THORPE, F.R.S., offer courses of systematic lectures in Organic and Inorganic Chemistry, Chemical Calculations, Chemistry as applied to Coal Mining, Chemical Technology, Chemical Physics, and Photographic Manipulation; and practical work for periods to suit the other engagements of Students.

The Dyeing Classes and Dye-house, under Instructor HUMMEL, F.C.S., late of the Polytechnikum, Zürich, provide lectures on Textile Fibres, Natural and Artificial Colouring-matters, Mordants, and other subjects included in a complete course of dyeing instruction; and practical dyeing and printing of textile fabrics, &c.

Prospectuses may be obtained from the Secretary.

THE CHEMICAL NEWS.

VOL. L. No. 1296.

ADDRESS TO THE MECHANICAL SCIENCE SECTION OF THE BRITISH ASSOCIATION.

By Sir F. J. BRAMWELL, F.R.S., V.P.Inst.C.E., President of the Section.

In a family of seven children there are two who are of paramount importance:—the eldest, at the one end of the scale, important, because he is the heir, the first-born; and at the other end of the scale, the little Benjamin, important because he is the last, the youngest, and the dearest. The position of little Benjamin is not, perhaps, quite as honourable as that of the heir, and not, when the family breaks up, by any means as good; but while the family holds together, Benjamin receives an amount of attention and consideration that does not fall to the lot of any one of the intermediates, not even to the heir himself. But there is one risk about Benjamin's position, a risk that cannot appertain to the post of the first-born; little Benjamin may be deposed by the advent of a lesser Benjamin than himself, whereas the first-born becomes (if possible) still more the first-born for each addition to the family. Perhaps some of you may say, Be it so; but what has this to do with the address of the President of Section G? Those who make this inquiry, however, certainly have not present to their minds the change that has this year taken place. Up to and including the Southport meeting, Section G was the little Benjamin among the seven sons of the B.A. (I will not waste your time by giving the name of the Association in full, nor will I affront you by using an abbreviation which is occasionally improperly applied), but at Montreal appears Section H, and G becomes relegated among those uninteresting members of the family who are neither the important head nor the cherished tail. I grieve for Benjamin, and I think the present occasion an apt one for magnifying Section G. Apt for two reasons: the foregoing one, that H has deposed it from its position; the other, that we are meeting in Montreal—and in reference to this latter reason, let me ask, Is it not the fact that to the labours of the men who have been, or are (or ought to be) members of Section G is due the possibility of the meeting taking place on this side of the Atlantic?

At our Jubilee meeting at York, I called the attention of the Section to the fact that in 1831, when the Association first met in that city, they arrived there laboriously by the stage-coach, and that practically the Manchester and Liverpool, the Stockton and Darlington, and some few others, were the only railways then in existence. I also called their attention to the fact that in 1831 there were but very few steamers. I find the total number registered in the United Kingdom in that year was only 447. If under this condition of things, the proposition had been made in 1832 at Oxford, as it was made in 1882 at Southampton, that the next meeting but one of the Association should take place in Montreal, the extreme probability is that the proposer would have been safely lodged in a lunatic asylum, for suggesting that that which might have involved a six-weeks' voyage out, and a four weeks voyage back, could ever be seriously entertained. Further, to give once more the hackneyed quotation, some few years after this, *i.e.* in 1836, Dr. Lardner established to his own satisfaction conclusively, that no vessel could ever steam across the Atlantic the whole way. A striking instance of the mistakes made by scientific speculation; a branch of science widely differing in the value of its results from those branches which deal with absolute demonstration. Undeterred, however, by such adverse opinion, the en-

gineers "kept on pegging away," experimenting, improving, and progressing, until the scientific speculation was met with the hard fact of the Atlantic voyage steamed the whole way by the "Sirius" and by the "Great Western" in 1838. The impossible was proved to be the possible, and from that day to this the advancement of steam ocean navigation has continued. The six-weeks' voyage, sailing westward of the year 1831, has become converted into but little over six days. And thus it is that that which would have been a mad proposition in the year 1832, became a perfectly rational one in 1882; and the deliberations of the General Committee on the proposition were not directed as to whether it would be possible to convey the members with certainty, expedition, and economy across the Atlantic, but as to whether it was expedient or not on general grounds to hold for the first time a meeting of the British Association elsewhere than in some city of the United Kingdom. I say again that the possibility of such a meeting is absolutely due to the engineer, and that therefore, on this ground, the present is an appropriate occasion to magnify G, the Mechanical Section of this Association.

It is true that the man who looks only at that which is on the surface may say, "You arrogate too much to yourselves. You ignore (to which I say Heaven forbid!) the skill and daring of your sailors. You ignore commercial enterprise. You ignore the development of iron and steel manufacture, which have enabled you to build the steamers of the present day. You ignore the increased output of the best steam coal in the world, and the attribute the whole result to the engineer." Such an objector would be in the condition of that man who, in answer to George Stephenson's question, "What is causing that railway train to move?" said, "Why, I suppose the coal that is burning in the locomotive;" and who was met by that grand and comprehensive answer, that it was the "Sun," for the coals were a consequence, and not a first cause. Similarly I venture to say that the mechanical engineer may lay claim to be the central source which has vivified and given rise to the improvements in the manufacture of iron and steel, in the construction of engines, and in the development of our collieries.

There are those I know who object that Section G deals too little with pure science, too much with its applications. It may be as the members of Section G might retort, that it is possible to attend so much to pure science as to get into the unchecked region of scientific speculation, and that had the members of Section G been debarred from the application of science, the speculation of Dr. Lardner might to the present day have been accepted as fact.

I have quoted it before, but it has so important a bearing on this point, and comes from a man of such high authority, that I cannot refrain from once more giving you Dr. Tyndall's views on this question.

"The knowledge of nature, and the progressive mastery over the powers of nature, imply the interaction of two things—namely, thought conceived and thought executed; the conceptions of the brain, and the realisation of those conceptions by the hand. The history of the human intellect hardly furnishes a more striking illustration of this interaction of thought and fact than that furnished by the Association of Physics and Engineering. Take for instance the case of steam. Without knowing its properties, the thought of applying steam could not have arisen; hence the first step was physical examination. But that examination suggested practice, and the steam-engine at last saw the light; thus experimental physics was the seedling from which the steam-engine sprang. But the matter did not end here: the positions of debtor and creditor were soon reversed, for the stupendous operations of the steam-engine forced men of thoughtful philosophic minds to inquire into the origin of the power of steam. Guess succeeded guess, inspiration succeeded inspiration; the ever present fact of our railways, and our power-looms, and our steamships gave the mind no rest until it had answered the question, How are heat and

steam, its instruments, related to mechanical power? Had the works of the engineer not preceded the work of the natural philosopher, this question would never have been asked with the emphasis, nor pursued with the vigour, nor answered with the success, which have attended it. It was the intellectual activity excited by the work which the civil engineers of England had accomplished that gave to philosophy the theory of the conservation of energy including the dynamical theory of heat. . . . The engineering genius of the future is certain to derive from this theory strength and guidance. Thus necessarily has thought originated fact, and fact originated thought. In the development of science these two powers are coequal; each in turn ceasing to be a consequence, and becoming a creative cause. The Atlantic cable also had its small beginnings in the laboratory of the physical inquirer. Here, as before, experimental physics led the way to engineering facts of astounding magnitude and skill. But here also the positions of debtor and creditor have been reversed, for the work of the engineer has caused the physical inquirer to pursue his investigations with a thoroughness and vigour, and has given to those investigations a scope and magnitude which, without the practical stimulus, would have been impossible. The consequence is that the practical realisation of sending electric messages along the bottom of the Atlantic has been an immense augmentation of our knowledge regarding electricity itself. Thus does the human intelligence oscillate between sound theory and sound practice, gaining by every contact with each an accession of strength. These two things are the soul and body of science. Sever sound theory from sound practice, and both die of atrophy. The one becomes a ghost and the other becomes a corpse."

I think all men, even although they be followers of science in its purest and most abstract form, must agree that these words are words of sound sense, well worthy of being borne in mind and of being acted on, and will, therefore, concur in the propriety of Section G dealing with engineering subjects generally as well as with abstract mechanical science. Once admitting this, I may ask—certain what the answer must be—whether there is any body of men who more appreciate and make greater use of the applications of pure science than do the members of this Section. Surely every one must agree that we engineers are those who make the greatest practical use not only of the Science of Mechanics but of the researches and discoveries of the members of the other sections of this Association.

Section A, Mathematical and Physical Science. The connection between this Section and Section G is most intimate. With any ordinary man I should have referred, in proof of this intimate connection, to the fact that the President of A this year is a member of the Council of the Institution of Civil Engineers, but when I remind you that it is Sir William Thomson who fills this double office, you will see that no deduction such as I have hinted at can be drawn from his dual functions, because the remarkable extent and versatility of his attainments qualify him for so many offices, that the mere fact of his holding some one double position is no certain evidence of the intimate connection between the two. But setting aside this fact of the occupancy of the chair of A by a civil engineer, let us remember that the accomplished engineer of the present day must be one well grounded in thermal science, in electrical science, and for some branches of the profession in the sciences relating to the production of light, in optical science and in acoustics; while, in other branches, meteorological science, photometrical science, and tidal laws are all important. Without a knowledge of thermal laws, the engineer engaged in the construction of heat motors, whether they be the steam-engine, the gas engine, or the hot-air engine, or engines depending upon the expansion and contraction under changes of temperature of fluids or of solids, will find himself groping in the dark; he will not even understand the value of his own experiments, and therefore will be unable

to deduce laws from them; and if he make any progress at all, it will not guide him with certainty to further development, and it may be that he will waste time and money in the endeavour to obtain results which a knowledge of thermal science would have shown him were impossible. Furnished, however, with this knowledge, the engineer starting with the mechanical equivalent of heat, knowing the utmost that is to be attained, and starting with the knowledge of the calorific effect of different fuels, is enabled to compare the results that he obtains with the maximum, and to ascertain how far the one falls short of the other; he sees even at the present day that the difference is deplorably large, but he further sees in the case of the steam engine, that which the pure scientist would not so readily appreciate, and that is, how a great part of this loss is due to the inability of materials to resist temperature and pressure beyond certain comparatively low limits; and he thus perceives that unless some hitherto wholly unsuspected, and apparently impossible, improvement in these respects should be made, practically speaking the maximum of useful effect must be far below that which pure science would say was possible. Nevertheless, he knows that within the practical limits great improvements can be made, he can draw up a debtor and creditor account, as Dr. Russell and myself have done, and as has been done by Mr. William Anderson, the engineer, in the admirable lecture he gave at the Institution of Civil Engineers in December last on *The Generation of Steam and the Thermo-dynamic principles involved*. Furnished with such an account, the engineer is able to say, in the language of commerce, I am debtor to the fuel for so many heat units, how, on the credit side of my account, do I discharge that debt? Usefully I have done so much work, converted that much heat into energy. Uselessly I have raised the air needed for combustion from the temperature of the atmosphere to that of the gases escaping by the chimney; and he sets himself to consider whether some portion of the heat cannot be abstracted from these gases and be transmitted to the incoming air. As was first pointed out by Mr. Anderson, he will have to say a portion of the heat has been converted into energy in displacing the atmosphere, and that, so far as the gaseous products of the coal are concerned, must, I fear, be put up with. He will say, I have allowed more air than was needed for combustion to pass through the fuel, and I did it to prevent another source of loss—the waste which occurs when the combustion is imperfect; and he will begin to direct his attention to the use of gaseous or of liquid fuel, or of solid fuel reduced to fine dust, as by Crampton's process, as in these conditions the supply may be made continuous and uniform, and the introduction of air may be easily regulated with the greatest nicety. He will say, I am obliged to put among my credits—loss of heat by convection and radiation, loss by carrying particles of water over with the steam, loss by condensation within the cylinder, loss by strangulation in valves and passages, loss by excessive friction or by leakage; and he will as steadily apply himself to the extinction or the diminution of all such causes of loss, as a prudent Chancellor of the Exchequer would watch and cut down every unproductive and unnecessary expenditure. It is due to the guidance of such considerations as these that the scientific engineer has been enabled to bring down the consumption of fuel in the steam-engine, even in marine engines such as those which propelled the ship that brought us here, to less than one-half of that which it was but a few years back. It is true that the daily consumption may not have been reduced, that it may be even greater, but if so it arises from this, that the travelling public will have high speed, and at present the engineer, in his capacity of naval architect, has not seen how—notwithstanding the great improvements that have been made in the forms of vessels—to obtain high speed without a large expenditure of power. I anticipate from the application of thermal science to practical engineering, that great results are before us in these heat motors, such

as the gas-engine, where the heat is developed in the engine itself. Passing away from heat motors, and considering heat as applied to metallurgy: From the time of the hot blast to the regenerative furnace, it is due to the application of Science by the engineer that the economy of the hot blast was originated and that it has been developed by the labours of Lowthian Bell, Cowper, and Cochrane. Equally due to this application are the results obtained in the regenerative furnace, in the dust furnace of Crampton, and in the employment of liquid fuel, and also in operations connected with the rarer metals, the oxygen furnace and the atmospheric gas furnace, and, in its incipient stage, the electrical furnace. To a right knowledge of the laws of heat and to their application by the engineer must be attributed the success that has attended the air-refrigerating machines, by the aid of which fresh meat is at the end of a long voyage delivered in a perfect condition; and to this application we owe the economic distillation of sea water by repeated ebullitions and condensations at successively decreasing temperatures, thus converting the brine that caused the Ancient Mariner to exclaim, "Water, water everywhere, nor any drop to drink," into the purest of potable waters, and thereby rendering the sailor independent of fresh water storage.

With respect to the application by the engineer of electrical science, it is within the present generation that electricity has passed from the state of a somewhat neglected scientific abstraction into practical use: first, by the establishment of the land telegraph, then by the development into the submarine cable, by means of which any one of us visitors here in Canada may be in instant communication with his own country, and may be so without a selfish exclusive occupation of the cable, for once more the application of science has solved that apparently impossible problem of employing a single wire to be at one and the same time the transmitter of multiple electric messages, and messages in opposite directions. Then, thanks to the application of Faraday's great discovery of induced electricity, there has been, during the last quarter of a century, the progressive development of the dynamo-machine, whereby the energy of ordinary motors, such as steam-engines, is converted into electrical energy, competent to deposit metals, to (as has already been said) fuse them, to light not only isolated buildings, but extensive areas of towns and cities, and to transmit power to a distance, whether for manufacturing purposes or for the railway or tramcar; and thus the miracle is performed of converting a waterfall into a source of light, as at Sir William Armstrong's house, or into the origin of power for a railway, as at the Giant's Causeway. To the application of electrical science is due the self-exciting of the dynamos and the construction of secondary batteries, enabling a development of electricity to be continued for many hours. In the United Kingdom, general electric lighting, that is to say, the lighting of large sections of a town from a central station, has been stopped by the most unwise, because most unjust, conditions imposed by the Government General Electric Lighting Act of 1882. A new and meritorious industry, which should have been granted the same privileges as are accorded to other industrial undertakings needing Parliamentary powers, was subjected to this most unjust condition: that at the end of twenty-one years the public authority of the town or place lighted should have the option of buying the undertaking for the then value of the mere materials, and that if the authority did not choose to purchase (for it was not bound to buy), at every subsequent five-year period this option should re-arise; that is to say, that a new undertaking, which would require years for its general acceptance (for the public is slow to take up a novelty), was, after the experimental and non-paying stage had been passed, to be practically forthwith taken away for a mere fraction of the capital that had been outlaid if the undertaking paid, but was not to be taken away if it did not pay. Such, in spite of the teaching of Section F, is the condition to which our Government has arrived in respect

of economic science. The next electrical matter I have to touch upon, that of the telephone and microphone, with which will for ever be associated the names of Graham-Bell, Edison, and Hughes, has, as regards the public use of the telephone, been all but similarly treated in the United Kingdom. It has been declared to be within the telegraphic monopoly given by Parliament to the Post Office nine years before the telephone was invented, and the power to use it depends entirely upon the grace and favour of the Post Office, a grace and favour not always accorded; and even when accorded, coupled with limitations as to distance, and coupled with a condition of payment of 10 per cent of the gross receipts by the companies to the Post Office as a royalty; and all this because Government has become a trader in electrical intelligence, and fears the competition of the telephone with its telegraphs.

No one in the ship-loving countries of England, Canada, and the United States, can refrain from feeling the warmest interest in all connected with navigation, and we know how frequently, alas! the prosperous voyage across the wide and fathomless ocean ends in shipwreck and disaster when the wished-for shore is approached, and when the sea is comparatively shallow. Except for the chance of collision, there is in a staunch ship little danger in the open ocean, but on nearing the shore, not only is the liability to collision increased, but shoals and sunken rocks render navigation perilous, and it is on the excellence of the lighthouses and lightships that (coupled with soundings) the sailor relies. These structures and appliances are confided to the engineer, and to be efficient they require him to be able to apply the teachings of Section A in optical science, and in the case of fogs, or as regards buoys at night time, the science of sound. I parenthetically alluded to soundings as one (indeed a principal one) of the safeguards of ships when approaching shore. It is important in these days of high speeds that these should be made with ease and without the necessity of stopping the ship, or even of diminishing its velocity. Sir William Thomson, by the application of the science of pneumatics, has enabled this to be done. Again, most important is it that the compass, midst all the difficulties attendant upon its being situated on an iron or steel structure, should be trustworthy. And here Sir William has applied the science of magnetism in his improved compass to the practical purposes of navigation.

To go to another important branch of engineering—water supply. The engineer dealing with a district to be fed from the surface will find himself very deficient if he have not the power of applying the science of meteorology to the work that he has in hand; he must know, not the average rainfall, for that is of but little use to him, but the maximum, and most important of all, the minimum rainfall over a consecutive period of years: the maximum so that he may provide sufficient channels and by-washes for floods; the minimum so as to provide sufficient storage. He must know what are the losses by evaporation, what are the chances of frost interfering with his filters and with his distributive plant.

Coming to the mathematical side of Section A—whether we consider the naval architect preparing his design of a vessel to cleave the waves with the least resistance at the highest speed, or whether we consider the unparalleled series of experiments of that most able Associate of Naval Architects, the late William Froude, carried out as they were by means of models which were admirable in their material, their mode of manufacture, with absolute accuracy to the desired shape, and their mode of traction and of record, we must see that both architect and experimenter should be able to apply mathematical science to their work, and that it is in the highest degree desirable that they should possess, as Froude did, those most excellent gifts, science and practical knowledge.

Again, the mathematical side of Section A has to be applied by engineers when considering the strength and proportion of boilers, ships, bridges, girders, viaducts, re-

taining walls, and in short the whole of the work with which an engineer is entrusted. Notable instances of great bridges will occur to all our minds, especially meeting as we are in this Continent of grand streams, Ead's St. Louis Bridge, Roebing's Niagara Bridge, and his and his sons' East River Bridge, Gzowski's International Bridge, and going back to our own land, Fowler and Baker's Bridge over the Forth.

Passing from Section A to Section B, there is evidently so much overlapping of these sections that a good deal that I have said in reference to Section A might properly have been reserved for Section B. The preparation from the ore of the various metals is in truth a branch of engineering; but to enable this to be accomplished with certainty, with economy, involving the not throwing away of that which is called the waste product, but which is frequently a valuable material, it is essential that the engineer and the chemist should either be combined in one and the same person, or should go hand in hand. In the manufacture of pig-iron it is absolutely necessary that the chemical constituents of the ore, the fuel, and the flux should be thoroughly understood, and that the excellence of the process followed should be tested by an analysis of the slag. For want of this chemical knowledge thousands upon thousands of tons of bad pig-iron have been made, and thousands upon thousands of tons were formerly left in the issuing slag. Similar remarks apply to the production of lead and of copper from the ores, and still more do they apply to that great metallurgical manufacture of the last few years—"steel." In the outset steel was distrusted because of the uncertainty of its behaviour, but the application of chemical science now enables the manufacturer to produce with precision the material required to fulfil the physical tests imposed by the engineer.

Reverting to the water engineer, the chemist and the microscopist have their sciences applied to ascertain the purity of the intended source, and, as in the case of Clarke's beautiful process, by the application of chemistry, water, owing its hardness to that common cause, carbonate of lime, is rendered as soft as the water from the mountain lake. Taking that other branch of engineering commonly coupled with water, viz., the supply of gas, the engineer is helpless without the application of chemistry. From the examination of the coal to be used, to the testing of the gas to be supplied, there is not one stage where chemical science is not necessary. The consumer requires gas which shall be as nearly as possible a pure hydrocarbon of high illuminating power, and it might well have been that a person to whom was delivered the crude gas as it issued from the retort would have said, "Certain things may be separated out more or less, but to practise on a wholesale scale the delicate operations which will be needed to cleanse the illuminating gas from its multifarious accompanying impurities is a hopeless undertaking, and must be so if for no other reason than this—the excessive cost that would be entailed." But what are the facts? Although I for one do not like to sit in a room where gas is burnt, unless special provision is made for taking away the products of combustion, the engineer of the present day, thanks to the application of chemical science, delivers gas to the consumer in a state of comparative purity (although it may have been made from impure coal) which but a few years ago would have been deemed impossible; and so far is this improvement from being attended with extra cost, that the residual products not now uncommonly all but pay the whole cost of the coal, and in some rare instances even leave a slight profit to go towards the charge for labour. Again, it is by the application of chemical science in the dynamite and the gun-cotton of the present day that the engineer is enabled to prepare submarine foundations, to blast away shoals, and to drive tunnels through rock of a character that cannot be dealt with by mere cutting machines. Equally to the application of chemistry is it due that there are hopes, by the employment of lime cartridges, of breaking down coal without that risk of igniting fire-damp which is attendant

upon the use of gunpowder. I need hardly observe that much more might most pertinently be said on the way in which the engineer applies chemical science. In fact, those ways are so multifarious, that a volume might be written upon them, but I must pass on and ask you to consider how the engineer applies geological science, the science treated by Section C.

I have already spoken of the engineer supplying towns by water collected from the surface; even he, however, must have a knowledge of geology, for without it he will not know what places are apt for the huge reservoirs he constructs, nor where he can in safety make his enormous embankments. In this continent of vast lakes one feels it must excite a sensation of the ridiculous when a "Welsh lake" is spoken of, but I must ask you to believe that you are in Lilliput, and to imagine that the "Bala Pond" of eleven hundred acres in extent is really "Bala Lake," as it is called. Within a few miles of that, our friends at the other end of the Atlantic steam ferry, the inhabitants of Liverpool, are now constructing under the engineering and advice of Mr. Hawksley, a waterworks which will involve the formation, I believe one may safely say the re-formation, of a lake, practically the same area as that of Bala, of some 80 feet in depth, and containing between the overflow and the point of lowest discharge nearly twelve thousand million gallons. This lake will be made by the throwing from side to side of the valley of a solid stone bank, 100 feet above the ground, 140 feet above the deepest part of the foundations, and 113 feet thick at its thickest. Contrasted with Lake Superior this new lake will be small, a thing demanding a microscope even, but the bursting of the wall would liberate a body of water sufficient to carry death and ruin throughout a considerable district. It is, therefore, in the highest degree important that whether he be constructing the solid stone wall, or the more common earthen embankment with a puddle trench, the engineer should so apply geological science as to ensure the safety of his work. But in those cases where the waterworks engineer has to derive the supply from underground sources, the application of this science is still more necessary; he must know whether he is likely to find a water-bearing stratification at all—if so, where it receives the rain from heaven, and the extent of the area which receives it; in what direction the water travels through it, what is the varying height of water in the different parts of the stratification giving the "head" to produce that travel; how far this height is likely to be affected by the pumping of the desired quantity; whether, if near the outflow into the sea, the pumping is likely to reverse the direction of the current, and to bring back brackish water, and whether the rocks are of such a character as to be liable to yield a water impregnated with iron or with lime, and whether these water-bearing rocks are accessible from the surface without the execution of costly and laborious work in passing through overlying stratifications of an unfit or it may be even of a dangerous character. It need hardly be said that the engineer when engaged in metalliferous mining, or in the extraction of coal or of petroleum, unless he applies the science of Section C, is but an haphazard explorer whose work is more likely to end in disaster than in success. Again, the engineer, when laying out a railway, has to consider the geological features of the country in determining the angles of his cuttings, and to determine where it becomes more economical to tunnel than to cut. Indeed, without the application of that science to engineering there are some enterprises on the feasibility of which the engineer would not be able to pronounce an opinion—a notable instance, the Channel Tunnel. The engineers, of whom I am one, said there is a material, the compact non-water-bearing grey chalk, which we have at a convenient depth on the English side and is of all materials the most suitable; if that exist the whole way across, success is certain. Then came geological science, and that told the engineer that in France the same material existed; that it existed in the same position in relation to other stratifications as it

existed in England; that the line of outcrop of the gault lying below it had been checked across; and that taken together, these indications enabled a confident opinion to be expressed that it was all but certain this grey chalk stratification did prevail from side to side. The engineers believed it, an intelligent section of the public believed it, and came forward with their money; large sums were expended in England and in France on the faith of the repeated declaration of the English Government (of both sides of politics), that so long as the nation was not called on to contribute towards the cost of the work, it would hail with satisfaction the improved means of communication between England and the Continent; the experimental works were carried on from both sides with the happiest results, and then, when success appeared certain, the whole work was stopped by the incredible suggestion that in the event of a war the soldiers of England, and the science of England, could not defend a couple of rat-holes, holes 14 feet in diameter and 20 miles long, situated far below the surface of the sea, having a rapid dip from the shore to a low point, gradually rising from there to the centre of the length of the tunnel, so that the English end could be flooded with sea-water in twenty-five minutes up to the soffit of the arch at the dip; and in consequence of this incredible and most-to-be-ashamed-of scare it is due that one of the finest instances of civil engineering work in connection with the science of geology, and as I believe one of the most useful works that has even been proposed, has been put a stop to.

To come to Section D, the botanical side of it is interesting to the engineer as instructing him in the locality and quality of the various woods that he occasionally uses in his work. With regard to that most important part of the work of D, which relates to "germs" and their influence upon health, the engineer deals with it thus far: he bears in mind that the water supply must be pure, and that the building must be ventilated, and that the excreta must be removed without causing contamination; thus the waterworks engineer, the warming and ventilating engineer, and the sewage engineer can (and do) all of them profit by the labours of Section D, and can by their works assist in giving practical value to the pure science of that section.

Section E, *Geography*. Probably in these days, when our kingdom at home and the old countries near us are all but full of the works of the engineer, there are few who take a greater interest in geography than he does, and I am quite sure there are none who make a more useful application of geographical knowledge for the benefit of mankind at large than does the engineer. Almost at the outset of this address I claimed to magnify Section G, on the ground that without the aid of its members we should not have had that practical lesson in geography which we have received by our visit here, a lesson that will no doubt be continued and amplified by many of us before we return to our homes. Whether it be by the ocean steamer or by the railway train, the enterprising geographical explorer is carried to or through countries which now, thanks to the engineer, are well known and settled, up to the beginning of the unknown and not settled; and thus his labours are lightened, he consumes his energies only upon his true work, brings back his report, which is, as I have said, studied by the engineer with a view to still further development, and thus turn by turn the geographer and engineer carry civilisation over the face of the world.

Now to come to Section F, which treats of Economic Science. The matters with which this section deals—birth-rate, death-rate, the increase or the diminution of populations, the development of particular industries in different localities, the varying rates of wages, the extent and nature of taxation, the cost of production, the cost of transport, the statistics of railway and of marine disasters, the consumption of fuel, and many matters which come within the purview of F, are of importance to the engineer. Guided by the information given him by the labours of this section, he comes to the conclusion that a work

having a particular object in view should or should not be undertaken. With the information derived from the past he judges of the future; he sees what provision should be made for prospective increase of population or of industries; he sees the chances of the commercial success of an undertaking or of its failure, and he advises accordingly.

I do not propose to say anything about Section H, for I have dealt with it as being still included within D.

I trust I have now established the proposition with which I set out, viz., that not only is Section G the section of Mechanical Science, but it is emphatically the section of all others that applies in engineering to the uses of man the several sciences appertaining to the other sections—an application most important in the progress of the world, and an application not to be lightly regarded, even by the strictest votaries of pure science, for it would be vain to hope that pure science would continue to be pursued if from time to time its discoveries were not brought into practical use.

Under ordinary circumstances I should have closed my address at this point, but there is a subject which at this, the first meeting of Section G after the meeting at Southport, must be touched upon. It is one of so sad a character that I have avoided all allusion to it until this very last moment, but now I am compelled to grapple with it.

In the course of this address I have had occasion to mention several names of eminent men, many of them happily still with us, some of them passed away; but I doubt not you have been struck by the absence of one name, which of all others demands mention when considering physical science, and still more does it come vividly before us when considering the application of science to industrial purposes. I am sure I need not tell you that this name, which I can hardly trust myself to speak, is that of our dear friend William Siemens, whose contributions to science, and whose ability in the application of science, have for years enriched the transactions of this Section, and of Section A and B, for in him were combined the mechanic, the physicist, and the chemist.

But a brief year has elapsed since he quitted the Presidential chair of the Association, and, with us at Southport, was taking his accustomed part in the work of this and of other sections, apparently in good health, and with a reasonable prospect of being further useful to science for many valuable years to come. But it was not to be; he is lost to us, and in losing him we are deprived of a man whose electrical work has been second to none, whose thermic work has been second to none, and whose enlarged views justified him in embarking in scientific speculations of the grandest and most profound character. Whether or not his theory on the conservation of the energy of the sun shall prove to be correct, it cannot be denied that it was a bold and original conception, and one thoroughly well reasoned out from first to last.

I feel that were I to attempt anything like the barest summary of his discoveries and inventions, I should set myself a task which could not have been fulfilled had I devoted the whole of the time I had at my command to the purpose. I had, indeed, thought of making his work the subject of my address, but I felt that his loss was so recent that I could not trust myself to attempt it. There is no need for me to dwell further upon this most painful topic. He was known to you all, he was honoured and loved by you all, and by every member of this Association he had so faithfully served, and over which he had so ably presided; and he had enjoyed the respect and esteem of the best intelligence in England, the land of his adoption; of the Continent his birthplace; and of Canada, and of the United States, whose populations are always ready to appreciate scientific talent and the resulting industrial progress. It is not too much to say that few more gifted men have ever lived, and that with all his ability and talent he combined a simplicity, a modesty, and an affectionate disposition that endeared him to all.

I am sorry to conclude my address to you in this mourn-

ful strain. I have endeavoured to confine my allusions to our dear friend within the narrowest limits, but if I have overstepped these I trust you will 'orgive me, remembering that "out of the fulness of the heart the mouth speaketh."

ON THE ELECTROLYSIS OF FLUORIDE, CHLORATE, AND PERCHLORATE OF SILVER.*

By G. GORE, LL.D., F.R.S.

By means of pure dilute hydrofluoric acid (prepared as described in *Phil. Trans. Roy. Soc.*, 1869, p. 196) and pure oxide or carbonate of silver, a rather strong solution of pure argentic fluoride was obtained, and was then acidified by addition of pure hydrofluoric acid, in order to fit it for electrolysis.

This liquid is a remarkably good conductor of electricity, and is decomposed with the greatest ease by employing electrodes of silver, and an electric current derived from a single cell composed of zinc and platinum in dilute sulphuric acid.

I have elsewhere (*Phil. Trans. Roy. Soc.*, 1870, p. 235), described some of the phenomena attending the electrolysis of a strong aqueous solution of this salt not containing any free acid, such as the extremely rapid formation of a very thick coating of beautiful and bright crystals of silver upon the cathode, soon becoming half an inch in thickness and rapidly extending over the bottom of the vessel to the anode, and metallically uniting the electrodes unless the deposit is frequently removed. The increase of these crystals is so rapid with a strong solution and current, that if the vessel is a small one it soon becomes half filled with them. There is, however, another phenomenon to which I now desire to call attention, viz., that whilst a thick and smooth anode of pure sheet silver in a suitable solution of potassic cyanide dissolves gradually away and retains its original whiteness, cohesive strength, and most of its original smoothness, until it has become extremely thin, a similar anode in the fluoride solution quickly becomes exceedingly rough, of a grey aspect, and very friable throughout its thickness, having lost its original degree of cohesive strength.

Imagining that this loss of cohesion might be due to some substance set free by electrolysis and absorbed by the silver, as in similar cases of absorption of hydrogen and other liberated ions, at metallic cathodes, I took a tube of pure silver, $\frac{1}{4}$ in. deep, $\frac{3}{8}$ in. diameter, and about 1 mm. thick, closed at the bottom by pure silver, and employed it as the anode. The upper end of the cup being tightly closed by cork, through which was fixed a slender platinum tube, connected by an indiarubber tube with an open, slender, and bent glass tube containing mercury, in order to render manifest any diffusion of gas into the interior of the tube.

Under these conditions, the liquid was electrolysed until a large hole was corroded in the tube; no signs of gas or odour, however, appeared, nor was the cork which closed the tube bleached or blackened. I conclude, therefore, that the loss of cohesion of the silver was not due to diffusion of liberated fluorine, through the silver.

A solution of chlorate of silver was formed by adding to 1½ ounce of aqueous chloric acid (containing as impurity traces only of hydrochloric acid or a chloride) ten grains of argentic oxide: it nearly all dissolved. The liquid was filtered and then electrolysed by means of electrodes of pure sheet silver and a current from two Smee's cells charged with a mixture of one vol. of sulphuric acid and fifty of water. Conduction was very free for a short time; the anode, however, soon became coated with a black film, probably of peroxide of silver, which appeared to

stop the current. Silver was freely deposited at first. The deposit was loose and not very white. The anode corroded but slowly, and permanently continued nearly black. By employing one Smee's cell only, the deposit was more slow, and more coherent, and remained attached to the cathode. The solution requires a feeble current, a large cathode, and a much larger anode.

To form the solution of argentic perchloride, fifteen grains of oxide of silver were added to one ounce by measure of aqueous perchloric acid. It nearly all dissolved. The liquid contained either hydrochloric acid or a chloride rather freely. The solution was then filtered and electrolysed by means of a current from two Smee's elements feebly charged, and electrodes of pure sheet silver; copious conduction occurred. The anode quickly became black, as if peroxide of silver was formed, but the current did not much diminish. The cathode soon acquired a very bulky deposit of loosely adherent silky crystals of silver. The liquid was again filtered, and then diluted with half an ounce of water, and a current from only one Smee's cell now employed. The anode became less dark in colour; the conduction was still very free, and a smaller bulk of crystals was deposited. A wire of silver was now substituted as the anode, and the crystals removed. The anode rapidly corroded, and acquired a thick loose coating of black matter, which kept falling off; it then acquired a thick green coating, but evolved no gas. The solution is a remarkably good conductor. It requires a very large cathode and a rather small anode.

ANALYSIS OF ANTIMONY ALLOYS, SUCH AS TYPE-METAL, CONSISTING OF LEAD, ANTIMONY, AND TIN.

By F. WEIL.

1. From 2 to 3 grms. of the comminuted alloy are treated with nitric acid in a boiling-flask; almost all the nitric acid is evaporated off, a large excess of pure hydrochloric acid is added, and the mixture is boiled until the fumes no longer turn iodised starch paper brown, or but very faintly so. Hydrochloric acid is again added, and a little potassium permanganate or chlorate, to make sure that all the antimony is dissolved as antimonic acid. The liquid is then boiled until the fumes no longer act upon the iodised starch paper, i.e., until all the free chlorine is expelled.

The solution is then introduced into a narrow measuring glass, and filled up to the mark (200 c.c.) with hydrochloric acid and water containing much tartaric acid, and well shaken.

The antimony is then determined in 10 c.c. of the solution volumetrically with stannous chloride, according to the method of Weil (see "Fresenius's Quant. Analysis," 6 edit., vol. ii., part 5, p. 542).

If the alloy contains very much lead it is better to proceed as follows, in order to have in the measuring glass a clear liquid not rendered turbid by lead chloride.

The flask which contains the insoluble stannic and antimonic acids suspended in nitric acid, is filled up with hot water, shaken up, and let stand. After the precipitate is completely deposited the clear solution of lead nitrate is drawn off with a pipette.

The precipitate is washed in the same manner with hot water, decanted, and the residue is boiled in the flask with much hydrochloric acid and some potassium permanganate or chlorate until all chlorine is expelled.

The liquid, along with the aqueous and hydrochloric solution of tartaric acid, is then poured into the graduated cylinder up to the mark of 200 c.c., and 10 c.c. are lastly titrated as above for antimony.

2. From 2 to 3 grms. of the alloy, finely divided, are again treated with strong nitric acid, and the lead is deter-

* Read before the Birmingham Philosophical Society, June, 1884.

mined as sulphate in the well-known manner, and in the well-washed residue the joint quantity of lead and antimony is determined by ignition and weighing as antimonious and stannic acids.

3. The antimony as determined in No. 1 is calculated as SbO_3 and deducted from the weight of the joint antimonious and stannic acids already found. The residue is the stannic acid.

This method has the advantage of evading the tedious and difficult separation of antimony and tin.—*Zeitschrift f. Analytische Chemie.*

SEPARATION OF ZINC FROM NICKEL.

By THOMAS MOORE.

THE usual method for the separation of the two metals by sulphuretted hydrogen is open to many objections, and it is only in the hands of experienced chemists that good results can be depended upon, as, unless the exact amount of sodic acetate is added, either some of the zinc will not be thrown down, or the precipitate of zinc sulphide will be contaminated with nickel sulphide. In the following process, however, I obtain the zinc sulphide perfectly pure, and without any of the difficulties always attending the neutralising of the solution with sodic carbonate.

Excess of acid is got rid of by evaporation, and the residue dissolved in from 20 to 25 c.c. water and completely precipitated with excess of ammoniac sulphide; the precipitate is then dissolved in potassic cyanide, the solution being effected by heating. When completely dissolved, dilute to about 250 c.c., and, after adding a few c.c. of sodic acetate, acidify with acetic acid and raise to the boiling point. The zinc is thrown down as the sulphide, and, after standing a few hours, is washed thoroughly by decantation, using hot water containing a little acetate of sodium and a few c.c. sulphuretted hydrogen water, and finally converted into oxide by the usual process. The filtrate and washings are evaporated to dryness with aqua regia, and the nickel estimated in the residue by dissolving in water and precipitating with potassic hydrate and bromine, re-dissolving in dilute sulphuric acid, adding ammonia, and precipitating as the metal by electrolysis.

The results are very accurate, and as I have had considerable experience with it in its application to German silver analysis, I can appreciate the smoothness, cleanliness, and rapidity with which it works.

Edrington.

SOME NOTES ON THE REICHERT METHOD OF BUTTER ANALYSIS.

By LEROY W. McCAY, M.A., D.Sc.

HAVING been lately called upon to report on some samples of suspected butter, and having, during my examination, made quite a study of the Reichert method of analysis, it may not be out of place to here call attention to a few points, a knowledge of which may prove of value to those who have occasion to try the process for the first time.

(1). First, then, I found, in the beginning, considerable trouble in apprehending what the author means when he directs that the mixture of fat, caustic potash, and 80 % alcohol be heated in a flask and upon the water-bath, with constant shaking, until the soap no longer forms a foaming, smeary mass. Indeed a solution of the problem has been arrived at entirely by experience. What Reichert wishes to impress upon the chemist is that an *evaporation of the alcohol is essential*. Now, although upon a fulfilment of this condition the correctness of the method depends, not one word has the author to say which bears *directly* upon the subject. In fact, the

word evaporation does not occur at all in the article. He seems to take it *for granted* that a complete evaporation of the alcohol is essential, but considers it as worth while to *call attention* to the fact that this is alone possible, providing the flask containing the soap be heated upon the water-bath, with constant and violent agitation, until the mass no longer exhibits a tendency to froth or foam. He has left out a most valuable and suggestive direction, and seen fit to introduce one the ambiguity of which must, I fear, unless attention be called thereto, prove a ready stumbling-block to many who have occasion to try the process for the first time. I insist, therefore, that Reichert, in his directions, fails to state with sufficient prominence the necessity of a complete evaporation of the alcohol. It is surprising how incompletely the method has been described by those who have had opportunity to try it. In truth, there has generally been no description at all, it being merely stated that Reichert's directions were followed. I know of four chemists who have experienced the same trouble that I have, and consequently it seemed proper to publish a word on the matter. The condition under consideration, however, being carried out, the process turns out to be fully as quick, easy, and accurate as it is claimed to be by its ingenious author, and, although less rapid and, to my mind, less satisfactory than the simple, beautiful, and elegant method of Dr. Koettstorfer, it certainly is very convenient and, on the whole, more trustworthy than that of Hehner.

(2). To get rid of the alcohol by merely heating upon the water-bath is no easy matter, and so I have endeavoured to hit upon some contrivance by means of which this difficulty may be obviated. I find that the alcohol is almost entirely removed, and that, too, in a very short time, by proceeding as follows: the flask containing the soap and residual alcohol is closed with a perforated cork through which passes a piece of glass tubing long enough to reach to about the centre of the flask, when the cork is in place, and, moreover, project a few inches above the end of the neck. This outer end of the tube is then connected with the suction pump by means of a piece of rubber tubing, and the flask firmly clamped in an upright position in the bath, the temperature of which is so regulated that the contents of the flask shall enter into a state of gentle ebullition. As soon as the smeary mass, upon shaking, no longer froths or exhibits a tendency to froth, the point is reached and the soap may be dissolved in water, decomposed with acid, and the distillation commenced.

(3). To avoid the violent bumping which is so marked during the process of distillation, and which so seriously interferes with the general method of procedure, Reichert recommends it as feasible to pass a slow current of air through the liquid in the retort. This, however, is troublesome, as will be evident at a glance. Ambuhl sought to steer clear of this difficulty by using bits of platinum and pumice stone, but entirely without success. Dr. G. C. Caldwell,* finding it inconvenient to use the stream of air, ventured to try a combination of platinum spirals and pieces of pumice, and with complete success. I have tried this gentleman's device and have found it to work admirably. Thus far I have made a great number of distillations, and in no case have I noticed an indication of what could be called bumping. The ebullition continues throughout the process perfectly constant, and the quiet manner in which the bubbles of vapour are given off at the surfaces of the bits of pumice attached to the spirals, resembles very much the gentle disengagement of the bubbles from the lead-loaded cork in the new Bunsen water-bath. I use three little spirals, a small piece of pumice being attached at either end of each coil. The spirals, with their attachments, are conveniently made by coiling a piece of ordinary platinum wire, about 7 to 8 inches long, around a stout stirring rod, passing each

* "Second Annual Report of the New York State Board of Health; 1881-1882." Butter, page 346.

end through a bit of perforated pumice and twisting fast. I also drop in two or three pieces of plain pumice. Dr. Caldwell, in his article, simply mentions the success attending his use of combinations of platinum spirals and pumice, without entering into detail; consequently, I trust I may be excused for dwelling at length upon the subject.

CORRESPONDENCE.

COPPER OXYCHLORIDE AS A PAINT.

To the Editor of the Chemical News.

SIR,—There would seem to be a diversity of opinion amongst medical men as to whether Dr. Koch's bacillus, or microbe, be the cause or the result of cholera; but whichever way that may be, it is a remarkable fact that preparations of the two metals mercury and copper, which are admittedly more eminently destructive than any others to plant and infusorial life, should be among the most favourite remedies for that disease, and their efficacy very probably depends on these same destructive powers. True, among the forms in which mercury is employed, mercurous chloride (calomel) has always held a favourite place with doctors, and this is one of the least active preparations of mercury, but this has probably been due to the fact that, being less poisonous than any of the mercuric preparations, it has been found to be a readier means of introducing into the stomach a certain quantity of the metal without disastrous effects to the patient. If it be desired to administer copper, reduced metallic copper (copper precipitate) would probably, on this same principle, be found to be the safest and best form in which to administer it, as, if pure and well prepared, it may be given in considerable doses without injury. But just as the mercuric preparations are more active than the mercurous, so the cupric are more active than the cuprous or than metallic copper, and it would probably be found advantageous to paint the insides of water tanks with the oxychloride of copper (Brunswick green) or some other insoluble cupric salt, as a means of antagonism to the development of microbia. Mercuric salts would, of course, act equally well, if not better, but they might be considered to be dangerous, being so very poisonous, whereas cupric salts, though excessively, inimical to plant and infusorial life, are even held by some to be not poisonous to man at all.

Though I should hardly be willing to go this length in view of the many notable and well accredited instances of poisoning by copper, I cannot but admit that copper acts less actively on the human system than had been supposed; but anyway, a paint made with so insoluble a salt as the cupric oxychloride could never make the water in the least unwholesome, much less dangerous. Of course this method does not pretend to be by any means a prophylactic against the presence of all microbia; it could only affect such as came in contact with the sides, or subsided to the bottom, and it would, at any rate, prevent all growth on the sides or bottom of the tank, and destroy such organisms as came into contact with them.

I thus propose it merely as in some sort a step towards sanitation, not to speak of it as a complete remedy. Iron pipes might also be so coated interiorly. We must not measure the activity of copper on microbia by its action on the human system. That which would kill microbia will often scarcely affect human beings, and *vice versa*, what would be inevitably fatal to a human being will often scarcely affect microbia. Thus a dose of copper, which is fatal to all growth, and to all the lower organisms, may scarcely affect the human subject. Borax

and salicylic acid have a fatal effect on microbia and on fermentation, but are with no poisonous effect on human beings; while, on the other hand, in the presence of a dose of arsenic, which would be inevitably fatal to man, saccharine liquids will enter into fermentation, the action being only rendered a little slower; and bacteria will also live in such a solution. It is now usual to paint iron tanks with red or white lead, and, apart from the fact of lead paint not being over good for iron, we know that some water exerts a solvent action on lead. Where, then, the choice lies between lead and copper, as a basis of a paint for water tanks, the latter is most certainly to be preferred. However, if an iron tank be painted with a cupric salt, whatever it may be, it is necessary, above all things, that the copper paint be perfectly isolated from the iron beneath, if it is desired to be maintained in a proper state of efficiency, and this either by a spirit or benzoline varnish, or, which is better, a paint composed with a metallic oxide the metal of which is electro-positive to iron, so that it may not be reduced thereby. Zinc oxide, magnesia, or even common cement, make a very good basis for a paint for this purpose, but magnesia is by far the best and most durable of these.

The paint may be made up with either addition of the calcined magnesia to varnish, or drying oil, and a sufficiency of driers added in this latter case, as without them magnesia paint does not dry well, and on this, when sufficiently dry, the cupric paint should be applied.—I am, &c.,

F. MAXWELL-LYTE.

IRON COMBUSTION TUBES.

To the Editor of the Chemical News.

SIR,—In the Proposals for Uniform Methods for the Determination of Nitrogen accepted by the German Manure Manufacturers' Association it is stated that "The use of iron combustion tubes cannot be generally recommended. They are only allowable with the modifications described by Prof. Paul Wagner (*Chemiker Zeitung*, viii., No. 37)." Would any of your readers kindly inform me through your columns what these modifications are?—I am, &c.,

W. W. M.

AN EXAMINATION QUESTION.

To the Editor of the Chemical News.

SIR,—Having recently presented myself for examination in Chemistry, I am naturally anxious to know whether I am likely to be passed or ploughed. One of the questions asked me to describe the behaviour of certain metals with hydrochloric acid. I think my answer was correct in most cases, but I am still doubtful about antimony, and take the liberty of writing to ask if any of your readers can set my mind at rest on the subject upon which the doctors disagree very much.

Roscoe and Schorlemmer say that antimony is "easily dissolved by hot hydrochloric acid." (1879, part. ii., p. 305).

Roscoe says "Antimony is not attacked by dilute hydrochloric acid." (*Elementary Chemistry*, 1877, p. 212.)

Kolbe says "Hydrochloric or dilute sulphuric acid have (sic) no action on antimony." (Humpidge's Translation, 1884, p. 252).

Watts (Fownes) says "Antimony is dissolved by hot hydrochloric acid." (1883, p. 531).

Fresenius (*Qualitative Analysis*, Vacher, 1872, p. 149) says "Hydrochloric acid, even boiling, does not attack antimony." Again (*Quantitative Analysis*, Vacher, 1876, p. 154) "Hydrochloric acid has very little action on it, even when concentrated and boiling."

Miller (*Elements of Chemistry*, 1868, p. 673) says—"When finely powdered it is dissolved by strong hydrochloric acid by the aid of heat."

I stated that antimony is but little affected by hydrochloric acid, so that I should be plucked by Roscoe, Schorlemmer, and Watts, and passed by Kolbe, Fresenius, and Miller.—I am, &c.,

A BENIGHTED STUDENT.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Journal de Pharmacie et de Chimie.

Series 5, Vol. ix., March, 1884.

Simple Means of Detecting Albumen in Urine.—M. Geisler.—The reagent employed consists of two slips of filter-paper, the one steeped in nitric acid and the other in a solution of potassium mercuric iodide, prepared as follows:—Potassium iodide, 3.32 parts; mercuric chloride, 1.35; acetic acid, 20.00; distilled water, 40.00. The paper thus prepared is dried and cut in slips; to make use of it the two slips are steeped in the sample of urine in question. If albumen is present the urine becomes turbid. The process is sensitive, and an excess of the reagent does not interfere. It certainly precipitates other principles contained in urine, such as uric acid, mucine, alkaloids, &c., but it will always be easy to recognise the nature of the turbidity produced. The precipitate of uric acid redissolves on heating, the precipitates of alkaloids dissolve in alcohol; mucine forms small clouds in the midst of the liquid, whilst albumen is thrown down in heavy flocks.

Extraction of Colouring-Matters by Means of Solutions of Borax.—R. Palm.—Already inserted.

Saffron, Containing Alumina.—E. Schmidt.—The question is here not of a sophistication, but of a small quantity of alumina naturally present in saffrons from the South of France. The only plants in which alumina has been hitherto discovered are certain Lycopods and *Rubus arcticus*. The saffrons in question contain from 0.115 to 0.123 per cent.

Determination of Starch.—Mr. O'Sullivan.—From the *Journal of the Chemical Society*.

April, 1884.

Assay of the Peppers of Commerce with reference to their Sophistication with Olive-Kernels and Husks.

—H. Rabourdin.—The author weighs out exactly a gramme of the sample and boils it continuously for an hour in 100 grms. distilled water and 4 grms. sulphuric acid, adding more water from time to time to make up for the loss by evaporation. The flask must be supported by the neck or it will be broken by the violent bumping. After boiling for an hour the liquid is allowed to cool, poured upon a plain double filter which has been previously well dried and tared. When the pepper contains olive-kernels they go to the bottom of the flask by reason of their higher specific gravity, and when the liquid is poured upon the filter they form upon the sides of the flask as it were a reddish sand, more or less plentiful. This character already is decisive, since pure pepper never gives these dense, reddish fragments. The flask is repeatedly rinsed out, and the filter with the residue are perfectly washed with boiling distilled water. It is then dried and weighed very carefully. The weight of this total residue forms the coefficient of the pepper. This value is variable for every kind of pepper, but for all pure kinds within very narrow limits, and is strikingly increased when the pepper is adulterated with kernels or shells. For white pepper the value is 0.175; Malabar, Tellichery, and Saigon peppers, 0.30; Alepy, 0.32; other pure peppers of commerce, 0.35. On the other hand, that of the olive-kernels is on the average 0.745, and that of the husks or shells 0.70.

Direct Volumetric Determination of Lime and Calcium Carbonate.—M. Prunier.—The difficulty of obtaining quickly a clear supernatant liquid, even at a boil, on precipitating a soluble calcium salt with ammonium oxalate has led to the abandonment of this reagent for the volumetric determination of calcium salts. This difficulty has been overcome by taking advantage of the property of starch, added in infinitesimal doses, of promoting the deposit of precipitates, when boiled with the calcareous solution in question, such liquid being neutral or neutralised with pure ammonia. The standard solution is prepared as follows:—Pure ammonium oxalate, 35.50 grms., and water to form a 1.4th normal solution. The oxalate should be very dry, but not effloresced, and should leave no perceptible residue when ignited on platinum foil. If there are any doubts as to its purity the standard solution may be titrated with a solution obtained by dissolving at a boil 1 gm. pure calcium carbonate in dilute hydrochloric acid, neutralising afterwards with ammonia, free from carbonate, and adding water enough to make up 40 grms. of liquid. We take of it, with a graduated pipette, 10 c.c., representing 0.25 gm. calcium carbonate, and ascertain, in a manner indicated below, that they precipitate exactly at a boil 10 c.c. of the solution of oxalate in presence of a little starch. To determine calcium carbonate in complex products, e.g., limestones, we make a solution at 1.40th by stirring up in a tared flask 1 gm. of the mineral finely powdered with 10 grms. of water, pouring then upon it 3 c.c. of hydrochloric acid and boiling the whole for a few moments. There are then added 20 grms. water, mixing and neutralising with ammonia free from carbonate until it gives a slight blue tint to red litmus. It is then made up to 40 grms. with distilled water and filtered. With a graduated pipette there are measured off 10 c.c. of the filtrate (= 0.25 gm. limestone) which is introduced into a test-tube, 2 to 2.5 centimetres wide and about 20 to 25 in length, after having wiped the outside of the pipette with blotting-paper, so as to have merely the exact 10 c.c. To determine the lime in such products as fat or lean limes, cements, &c., where it is associated with other elements, the substance in question is dissolved in the same manner as limestone, but making the solution at $\frac{1}{10}$, and introducing into the test-tube only 7 c.c. instead of 10 c.c. In either case there is added to the solution a small quantity of starch powder (about 1 centigram.), and the whole is heated to incipient ebullition, turning the tube round to distribute the heat evenly and avoid bumping. Then by means of a Mohr's burette, graduated into tenths of a c.c., and fitted with a delivery tube so long as to descend into the test-tube almost to the level of the solution, there are run in at once 4 to 5 c.c. of oxalate. It is heated again, shaken up, let settle for one or two minutes, and the oxalate liquid is then gradually added in small fractions until the precipitation ceases. Towards the end of the operation, when the turbidity produced on adding the oxalate diminishes in intensity, the standard solution is dropped in with the orifice of the delivery tube lowered almost to the level of the liquid, so that the falling drops may not stir up the deposit. The supernatant liquid may be examined as to its transparency by placing it against a black ground near a window. If there is formed on the surface of the liquid a persistent froth, which renders the end of the reaction difficult to detect, it may be removed by adding a few drops of strong alcohol and heating the upper part of the liquid column. The percentage of calcium carbonate or of lime is given at once and without calculation by the number of tenths of a c.c. of the standard solution employed to precipitate all the lime. The temperature of the solution during the analysis should not fall below 15°, or the ammonium oxalate may crystallise.

Action of Copper upon the Human Economy; History of a Workshop and of a Village.—M.M. A. Houles and de Pietra Santa.—The authors show that persons living in an atmosphere of copper dust are not subject to any special diseases; that the "copper cholic"

described by writers of the last century does not exist, but that workers in copper enjoy no immunity from cholera and typhoid fever.

On the Powders of Meat.—M. Yvon.—A continuation from the last number.

MISCELLANEOUS.

Appointment.—Mr. William M. Hamlet, F.C.S., has been appointed by the Board of Technical Education, Sydney, N.S.W., Lecturer on Practical Physics and Examiner in Physics at the Sydney Technical College.

South London School of Pharmacy.—The following is the list of successful competitors at the School examinations, held from the 26th June to the 5th July, 1884:—Senior Chemistry—Medal: R. Wilkinson; Certificates,—(equal): D. Arnott, and J. Jackson. Junior Chemistry—Medal: W. Rushton; Certificate—W. Holme. Botany—Medal: T. J. Clark; Certificate—R. Atkinson. Materia Medica—Medal: W. Holme; Certificate—T. J. Clarke. Pharmacy and Practical Dispensing—Medal: F. E. Brown; Certificate—W. Rushton. Extra Certificates of Merit: Messrs. Coleman, Cooper, Jackson, Kingan, Matthews, Taylor, Ward, and Williams.

The Chemical Laboratory of Wiesbaden.—In the Summer Term, 1884, there were 84 students on the books. Of these, 54 were from Germany, 6 from England, 6 from Russia, 4 from North America, 3 from Austro-Hungary, 2 from Luxemburg, Holland, Belgium, and Switzerland, and 1 from France, Spain, and Sweden. Besides the director, Geh. Hofrath Prof. Dr. R. Fresenius, there are engaged as teachers in the establishment, Dr. H. Fresenius, Dr. E. Borgmann, Dr. W. Fresenius, Dr. E. Hintz, Dr. med. F. Hueppe, and Architect F. Brahm. The assistants in the instruction laboratory were 2 in number, in the private laboratory 12, and in the Versuchsstation 2. The establishment has been enlarged by a special department for hygiene and bacteriology, directed by Dr. med. F. Hueppe. During the last term, besides the scientific researches, a great number of analyses were undertaken in the Laboratory and the Versuchsstation on behalf of manufacture, trade, mining, and agriculture.

NOTES AND QUERIES.

** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Bones.—Would any of your readers inform me by which method in this country (especially in Lancashire) artificial manure and glue are produced from bones? Has muriatic acid yet been employed for this purpose, and to what extent?—L. HUNDESHAGEN.

Indelible Ink.—I find that about 1 part of naphtha mixed with 2 parts of coal-tar makes a marking-ink for linen and cotton fabrics which for indelibility cannot be surpassed. It has also the great advantage of being in one mixture, and will keep if kept corked any length of time. It has the disadvantage, however, of being too faint. Could any of the readers of your valuable paper suggest any means of darkening the colour?—T. WILSON.

ERRATUM.—P. 26, col. 1, line 11 from top, for "more of the silica" read "none of the silica."

UNIVERSITY COLLEGE, LONDON.

ANALYTICAL CHEMISTRY.

The Laboratory of Analytical Chemistry, under the superintendence of Professor WILLIAMSON and Assistant Professor R. T. PLIMPTON, will re-open on Thursday, October 3rd.

For information as to other Courses on Chemistry, &c., apply to the Secretary of the College.

TALFOURD ELY, M.A., Secretary.

UNIVERSITY COLLEGE, BRISTOL. CHEMICAL DEPARTMENT.

PROFESSOR—W. RAMSAY, Ph.D.
LECTURER—SYDNEY YOUNG, D.Sc.

The SESSION 1884-85 begins on 7th OCTOBER. Lectures on Inorganic, Organic, Advanced, and Technical Chemistry will be delivered during the Session. The Laboratories are fitted with the most recent improvements for the study of Practical Chemistry in all its branches. In the evening, Lectures on Inorganic Chemistry at reduced fees are delivered; and a Special Course of Lectures on Technical Chemistry is also given, with the co-operation of the Worshipful Company of Clothworkers. A Correspondence Class especially adapted for those engaged in the Clothworking and Dyeing Industries will begin in October. Several Scholarships are tenable at the College. Calendar, containing full information, price 1s. (by post 1s. 3d.) For prospectus and further information apply to the Registrar.

INSTITUTE OF CHEMICAL TECHNOLOGY

AND ANALYTICAL LABORATORY,

5, 9, and 11, PHILADELPHIA CHAMBERS, HACKINS HEY,
and 3 and 12 A, ASHTON CHAMBERS, HACKINS HEY,
LIVERPOOL.

PRINCIPAL—A. NORMAN TATE, F.I.C.

Designed for the examination, for scientific, commercial, and industrial purposes, of substances used and produced in the Arts and Manufactures, and found in Commerce; and for the instruction of Students in Chemistry and the allied sciences in their relation to industrial and commercial pursuits.

The Laboratories have lately been entirely re-arranged and considerably extended, and are provided with all appliances necessary for analytical investigations, special technical examinations, and Students' work.

Students' fees, fifty guineas per annum.
In addition to their chemical studies, Students who desire it can enter upon a course of instruction calculated to afford them knowledge useful in the erection and arrangement of manufacturing buildings and plant, and construction of apparatus. Special fees are charged for this course.

All communications should be addressed to Mr. A. Norman Tate, 9, Hackins Hey, Liverpool, as, owing to similarity of name with that of the principal of another chemical establishment in Liverpool, misconception and mistakes have arisen.

COLLEGE OF APPLIED CHEMISTRY, KIEL.

This Institution affords special facilities for obtaining a thorough practical knowledge of the Manufacture and Analysis of Technical Products, as well as of the Analysis of all articles of Food and Drink.

Commencement of the Winter Season, 15th of October.

Prospectus with full particulars on application to the Director, DR. SCHNITZ.

Reference, Mr. LOUIS SIEBOLD, F.I.C., F.C.S.,
Carr Bank, Bury, Lancashire.

CHEMICAL LABORATORY, WIESBADEN, GERMANY.

Director—Prof. R. FRESENIUS, Ph.D.

Practical Instruction in the Laboratory
Prof. R. FRESENIUS, Ph.D.;
H. FRESENIUS, Ph.D.;
W. FRESENIUS, Ph.D.;
E. HINTZ, Ph.D.

LECTURES.

Experimental Chemistry (Inorganic)	H. FRESENIUS, Ph.D.
Experimental Physics	W. FRESENIUS, Ph.D.
Organic Chemistry	E. HINTZ, Ph.D.
Chemical Technology	E. HINTZ, Ph.D.
Microscopy, with exercises in microscopic work	E. BORGSMANN, Ph.D.
Chemistry and Analysis of Foods	H. FRESENIUS, Ph.D. E. BORGSMANN, Ph.D. W. FRESENIUS, Ph.D. and E. HINTZ, Ph.D.
Hygiene: practical exercises in Bacteriology	Dr. med. F. HUEPPE.
Technical Drawing, with exercises	F. BRAHM.

The next Session commences on the 15th of October. The Regulations of the Laboratory and the Syllabus of Lectures will be forwarded gratis on application to C. W. KREDEL'S Verlag, at Wiesbaden, or to the undersigned.

Prof. R. FRESENIUS, Ph.D.

THE CHEMICAL NEWS.

VOL. L. No. 1297.

ON SOME REACTIONS OF SILVER CYANIDE.

By CHARLES L. BLOXAM.

WHEN concentrated nitric acid is poured on precipitated silver cyanide, hydrocyanic acid is evolved, and, on boiling, the cyanide is entirely dissolved, the solution depositing crystals of silver nitrate on cooling; but if the solution be decanted when only a portion of the precipitate has dissolved, it deposits, on cooling, minute needles which mat together in a remarkable manner when the liquid is stirred. The formation of these needles on a glass microscope slide was recommended by me in a former communication for the identification of silver cyanide, and they can be distinctly perceived even with an inch objective. They are identical in appearance with the so-called silver nitrocyanide obtained by dissolving silver cyanide in silver nitrate which I had shown to have the composition $\text{AgCN} \cdot 2\text{AgNO}_3$. A quantity of the crystals from the nitric acid solution was freed from mother-liquor by pressure in filter-paper till dry, and decomposed by water, when amorphous silver cyanide was left, and silver nitrate passed into solution. Two different crops of crystals gave 21.5 and 22.44 per cent of Ag as AgCN . The above formula requires 22.78 per cent. The residue left by the nitric acid was a mixture of the needles with some unaltered silver cyanide, the silver nitrate contained in it amounting to 53.4 per cent. When silver cyanide was left for about twenty hours under cold concentrated nitric acid, about half of it had become converted into needles of nitrocyanide. The concentrated acid (1.4) diluted with an equal volume of water appears the most suitable for dissolving silver cyanide as nitrocyanide when boiled.

Precipitated silver cyanide, treated with a strong solution of sodium carbonate in the cold, loses its curdy appearance, and becomes granular. Under a quarter-inch objective, the edges of these granules exhibit minute needles, which become more distinct after some hours. On boiling, the silver cyanide becomes grey, and is converted into a mass of minute needles strongly matted together; the boiling solution, decanted into a beaker, deposits needle-like crystals in abundance. These crystals exhibit all the reactions of silver cyanide, and the mother-liquor contains only a trace of sodium cyanide.

The grey crystalline residue left after boiling the silver cyanide twice with a very strong solution of sodium carbonate, was well washed and dried at 100° . Its appearance under the microscope was unaltered, and it gave on ignition 81.3 per cent of silver; the cyanide would give 80.6 per cent, but the dark colour of the needles indicated slight reduction. Qualitative examination detected only cyanide and a little metallic silver.

The needles deposited from the sodium carbonate solution are voluminous, but shrink together into a small closely-matted mass when stirred. To obtain a sufficient quantity for analysis, 10 grains of silver nitrate were dissolved and precipitated by hydrocyanic acid, the precipitate well washed, drained, and heated to boiling with a solution of 300 grains of crystallised sodium carbonate in an ounce of water; the hot solution was decanted, crystallised by stirring, and the mother-liquor poured back on the undissolved cyanide, which was again boiled with it. Fifteen repetitions of this operation were required to dissolve all the silver cyanide. The crystals, which appeared very distinct under an inch objective, were thoroughly washed and dried at 100° without any alteration. On ignition they gave 80.46 per cent of silver instead of the 80.60 required for silver cyanide,

Potassium carbonate produces the crystals of silver cyanide more readily than the sodium salt. The cyanide precipitated from 10 grains of silver nitrate was boiled with a solution of 150 grains of potassium carbonate in an ounce of water; the decanted liquid deposited needles identical in appearance with those produced by sodium carbonate; the residual cyanide consisted almost entirely of matted needles, and dissolved completely on boiling ten times with the potassium carbonate. The mother-liquor from the last crystals contained only a trace of cyanogen. Silver cyanide, therefore, is practically undecomposed by boiling with very strong solutions of potassium and sodium carbonates, but is converted into small prismatic crystals, which are rather sparingly soluble in the hot solution of alkaline carbonate, and are entirely deposited on cooling.

King's College, London.

THE QUANTITATIVE DETERMINATION OF MORPHINE IN OPIUM.

By Dr. VON PERGER.

FROM 10 to 20 grms. of the sample in question, divided as finely as possible, are boiled for a short time with 15 to 30 grms. caustic baryta and about 150 to 200 c.c. water. The solution is separated by decantation and filtration from the residues, and the latter are boiled repeatedly with small quantities of hot water until a portion of the solution on evaporation no longer gives the reaction of morphine with molybdic sulphuric acid. In this process too frequent a repetition of the extraction should be avoided, and the volume of the filtrate will not be generally more than 400 to 500 c.c. Into this solution, which contains all the morphine, is passed a current of washed carbonic acid until the liquid is supersaturated with the gas, and the entire mass is evaporated to dryness in a capsule on the water-bath as quickly as possible.

The residue is moistened with absolute alcohol, removed from the capsule by means of a sharp spatula, introduced into a glass flask, and extracted with boiling absolute alcohol until a portion of the extract, evaporated to dryness on a watch-glass, no longer gives a distinct morphine reaction with molybdic sulphuric acid. For this purpose 300 to 400 c.c. are generally required. The clear, alcoholic filtrate is freed from alcohol by distillation in a small flask. When the volume of the liquid has been much reduced by pouring back the alcohol and distilling again the residue of the alcohol is completely expelled by placing the flask in a boiling water-bath.

The residue in the flask is resinous and sticky, of a yellowish brown colour. About 15 c.c. water are added, which has been mixed with a little ammonia, and the whole is allowed to stand for some time. The dark, resinous mass takes a light brown colour, and solidifies by taking up water. The transformation is promoted by stirring and rubbing with a glass rod covered with caoutchouc. The mass is then decanted through a small tared filter, and the finely-divided precipitate is brought upon the filter by repeatedly pouring back the filtrate. Finally it is washed with a little ammoniacal water, large volumes of liquid being avoided.

The filter is dried at 40° , and placed in a glass funnel which can be closed below. There is then poured upon it pure chloroform free from alcohol, which is left in contact with the contents of the filter for a considerable time; the tap is then opened and the chloroform run off. A fresh quantity is then poured on in its stead, and the operation repeated until if a portion of the almost colourless solvent is evaporated on a watch-glass, the residue dissolved in dilute hydrochloric acid, and the solution mixed with caustic soda-lye, merely a trace of turbidity appears; from 3 to 5 c.c. of the chloroform solution are sufficient for this purpose.

The filter is dried and weighed, and the product obtained is crude morphine. Its colour should be from a light-brown to a straw-yellow. It contains no narcotine, and is in many cases so pure that if covered with hydrochloric acid it dissolves with a yellow colour, and the solution, if shaken, congeals at once from the formation of morphine hydrochlorate.

In all cases, however, it requires to be purified. To this end the smallest possible quantity of very dilute acetic acid is poured upon the filter containing the crude morphine. If the weight of the crude morphine is from 1.0 to 1.5 gm., a mixture of 1.5 to 2 c.c. of acetic acid at 20 per cent with 20 to 25 c.c. of water will be sufficient. In order to promote the solution of the morphine as acetate the dilute acid may be heated to 30° to 50°. The filtrate is poured back several times into the filter, so as to dissolve all morphine. The filter is finally washed with 5 c.c. of water, and the yellowish brown filtrate is mixed with a few drops of a solution of potassium ferrocyanide, filtered again through the same filter, and washed with about 20 to 25 c.c. of water. The total volume must not exceed 50 to 60 c.c. The solution obtained is rendered alkaline with ammonia, and let stand for 24 hours. The crystalline morphine is collected on a dried tared filter, washed with ammoniacal water, dried at 102°, and weighed.—*Journal f. Praktische Chemie.*

ON THE EXAMINATION OF POTABLE WATERS.

By W. BACHMEYER.

HAVING been engaged for some months with the examination of potable waters I found the communication of A. R. Leeds (*see* CHEMICAL NEWS, vol. xlix., p. 150), very welcome. The necessity pointed out of a check-experiment with distilled water when determining organic matter by means of potassium permanganate in an acid solution led to a series of experiments which may possibly not be without value in throwing light upon the subject. The experiments and the conclusions deduced are therefore here briefly communicated. As A. R. Leeds prefers the determination of the organic matter in water in an acid solution to one in an alkaline solution, the experiments were confined to the former.

It was first ascertained that to give a distinct rose-colour to 100 c.c. of distilled water 2 drops = 0.14 c.c. of a solution of permanganate at $\frac{1}{10}$ were required.

The distilled water was prepared from a deep-well water, perfectly free from ammonia and nitrous acid, and when tested with Nessler's reagent and with starch-paste containing potassium iodide, it was found perfectly pure.

100 c.c. of this distilled water were heated to boiling, and mixed with 10 c.c. dilute (2:8) sulphuric acid, and then with 3 drops = 0.21 c.c. permanganate solution. After boiling for five minutes the colour was discharged, and for its reproduction 2 more drops = 0.14 c.c. were required,—a proof that 0.21 c.c. of the solution of permanganate had been consumed. This was confirmed in a second trial.

This experiment admits of several interpretations:—

1. The distilled water contains a reducing agent; 2, the acid employed contains a reducing agent; 3, both act simultaneously reductive; 4, potassium permanganate is gradually destroyed by boiling in an acid solution.

The following experiments were therefore undertaken to find the real cause of the phenomenon.

I. 100 c.c. of distilled water were heated to boiling, mixed with 10 c.c. of the above sulphuric acid, and the action of the water was observed on gradually adding single drops of permanganate solution ($\frac{1}{10}$) whilst the ebullition was maintained and the time of decolouration was accurately observed. On boiling for sixty-five minutes the consumption of permanganate increased to

0.63 c.c. Hence cause 4 does not suffice for the explanation of the phenomenon.

II. 25 c.c. of the water mixed with 10 c.c. of the above acid and further treated consumed 0.21 c.c. of permanganate in one case in twenty, and in another in eighteen minutes. The reducing agent is therefore not exclusively present in the acid.

III. 100 c.c. of distilled water treated as above and mixed with 0.63 c.c. permanganate were, after boiling for an hour (whereby decolouration had occurred), filled up with 100 c.c. of distilled water, heated again to a boil, and mixed with permanganate. After boiling for five minutes the quantities consumed were respectively 0.14 c.c. and 0.2 c.c. Hence the cause of the reduction in the initial experiment lay mainly in the nature of the distilled water.

IV. 100 c.c. of distilled water, boiled for fifteen minutes with 10 c.c. sulphuric acid, and then mixed with 3 drops = 0.21 permanganate, were decolourised in three minutes. Consequently the reducing agent is not readily volatile, but its efficacy is opened up by boiling with acid.

V. 100 c.c. of distilled water with 5 c.c. sulphuric acid did not completely decolourise 0.21 c.c. permanganate on boiling for ten minutes. The same result was obtained when only 3 c.c. of acid were used, but if 15 c.c. of acid were used 0.21 c.c. of permanganate were consumed in three minutes and 0.35 in ten minutes. Hence the energy of the reduction depends to a certain extent on the quantity of acid added.

VI. 10 c.c. of the acid of known strength were boiled and mixed with 3 drops = 0.21 c.c. of the permanganate solution. After boiling for five minutes the colour had disappeared. Hence, as might be expected, permanganate is more readily decomposed in a strongly acid solution.

VII. 100 c.c. of potable water gave the following consumption of permanganate. In five minutes' boiling, respectively, 0.35 and 0.4 c.c. Again in thirty minutes boiling 0.8, 0.7, and 0.7. In five minutes' boiling the quantity consumed was 0.35 c.c.; in ten, 0.49; in twenty, 0.63; in thirty-two, 0.77; and in forty-seven minutes, 0.91 c.c. Hence the reductive power of the water is by no means exhausted in five minutes.

VIII. 100 c.c. of the above-mentioned potable water consumed on boiling for four minutes, 0.35 c.c.; nine minutes, 0.49 c.c.; fifteen, 0.63; and twenty-five minutes, 0.77 c.c. The energy of the reduction is here greater and the reductive values decrease with the time. It remains, however, undetermined how much must be ascribed to the greater quantity of acid.

In the determination of organic matter in potable water by means of permanganate in an acid solution the degree of decomposition is affected by: 1, the duration of the ebullition; and 2, the quantity and concentration of the acid employed.

In this process it is therefore advisable to fix the time of boiling at thirty minutes; to use 100 c.c. of water 10 c.c. of sulphuric acid (2:8) and, to deduct from the result obtained that quantity of permanganate which is found in an experiment with the purest distilled water in a second thirty minutes' boiling. Of course also the quantity of permanganate must be taken into account which is needed to colour the liquid. A too rapid evaporation of the water is to be prevented by the use of a flask with a long neck.

A quiet, steady boiling of the liquid, avoiding any vapour-tension is absolutely necessary. Of the permanganate solution used 1.14 c.c. corresponded to 1 c.c. solution of oxalic acid at $\frac{1}{10}$.—*Zeitschrift f. Analytische Chemie.*

Preparation of Ditolyl-phthalide.—P. de Berchem.—This compound is obtained by means of Friedel and Crafts's reaction, by heating to 100° in the water-bath a mixture of 100 parts phthalyl chloride, 450 toluene and 40 of aluminium chloride.—*Bull. Soc. Chim.*

ON THE SUBOXIDE OF MAGNESIUM.*

By G. GORE, LL.D., F.R.S.

BERTZ observed (*Poggendorff's Annalen der Physik und Chemie*, vol. c., xxvii., 1866, p. 45; also *Philosophical Magazine*, Oct., 1866, vol. xxxii., p. 269) that in the electrolysis of a solution of chloride of sodium by means of magnesium electrodes, a considerable quantity of black matter formed on the positive pole. He attempted to analyse it, but as the substance oxidised rapidly during the process of washing and drying, he had to abandon the attempt; in consequence, however, of this substance evolving hydrogen by contact with certain aqueous solutions, he came to the conclusion that it was a suboxide of the metal.

On many occasions whilst making experiments with other objects in view, I also observed a black substance form upon magnesium under the following conditions.

Magnesium in contact with platinum, both being immersed either in a solution of creosote, toluol, or xylol in vegetable naphtha. With the two metals in a solution of glacial acetic acid in absolute alcohol, the magnesium was rapidly corroded, and in one hour acquired the black coating, which increased during three days. The coating was instantly dissolved by dilute nitric acid, and the solution became green, evidently by deoxidation.

On other occasions I observed that rods of magnesium when in contact with either platinum, gold, palladium, silver, or iron, partly immersed in water and exposed to coal gas, carbonic anhydride, vapour of CCl_4 , C_2Cl_4 (but not CS_2), became in one or two days more or less coated with patches of black matter. Aluminium under the same conditions did not produce the black substance.

By further experiments it was found that the black substance was formed, though less rapidly, when magnesium not in contact with those metals was similarly circumstanced, but not in any case with the vapour of the bisulphide of carbon. That vapour produced yellow solutions, probably in consequence of the alkalinity of the magnesic hydrate.

Magnesium alone in a mixture of absolute alcohol and glacial acetic acid also produced the black substance freely in a few hours; on removing the metal, washing and re-immersing it, the black deposit again occurred. In liquefied glacial acetic acid alone or in absolute alcohol, with either toluol or formic acid dissolved in it, very little of the black matter appeared. In a mixture of glacial acetic acid and either sulphuric ether or vegetable naphtha, the deposit was less than when alcohol was employed. With absolute alcohol and acetic ether, the deposit did not take place.

Ultimately it was observed that the black substance was formed when magnesium in water, either alone or in contact with the above-named metals, was exposed to the atmosphere, but most quickly when one of those metals, especially palladium, was in contact with it. With magnesium in contact with that metal, water, and vapour of CCl_4 , much black deposit was formed during one hour.

In all these cases where the deposit took place it occurred within the first few days, and subsequently disappeared, whilst a white crust of magnesic hydrate formed. The black matter appeared also with magnesium alone in dilute solutions of the chlorides of potassium, sodium, ammonium, lithium, barium, strontium, calcium, and magnesium; also with the bromides of potassium, sodium, and ammonium; and with potassic iodide, each containing five grains of salt per ounce of water; also when connected with platinum in a solution of $\frac{1}{2}$ minim of hydrochloric acid per ounce of water. The solution of sodic chloride gave the largest amount, and showed a deposit in less than one hour. Magnesium was scarcely corroded at all in a weak solution of potassic sulphate,

and acquired no black coating. All the results indicated that the black substance came from the magnesium and not from the liquids.

The black powder became white when heated to a temperature below redness. It dissolved with effervescence in dilute hydrochloric acid, also in sulphuric acid; it was probably also soluble in alkaline sulphides (see above). Traces only of iron were found in its hydrochloric acid solution by the usual tests. That solution was not precipitated, either by ferrocyanide, ferrid-cyanide, or sulphocyanide of potassium, nor was it, after being rendered slightly alkaline by means of ammonia, and ammoniac chloride then added, precipitated by sulphide of ammonium.

By repeatedly immersing a plate of magnesium in a solution of about twenty grains of sodic chloride per ounce of water for an hour at a time until it acquired the blackish coating, and removing the coating by means of a hard brush wetted with dilute hydrochloric acid, a solution of the substance was obtained. The anhydrous salt formed by evaporation of this solution was subjected to a number of physical and chemical tests in comparison with ordinary magnesic chloride, but no difference was detected. The results, therefore, in every way confirm the conclusion that the substance was a suboxide of magnesium.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING AUGUST 31ST, 1884.

By WILLIAM CROOKES, F.R.S.

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford.

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To COLONEL SIR FRANCIS BOLTON, *Water Examiner, Metropolis Water Act, 1871.*

London, September 5th, 1884.

SIR,—We submit herewith the results of our analyses of the 168 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily from August 1st to August 31st inclusive. The purity of the water, in respect of organic matter, has been determined by the Oxygen and the Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter, and the quantities of free oxygen present in the whole of the samples submitted to analysis.

Of these 168 samples of water, the whole were, without exception, clear, bright, and well filtered.

The excellence of the water supplied to the Metropolis during the past month was indicated by its state of aëration and by its freedom both from colour and from any excess of organic matter. Further, its perfect filtration was evident by the absence of even a trace of suspended matter in any one of the numerous samples submitted to examination.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES,
WILLIAM ODLING,
C. MEYMOTT TIDY.

ALLOYS USED FOR COINAGE.*

By W. CHANDLER ROBERTS, F.R.S.

In the last lecture (*see* CHEMICAL NEWS, vol. xlix., page 188) we considered the changes through which the standard fineness of alloys used for coinage have passed in this country since the Norman conquest, and we saw that at a critical period of our numismatic history the silver coins contained only a quarter of their weight of precious metal, and therefore fully justified Latimer's attribution, "Your silver has become dross."

The questions we have now to deal with relate to no violent changes, and do not comprise the history of either national disaster or national success; but they have a certain importance of their own, as they refer to the methods by which standard fineness can be recognised and maintained.

The want of a method for ascertaining the degree of purity of gold and silver, or for determining the amount of precious metals present in their alloys, must have been felt as soon as the use of metals for currency was established. The history of assaying has yet to be written, but in rapidly reviewing the methods of assay which have been practised or proposed, it will be well to consider them in an order that is in the main chronological, but which enables the physical methods, as distinguished from the chemical, to be dealt with first.

The nation for which the honour of striking the first coins is claimed, gave its name to the "Lydian stone," or, as it is called in more recent times, the "touchstone." It is a dark basaltic rock, of fine texture, upon which a fragment of precious metal readily leaves a streak when drawn over its surface. The comparison of the streak left by the gold to be tested with similar traces derived from alloys of known standard and composition, afforded a ready means of ascertaining, approximately, the fineness of the metal under examination; while further insight into the character of the alloy was gained by submitting the streaks to the solvent action of an acid. There is an abundant literature† showing the degree of accuracy that may be attained by means of this stone; its use has survived for approximate assays until the present day.

Then, again, there was the method of ascertaining the purity of metals by their density, as compared with that of water, devised by Archimedes, B.C. 212, which is applicable to both gold and silver, and is still often resorted to when the metal to be examined must be preserved intact. The usefulness of density, as affording a trustworthy indication of standard fineness, has often been pointed out, notably by W. Symonds,‡ in 1756, and more recently by Dr. O. Broch.||

The possibility of ascertaining the standard fineness of alloys by the aid of electricity long ago occupied the attention of physicists. In 1823, Becquerel§ suggested that trustworthy indications might be afforded by the electromotive force developed when the alloy to be tested is placed in an exciting fluid together with an alloy of known composition. The subject was partially investigated by Oersted,¶ in 1828, and its practical importance was further pointed out by Gay-Lussac,** in 1830. In 1878, the use of magnetic induction for indicating the composition of alloys was suggested by Professor Hughes,†† who showed incidentally that the induction balance affords a ready means for detecting counterfeits, and I have elsewhere pointed out the degree of accuracy of which this instrument is susceptible.‡‡ The method which involves

the use of the spectroscope also deserves mention here, although it is, as yet, more delicate than trustworthy.*

These physical methods, both ancient and modern, are open to the objection that the uncertainty of the results they afford increases with the complexity of the alloys under examination; and further, the indications are complicated by changes in the physical state of the metals, produced either by hammering or annealing.

Pliny states that in his time a method was in use for estimating the amount of silver in an alloy of silver and copper, by the degree of discolouration or blackening which attends the heating of the alloy in air. This method, long practised in France, and known by the name of *essais d la raclure* (scrapings), or *d l'échoppe*, is described by Rochon,† who says that it was generally recognised in the Roman mints in the time of Marius Gratidianus, triumvir of the money, and later by Chaudet,‡ who gives a table showing that silver of the English standard (925), when heated to low redness in a muffle, becomes uniformly grey-white, while intermediate tints are produced by heating lower alloys, until the standard used for the French subsidiary coinage (835), is reached. As this becomes quite black under the treatment, the process ceases to be useful for alloys of lower standard.

In very early times the need must have been felt of some chemical method of isolating the precious metals—of separating them, that is, from their base associates, so that the gold or silver, when purified, could be weighed, and the amount originally present in the mass deduced by calculation.

The crude method of assay, already described, which depends on the change of colour produced by oxidation of the baser constituent of an alloy, leads up to the method used from very early times, which also depends on the principle that precious metals will resist oxidation, while the metals with which they are usually associated will not.

Its main outlines may be indicated as follows. When lead is melted with free access of air, a readily fusible substance forms upon its surface. This substance may be allowed to flow away, or, if the metal is contained in a suitable porous receptacle, called a cupel, the fusible oxide sinks into this containing vessel; in either case the oxidation of the lead affords a means of separating it from precious or inoxidisable metals, if any be originally present in the lead. I found lead in the ancient ornaments both of gold and silver, which Dr. Schliemann permitted me to analyse, and Pliny teaches that the Roman metallurgist used lead for the purification of gold and silver, for he says, "excoqui non potest, nisi cum plumbo nigro aut cum vena plumbi." The greatest of the early alchemists, Geber, who died in A.D. 777, knew perfectly that the lead "acquired a new weight" when heated in air, and I have elsewhere|| tried to show how important the recognition of this fact was to the whole fabric of modern chemistry; it is not a little interesting that, among the very first experiments recorded by our own Royal Society, is a metallurgical series relating to the weight of lead increased in the fire on the "copels" at the assay office in the Tower, the account being brought in by Lord Brouncker, in February, 1661.§

The interest of the art of assaying, from a purely scientific point of view, was generally admitted in the 17th century. Lazarus Erckern, for instance, described it as "the very inlet and mother of many other honourable and profitable sciences," while William Badrock,¶ apparently regarding the art as an element of general culture, pleads its claims to be studied by "all gentlemen."

Having shown the great amount of interest attached to the subject, I will now return to the actual practice of the art as a metallurgical operation.

Geber, the Arabian, gives, if medieval translations of his works are to be trusted,* a sufficiently accurate description of the process to enable it to be conducted at the present day with no other aid than his; but it must be remembered that it was the object of the alchemist to distinguish silver from gold, and to isolate the metals, rather than to determine the amount of one metal present in admixture with another. Geber calls the process of cupellation the trial of the *cineritium*, and he points out, in the course of a description that deserves to be reproduced here, that "there are two bodies perfect, abiding the trial, to wit, *sol* (gold), and *luna* (silver). Take," he says, "sifted ashes or calx, or powder of bones of animals calcined . . . moistened with water, and make the mixture firm and solid with your hands, and, in the midst of it, worked into a round flattish lump, make a round and smooth hollowness, and upon the bottom of it strew a small quantity of glass beaten to powder, which lay to dry. When dry, put your metal into the hollowness thereof, which you would try to prove, put coals of fire upon it, then blow with bellows upon the surface till the metal flows; upon which, being in flux, cast part after part of lead, and blow with a flame of strong ignition." This is to be continued "until the lead is vanished," and precious metal is left "still or quiet, and you see it clean and clear in its superficies,"—that is, the lead has dissolved the oxides of the base metals, and has carried them into the cupel, leaving the gold or silver, or an alloy of both, in the form of a button on the cupel.

This operation, as described by Geber, would more nearly correspond to a refining operation conducted on a large scale, with a view to the extraction of silver from lead, rather than to the method of assay as practised at the present day on a few grains of metal.

The method of conducting assays, on what would at the present day be considered to be a very large sample of metal, seems to have been held to be necessary in the 12th century, for in the official trials of the coin in the time of King Henry II., 1154-89, the "*Miles Argentarius*" and the "*Fusor*"† are instructed to take before the Barons of the Exchequer a pound of "twenty solidi" of the coin, which they are to place on a "*vasculum ignitorium cinerum quod in fornace est*." The metal resulting from the trial is then weighed, and the amount it has lost is noted, and, if it is considered that the result of the trial is inaccurate, or "too much metal has been lost, say by the boiling, or by being carried off in the lead" [*illud quasi plus justo consumptum fuerit ignis scilicet exustatione vel plumbi infusione*], then it is to be repeated.

The amount of metal which has, for at least two centuries, been taken for assay is 12 grains troy, and this weight, which is known as the "assayer's pound," has the same number of divisions as the troy pound; the fineness of any given weight of metal is, therefore, indicated by the results of an assay, without tedious calculation. It has been shown that the process was officially recognised in this country in the reign of Henry II., and in France the first official mention of it occurs about the year 1314. It is the only method of assaying silver practised at the present day at the English Mint, although another method is used for verifying the composition of its alloys.

With regard to the apparatus required:—In Geber's work "of furnaces" there is no mention or illustration of the "muffle" furnace, so that he seems to have conducted the process in a cupel surrounded by incandescent fuel.

Biringuccio (1540) gives illustrations and detailed

descriptions of appliances which hardly differ from those now in use, and so does his contemporary Agricola.* Budeliust† (1591) gives a drawing of a furnace which somewhat resembles the type still used in continental mints, except that the muffle, or oven, is placed close to the base of the furnace; and the "Sculptures" of Sir John Pettus, reproduced from the works of Lazarus Erckern,‡ show various forms of muffles and furnaces, some used by the ancient assayers, others adopted in the middle of the 17th century at Nuremberg, where the goldsmiths flourished so vigorously. He also gives an improved form of furnace, "made of armour plates," closely corresponding in its general arrangement with a furnace now lent by the Mint to the science collection at South Kensington, which is specially interesting, as tradition points to it as being the furnace used by Sir Isaac Newton in his experiments on cupellation when Master of the Mint. Several transitional forms of furnace between the old one just mentioned and those now used by the Mint are still preserved in the Assay Office. The tongs and other tools incidentally used do not require special notice, as the changes that have from time to time been made in them have only rendered their forms more delicate and handy, and have hardly altered their general type.

With regard to the balances employed, it may be sufficient to point out that, for centuries, they have been constructed with great delicacy, and that they now turn with 2-1000ths of a grain, when loaded with 10 grains. In fact, the use of the balance in very early times, for the purpose of assay, absolutely demolishes the claim of quantitative chemistry to be considered of comparatively modern origin. The indications afforded by the balance as to the result of an assay are not absolute, as the process is liable to error from several sources, and needs to be controlled in the manner which will be described subsequently.

The point to bear in mind at this moment is, that if the silver has been associated only with readily oxidisable metals, especially copper, as is usually the case when silver coins are assayed, then it only becomes a question of providing the amount of lead necessary to furnish, by oxidation, sufficient litharge to dissolve the oxides and carry them away. If, however, the silver is associated with gold, the latter metal resists oxidation, and will remain on the cupel with the silver, for—again to quote Geber—it will in "no wise forsake it." The cupellation stage must then be supplemented by a "parting" operation,—that is, the silver must be dissolved away by some solvent which will leave the gold untouched, and for this purpose nitric acid is universally employed. If the silver contains but a minute quantity of gold, the presence of the latter will be indicated by a few specks of brown powder left at the bottom of the vessel in which the silver is dissolved; if, however, the silver contains about one-third of its mass of gold, and has been extended into a strip, the gold will remain after the action of the acid as a coherent band, retaining the original form of the strip, but much reduced in volume. This action of nitric acid on an alloy of gold and silver was certainly known to Geber and the early alchemists; but the first official mention of the use of the parting assay appears to be in a decree of Philippe de Valois,§ in the year 1343, confirming its use in the French Mint. The assay methods for silver and gold are analogous, in so far that both are purified by the action of a solvent; but the base metals are removed from silver by fused litharge, while in its turn silver is parted from gold by nitric acid. There is, then, this difference between the assay of gold and silver. In the case of the cupellation assay of silver the button of metal has only to be removed from the cupel, and when the adhering

* There is a good English edition of the 17th century, "The Works of Geber," translated by R. Russell. 1686.

bone-ash has been removed by a brush it passes direct to the balance. The process would also be sufficient for gold if it contained no other precious metal; when, however, the problem is to ascertain by assay how much gold is contained in an alloy, which may contain silver, or platinum and other metals of similar properties, then care must be taken that the amount of gold believed to be present in the alloy does not exceed the one-third part of the mass, as a larger proportion of gold would protect the alloy from the solvent action of the acid, and the greater the amount of gold the less perfect would be the attack of the acid.

In any case the first stage of assaying a gold alloy, say a sovereign, is to melt it with such an amount of silver as shall yield a button containing rather less than one-third of its weight of gold.

For the sake of convenience, and for the incidental advantage that the solvent action of fused litharge removes copper and other impurities, the first stage of the assay of gold is conducted on a cupel, the object to be attained being mainly to secure a button of gold and silver in a convenient form for submitting to the subsequent operations. The alloying stage would, however, be just as effective if it were conducted in a small non-porous receptacle, such as a small crucible of glazed porcelain.

The subsequent operations are, flattening the button, annealing it, rolling it into a strip, and annealing it a second time. It is then coiled into a spiral, or cornet, and treated by two successive portions of nitric acid, in order to remove the silver; after this the spiral of spongy gold, which retains the original form given to the silver-gold alloy, is heated to redness, when it becomes bright, and is sometimes so coherent that it may be unrolled without fracture.

This is an outline of the processes of assaying: the precautions which are adopted with a view to secure accuracy remain to be considered. Inaccuracy in silver assaying mainly arises from loss of silver, which may disappear in small but variable quantities, either by volatilisation or by sinking into the cupel with the litharge. The amount of metal lost varies with the temperature, which is never uniform throughout the muffle; and the results of assays, as indicated by the balance, have therefore to be controlled by assays on pieces of metal of known standard, distributed in such a way as to represent the varying degrees of temperature throughout the muffle. The metal lost by any given check-piece is added to the assays in close proximity to it, and, as the amount of metal lost very often amounts to $1\frac{1}{2}$ per cent, the apportioning of the additions to be made demands great skill on the part of the assayer, who has also to decide from the appearance of the buttons whether they have retained lead or not, in which case they would, of course, be unduly heavy. In gold assaying, on the other hand, although, as Geber knew, gold resists the action of molten litharge better than silver does, some precious metal may be lost either by volatilisation or by retention in the cupel; but the chief sources of error are (1st), solution of gold in the acid used, which would reduce the weight of the cornets, and (2nd), retention of silver by the cornets; but these inverse causes of error may be combined without neutralising each other. Some means of checking the results must therefore be provided, and it would appear that for centuries implicit confidence has not been placed in the indications afforded solely by the assays, as comparisons have invariably been instituted between the pieces of metal taken for assays and standard trial plates, or pieces of known composition, assayed side by side with the coins, so that any error affecting the coin assays also affects the check-pieces, and therefore the error can be allowed for.

The trial plates by which silver and gold coin have been tested possess, it seems to me, an amount of interest that can hardly be over-rated. The oldest of them to which a date can be assigned is a silver plate, imperfectly impressed with the dies of a coin of the time of Henry III.

(1216-1272). A silver plate is alluded to as follows, in the *Rotulus de Moneta*, of the 7th and 8th years of King Edward I.:—"Premerement qe hom doit fere un estandart, qe doit demorer al Eschequer, ou en quel lieu qe nostre seignor le Roy vodra"; and in 1326 there is a record of the provision of two silver-plates for testing the silver coined by King Edward II. for his Duchy of Aquitaine, "one plate to be of the just weight before the fire, and the other such as it (the metal tested) ought to be after the assays." * This is interesting, because it seems to point to the fact that the amount of silver which should be "lost in the fire" had been experimentally determined at that early period. Many of the old trial plates were formerly kept in the Pyx Chapel Abbey, Westminster Abbey, almost the only relic which remains of the church built by Edward the Confessor; and on the altar tomb believed to be that of Hugolin, the first Chancellor of the Exchequer, there is a circular dish-shaped cavity on which a small furnace may have rested, if,† as is probable, the trial of the Pyx was at one time conducted in this building. The trial plates were removed in 1842 from the Pyx Chapel to the office of the Queen's Assay Master in the Mint; and I am fortunate in being able to offer to the Society photographs of some of the more interesting of these. The trial plates were always divided into several portions, and, like the old Exchequer "tallies," this division was effected in rough serrations, so that portions of the original plate entrusted to the different officers could be readily identified. Of those which are photographed the more interesting are probably No. 1, made in the 17th year of King Edward IV. (1477), and No. 2, which marks the introduction of the standard now in use, 916.6, by King Henry VIII. All the plates, however, possess peculiar interest, for in relation to the assays of the "alloys used for coinage" they are the signs of centuries of responsibilities, which I am fully sensible it is a privilege to be permitted to sustain.

An examination of a series of assays made of the trial plates shows that, although the standards of fineness were always prescribed by law, the plates have, nevertheless, at times been very inaccurate.

The imperfections of the gold plates are mainly due to sources of error which had been recognised, but which were ignored when the last plates were made; and it is well to explain, therefore, that plates were in former times authoritatively pronounced to be "standard" simply with reference to the results of an inaccurate process of assay. The process now consists in submitting an accurately weighed portion of the alloy to a rapid method of chemical analysis, whereby impurities are eliminated, and the precious metal thus purified is again weighed, but the method is complicated, and the accuracy of the result may be affected by the retention of impurities, or by an actual loss of metal during the process. The weight of gold as indicated by the balance will, in consequence, not represent the amount originally present in the alloy, and it is therefore necessary to control the results by assaying, side by side with the alloys under examination, "standards" or check-pieces the composition of which is known. As, however, any error in the composition of these checks will be reflected in the result of the assay, it is preferable to use pieces of pure metal corresponding in weight to the amount which the alloys to be tested are anticipated to contain.‡ Formerly such checks of pure metal were not

* "Ruding" vol. i., p. 209.

† Notes and Queries, Nos. 17, 19, 20, and 23. 1880.

‡ The corrections to be applied to a gold assay will be readily understood from the following formula:—

Let 1000 be the weight of alloy originally taken;
p. The weight of the piece of gold finally obtained;
x. The actual amount of gold in the alloy expressed in thousandths;
a. The weight of gold (supposed to be absolutely pure) taken as a check, which approximately equals x;
b. Loss or gain in weight experienced by (a) during the process of assay;
k. Variation of "check gold" from absolute purity, expressed in thousandths;

employed, and a small amount of silver varying from 2-10,000ths to 1-1000th part of the initial weight of the assay piece which remained in association with the gold was consequently reckoned as gold in the assay report. It follows, therefore, that even the more recent plates, when accurately assayed, are usually found to be sensibly below the exact standards which they were intended to represent.

The experiments made with a view to ascertain the composition of the standard gold plate prepared by me, in 1873, show that the greatest variation of this plate from the exact standard does not exceed the 2-10,000th part; but the use of even a fairly accurate standard plate is liable to be attended with error, as the actual amount of precious metal in the amount taken for the check-piece may exceed or fall short of the true standard. It follows, therefore, that the assay reports on portions of metal tested by comparison with this check may indicate the presence of too little or too much precious metal.

The objections to the use of a standard silver plate are far greater, as the alloys used for the silver coinage, in this and in other countries, are mechanical mixtures, the molecular arrangements of which are very peculiar, and, so far as my experience goes, a plate of the legal standard cannot be prepared of uniform composition.

With regard to the use of pure gold and silver plates, it should be pointed out that, if it were possible to obtain gold and silver of absolute purity, there would be no limits to accuracy in assaying, except such as arise from operations of a purely mechanical nature. Of course it is not possible to attain to chemical purity, and the presence of traces of impurity in the checks causes the results of assays made in comparison with them to indicate the presence of an amount of pure metal in excess of that actually present in the alloy; but as the converse can never be the case—that is to say, as the gold cannot be more than pure—no danger can arise from this cause, and the error can be easily allowed for.

The supplementary fine gold and silver plates, prepared in accordance with instructions I received from the Lords Commissioners of the Treasury in 1872, proved eminently satisfactory. I have not been able to prepare, or to obtain from any source, gold of greater purity, even in small quantities. The silver plate leaves little to be desired, although it is not quite as pure as silver prepared by M. Stas, in comparison with which it is as 999.95 to 1000.

In conducting official trials of the pyx, minute accuracy is secured by a final appeal from the standard plates themselves to pure gold or pure silver.

We are now in a position to consider another question, the importance of which has long been recognised by law, and that is, the difficulty of attaining an exact standard, either of weight or fineness, in the case of all the individual coins issued from a mint. The law has, for centuries, and in all nations, permitted a certain deviation from the exact standard. The amount of such "remedy," as it has always been termed in this country, has changed from time to time, but has gradually diminished as the art of coining has advanced.

It follows, that although the component parts of the alloy may not bear to each other with mathematical precision the proportion prescribed by the regulations under which they are manufactured, they may, nevertheless, be

considered to be of standard fineness. The earliest reference to a "remedy" I have met with is in the reign of Saint Louis, of France, 1253,* who granted an allowance of $\frac{1}{4}$ carat, for the fineness of Louis d'or. The mint agreement between King Edward I., and William de Turnemire,† in 1279, provides a remedy of 2½ dwts. on the pound troy of the silver coins. The law does not appear to have contemplated that the "remedy" should be systematically made use of as a source of profit, either to the Crown or to the Master of the Mint; it was rather considered to define the limits within which occasional variations of standard weight were unavoidable, and its true function has been well defined by the late M. de Jacobi, who, representing the Russian Government at the International Monetary Conference, held in Paris, in 1867, said, "the remedy is not an arbitrary stipulation, but is the limit of errors which belongs to every thought, to every chemical analysis, to every composition of alloy, and as such depends on the precision of the balances, and the methods employed in the fabrication of money. It may be determined rigorously by applying the calculus of probabilities."

The Mint indentures have been drawn up in just the same spirit. Remedies were accorded "because the said moneys may not continually be made in all things according to the right standard, but, peradventure, through default of the master or workers, they shall be found sometime too strong or too feeble in weight or alloy," but this has not prevented a very different view having been taken of the privileges accorded by them, both to the Sovereign on the one hand and the Master of the Mint on the other. Queen Mary, for instance,‡ seems to have considered that the Sovereign was entitled to add as much base metal to the coinage as the law permitted, the sum so derived after deducting coinage expenses, to be considered seignorage, but she held that the Crown could not debase the coin, or increase the amount of base metal in it for private ends.

With regard to the action of Mint Masters in this respect, the history of the coinage abundantly proves that they frequently availed themselves of the "remedies," viewing them as a legitimate source of profit, or as a means, incidentally provided by their contracts, for reducing the current expenses of working; the best known case being probably that of Lonison, Master of the Mint in the reign of Queen Elizabeth.

The scale of remedies is fixed by the Coinage Act of 1870. At present we will only consider the remedy of fineness, which, in the case of the gold coin, has a range of $\pm 1\frac{1}{1000}$ th, and in the case of silver $\pm 1\frac{1}{1000}$ th. The gold coins of the nations who have joined the Latin Union have also a remedy of $\pm 1\frac{1}{1000}$ th. In America the remedy in the case of the gold coins has been reduced to $\pm 1\frac{1}{1000}$ th. "I do find," said Rice Vaughan,|| writing in 1675, "that some men of great experience and understanding, even in this mechanical part, do hold that the moneys, both of gold and silver, may be made without any remedy to be allowed either for weight or fineness," but he subsequently adds, "I undertook this discourse of the mechanical part of money with scruple, so I do leave it with alacrity." It is certainly not the opinion of Mint officers of the present day that the remedies should be reduced to the lowest possible point, as this would involve the rejection and re-coinage of a large number of pieces before they could be permitted to leave the Mint; but, on the other hand, all agree that a persistent variation, however slight, above or below standard, has never been contemplated by law. The effect of such a mean variation would be remarkable.

If, for instance, the Mint were to issue sovereigns which were either persistently too rich or too poor in gold, to the extent actually permitted by law, a loss or profit

Then the actual amount of fine gold in the check-piece—

$$= a \left(1 - \frac{h}{1000} \right),$$

and the corrected weight will be—

$$x = p - \frac{a h}{1000} \pm b,$$

b) being added or subtracted according as it is a loss or gain.

If (a) be assumed to be equal to (x) this equation becomes—

$$= \frac{p \pm b}{1 + \frac{h}{1000}}.$$

* Jean Boizard, "Traité des Monnoyes," p. 25, 1692.

would accrue of over £2000 on each million coined, and a persistent variation of only $\frac{1}{10000}$ th part would be equivalent to a profit or loss of £1000 million. In Mint practice at the present day, even this comparatively small variation should be avoided, and the public trials of the pyx prove that it does not exist.

I have dwelt on these facts because the maintenance of rigid accuracy in the operations of coinage becomes of great importance in international currency. One Government might, as the late Professor Stanley Jevons pointed out, "coin money slightly inferior to the proper standard, and such money once introduced would, in virtue of Gresham's law, be difficult to dislodge." I admit, with him, that it is hardly to be supposed that a State issuing money under international obligations would wish to make a profit of one or two parts in a thousand, which the remedy would legally cover; but, nevertheless, the degree of accuracy with which the coinage is executed would be of much importance, for the following reason. A nation would be bound by the International Convention to withdraw and re-coin such coins of other nations as might be circulating within its borders at the time they were reduced by wear below the lowest weight at which their circulation would be legal, and it follows that any deficiency of standard which might exist would have to be made good by the nation on whom the re-coinage happened to fall, and a nation coining with rigid accuracy would suffer from the shortcomings of those who did not.

(To be continued.)

Chemical and Physical Analysis of Milk, Condensed Milk, and Infants' Milk-Foods: with special regard to Hygiene and Sanitary Milk Inspection. A Laboratory Guide developed from Practical Experience, intended for Chemists, Physicians, Sanitarians, Students, &c. By Dr. N. GERBER. Translated from the revised German edition and edited by Dr. HERMANN ENDEMANN. New York and London: Trübner and Co.

WE have here a very complete manual of the analysis of milk. The author discusses in succession normal cows' milk, the physiological and other causes influencing this secretion, its general physical properties and chemical composition, and the composition of other milks, besides that of the cow. He then proceeds to the physical analysis with especial reference to its colour, consistency, odour, and taste. We come next to the microscopical examination, upon which the author does not lay much weight, though he agrees with Vieth in holding that microscopical examination may under circumstances furnish valuable indications if used for the detection of abnormal qualities in appearance, or behaviour, or the determination of foreign substances added to the milk. After directions for taking the specific gravity of samples he proceeds to the chemical analysis of milk. He determines water and solids, ash, phosphoric acid, albuminates and fat, and milk sugar.

The determination of total solids is effected by weighing 10 c.c. of milk in a dry covered platinum capsule, previously counterpoised. To the sample he adds absolute alcohol sufficient for coagulation, and then dries, first in the water-bath and then in an air-bath, at from 100° to 110°, until the weight of the residue is constant. He remarks that good milk should have 12.5 per cent of total solids. It will be remembered that Mr. Wanklyn—to whose published methods we find here not the slightest reference—gives 14.07 per cent as the mean of four determinations in which the utmost range of difference was only 0.04 per cent. Dr. Gerber does not, as far as we are able to perceive, refer to "solids minus fat" as a constant element in milk. He mentions, however, that milk must

be considered inferior or adulterated when it contains less than 3 per cent of fat. This would show for solids minus fat 9.5 per cent, a figure which agrees very closely with Mr. Wanklyn's mean value, country milk—9.65 per cent.

The determination of the ash is effected by ignition in a muffle, and the phosphoric acid volumetrically by the uranium process.

Albuminates Dr. Gerber determines by Ritthausen's process slightly modified, i.e., the precipitation of the albuminates and fats by a solution of copper sulphate and the subsequent extraction of the fat. For the determination of fat the author objects to treatment in an open vessel. Reference is made to the detection of mineral poisons, copper, lead, and zinc, which may be dissolved by sour milk from metal vessels.

On the subject of adulteration the author agrees substantially with English authorities. He considers that dealers mostly confine their operations to watering and skimming. He admits that the lactometer or lactodensimeter plays into the hands of sophisticators. Chevalier's creamometer is also justly condemned. The author insists that the indications of this instrument are very uncertain, and should never be brought forward before a court of justice, the cream even under identical conditions not rising equally, as the addition of water to milk makes the milk appear richer, and since the greater consistency of pure milk prevents the easy formation of the cream. The temperature also exerts an influence not only on the time required for complete separation, but also on the volume of the layer of cream.

Incidentally we meet with the following surprising passage; the author, speaking of the determination of specific gravity, says:—"All other instruments with scales differing from this (i.e., from direct specific gravity) have been abolished on the European continent. It is only in England and through English influence in America that instruments with arbitrary scales are as yet in use!" As a commentary upon this outburst of Anglophobia we merely remark that Dr. Gerber, like numbers of other French and German writers, makes use of Beaumé's hydrometer (pp. 91 and 100), the essence of arbitrariness, and not convertible into direct specific gravity by a simple calculation like Twaddle's scale. The strengths of alcohol and ether, again, are given in this treatise, not direct in specific gravity but in degrees of the scale of Tralles.

Condensed milks and milk-foods are discussed at some length. Concerning the former the author remarks: "Provided that only good cow's milk be used, and that with an unvarying addition of sugar it is condensed to a proper and equal degree, no good reasons exists why condensed milk produced in any other country should not be equal to that produced in Switzerland."

He considers it important that a rationally compounded infants' milk food should contain at least 2 per cent salts, 5 of fat, and 13 per cent of albuminates, whilst one of the most highly recommended brands contains not quite 10 per cent of albuminates. Indigestion in children, he maintains, will increase when a food is lacking in albumen, but contains in its place soluble carbohydrates.

In discussing official regulations as to the sale of milk, the author states that the average figures obtained by the examination of the mixed milk of cows supplying any dairy has been found to be the same in all countries: he admits fluctuations and abnormalities in the milk of single cows. His standard (12.5 per cent total solids and 3 per cent fat), we have already noticed. We find here quoted an opinion by Prof. Fezer, of Munich, which merits the serious consideration of sanitary authorities. He declares that "it is equally desirable to prevent the sale of milk which is below a certain standard as good milk, even if it be simply the unadulterated product of single animals reduced through insufficient and faulty feeding. . . . Ordinances passed for the prevention of adulteration would be powerless if it be lawful that milk may be adulterated before its production in the body of the animal, by injudicious treatment and feeding."

It is to be regretted that so useful a book should have been written in such bad English. On nearly every page we find expressions which are not idiomatic and words used incorrecly.

Proceedings of the American Pharmaceutical Association, at the Thirty-first Annual Meeting: held at Washington, Sept., 1883. Philadelphia: published by the American Pharmaceutical Association.

The first thing we notice in the present volume is a list of queries, some of them of great importance, proposed last year, and to which replies are expected at the present year's meeting. Among them we find required a paper on the tests for brucine in presence of strychnine and of strychnine in presence of brucine, together with a plan for the perfect separation of the alkaloids.

There is a short but significant paper on "Who is responsible for Adulteration?" Here, of course, we find a conflict of opinion. The merchant or the broker says "we have to supply adulterated drugs because the trade demand them . . . we furnish an article as pure as can be had for the price." On the other hand, the retailer intimates that whatever the price paid the drug always comes out of the same barrel.

A case is mentioned where so-called cream of tartar consisted of 95 per cent gypsum and 5 per cent tartaric acid.

There is a memoir on the "stathmetometric" method of analysis, in which a standard solution is made up to a given weight instead of to a given volume. It is recommended as preferable to volumetry in climates like that of New England, where extremes of temperature prevail and changes of 50 degrees (of course Fahrenheit) frequently occur in a few hours. Here stathmetrometry (a clumsy word) has the advantage, as the correction for temperature is obviated. The apparatus used is, of course, a "Schuster's alkalimeter."

CORRESPONDENCE.

AN EXAMINATION QUESTION.

To the Editor of the Chemical News.

SIR,—If a "Benighted Student" would remember that Chemistry is nothing if not an *experimental* science, and would, with balance, test-tube, metal, and acid, ascertain for himself what is the fact, he would be able, without much expenditure of time or trouble, to "set his mind at rest" and the "doctors who disagree" at defiance.—I am, &c.,

J. H. P.

AN EXAMINATION QUESTION.

To the Editor of the Chemical News.

SIR,—Your correspondent, "A Benighted Student," whose letter appears in the *CHEMICAL NEWS*, vol. xl., p. 152, really appears to be less benighted than some of the authors whom he cites respecting the solubility of antimony in hydrochloric acid. In order to satisfy myself that the properties of that metal have not changed—like its atomic weight—since I was a student, I have made the following experiments:—

(1.) Antimony was very finely powdered, until it had lost its metallic appearance, and boiled with ordinary concentrated HCl in a test-tube for a minute or two: a little SbH₃ was detected by AgNO₃ at the mouth of the tube, but no H₂S. No diminution in the quantity of the metal was perceived, and the solution gave only a slight orange precipitate with H₂S water.

(2.) Antimony precipitated by zinc was treated in the same way, with a similar result.

(3.) 15·6 grains of the very finely powdered antimony were boiled for fifteen minutes in a covered beaker with a measured ounce of concentrated HCl (sp. gr. 1·16). The undissolved metal, washed and dried, weighed 14·9 grains, so that 0·7 grain, or about 4·5 per cent, of the metal had been dissolved.

This confirms the statement which the benighted one quotes from "Fresenius's Quantitative Analysis" (1876), that hydrochloric acid has very little action on it even when concentrated and boiling.

In his Preface to "Fresenius's Quantitative Analysis" the Translator states that the author has a most firm conviction that for inorganic chemistry the old notation is the simplest and the best. Is it possible that chemists in this country are more anxious to produce elegant and expensive books containing the last new "fad" in notation than to verify experimentally the statements which they put forth?—I am, &c.,

A PRACTICAL CHEMIST.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 9, September 1, 1884.

Researches on the General Course of Vegetation in an Annual Plant. Hydrocarbons.—MM. Berthelot and André.—This memoir does not admit of useful abstraction.

Comparison between the Electro-chemical and the Thermic Coloured Rings.—O. Decharme.—If we expose a plate of copper to the flame of a spirit-lamp, of a Bunsen burner, or better to the fixed and narrow jet of an enameller's lamp, there are produced upon the metal iridescent coronæ around the heated point. If the experiment is well managed there are obtained fixed coloured rings, apparently inalterable in the air. These thermic rings are quite similar to the electro-chemical rings of Nobili; like them they follow one upon another and are propagated in waves. In both cases the colours succeed each other in the same order, which is that of Newton's rings as seen by transmission. Multiple thermic rings may be produced by means of drums surmounted by 2, 3, 4, &c., gas-burners. These same pieces serve equally for the production of the electro-chemical rings by fixing in the fine openings of the tubes needles of steel of equal length for each system. The thermic rings, simple or multiple, approximate the more closely to the corresponding electro-chemical rings as the jets of flame are feebler and less oxidising.

Determination of the Wave-lengths of the Principal Rays and Bands of the Ultra-red Solar Spectrum.—Henri Becquerel.—The author gives a table of wave-lengths, expressed in millionths of a millimetre and states that the phosphorographic method, when the phosphorescent substances are suitably chosen, enables us to explore the ultra-red spectrum as far as the thermoscopic methods and further than the chemical reactions.

No. 10, September 8, 1884.

Researches on the General Progress of Vegetation in an Annual Plant. Nitrogenous Principles and Mineral Matter.—MM. Berthelot and André.—The albumenoid principles are stationary at the moment of germination, and increase afterwards rapidly so as to attain a thousand times their original weight. Their pro-

portion to the total weight of the plant does not vary much (14 to 21 per cent) up to the epoch of flowering. It then declines, and at the moment of fructification and at the death of the plant is reduced to about 5 per cent. This depends partly on the destruction of the nitrogenous compounds and partly on the preponderant formation of lignine. In the plant deprived of its efflorescence the same cause determines a still wider deviation, the albumenoids being reduced to 3 per cent. The relative proportion of the albumenoids varies, therefore, inversely as that of the lignine. The albumenoids are found at first concentrated in the leaves—the seat of the chlorophyllaceous parts and of the work of reduction which fixes carbon and the elements of water. Later, they are transferred into the flowers and the fruit, whilst in the leaves, where the life is decreasing, the relative proportion of nitrogenised matter falls to a fourth of what it has lately been. The same diminution takes place in the stem and in the roots, by reason of the increase of the hydrocarbons. The salts of potassium increase in absolute weight until fructification, this increase being chiefly seated in the stem. Their relative proportion reaches its maximum in the stem and the roots at the moment of inflorescence. Subsequently, they are distributed more equally. The insoluble mineral matters accumulate in the leaves and in the flowers.

No. 11, September 15, 1884.

This number contains no chemical matter.

Journal für Praktische Chemie.
New Series, Vol. xxx., Part 1 and 2.
(Nos. 12 and 13 for 1884).

A Contribution to the Chemistry of the Chrome Ammoniacal Compounds.—S. M. Jørgensen.—In this paper the author examines at considerable length the luteo-chrome salts, describing the luteo-chrome nitrate, luteo-chrome-nitrate-platinum-chloride, luteo-chrome-platinum-chloride, the corresponding mercuric compound; luteo-chrome-bromide, luteo-chrome-platinum-bromide, the corresponding iodide and iodo-sulphate, luteo-chrome sulphate, luteo-chrome-sulphate-platinum-chloride, luteo-chrome orthophosphate, oxalate, luteo-chrome sodium pyrophosphate, luteo-chrome ferricyanide, luteo-chrome cobalticyanide, and luteo-chrome-chromicyanide.

Communications from the Agricultural-Chemical Laboratory of the University of Königsberg.—These communications consist of a paper on betaine obtained from cotton-seed cake, by H. Ritthausen and F. Weger.

On Mercury Fulminate.—Alex. Ehrenberg.—Aqueous hydrochloric acid decomposes mercury fulminate, forming hydroxylamine hydrochlorate, and formic acid, both atoms of nitrogen being transmitted into the hydroxylamine. This reaction argues against the conception of fulminic acid as nitro-aceto-nitrile. Aqueous hydrosulphocyanic acid decomposes mercury fulminate, with formation of ammonium sulphocyanide and carbonic acid. Free fulminic acid does not seem capable of existing, since the product dissolved in ether undergoes spontaneous decomposition even in a vacuum after the evaporation of the solvent. Ammonium sulphocyanide acts upon mercury fulminate in the same manner as the alkaline chlorides, forming a fulminurate.

Distribution of the Blood-Pigment between Carbon Monoxide and Oxygen: a Contribution to the Theory of Chemical Mass-Action.—G. Hüfner.—This memoir is not suitable for abstraction.

On Isatine.—H. Kolbe.—In this preliminary communication the author mentions an isatoic acid which he obtains by treating isatine with chromic acid in presence of glacial acetic acid or acetic anhydride. Its composition is $C_8H_5NO_3$. It is sparingly soluble in cold water and alcohol, more readily in the same liquids when hot. From

hot water it crystallises in long needles, and from boiling alcohol in yellow rhombic tables. It is a feeble acid, and forms salts with the alkalies. Isatoic acid may also be obtained from pure indigo-blue by treatment with chromic acid and glacial acetic acid.

On Certain Derivatives of Mercury Fulminate.—L. Scholvin.—A preliminary communication in which the author studies the action of sulphuric acid upon sodium fulminate, silver fulminate (whereby he shows that the compound obtained by precipitating sodium fulminate with silver nitrate is in all respects identical with that obtained from metallic silver), and the action of sulphurea upon mercury fulminate. The products of this reaction are carbonic acid, mercury sulphide, urea, and sulphurea-mercury sulpho-cyanide.

Electric Conductivity of the Acids.—W. Ostwald.—The author suggests that in reactions which take place under the influence of acids the rapidities of such reactions are proportional to the electric conductivity of the acids. He states that Svante Arrhenius had earlier, though unknown to him, arrived at essentially the same result.

MISCELLANEOUS.

Appointment.—Dr. A. B. Griffiths, F.C.S., &c., Lecturer on Metallurgy at the City of London College, has been appointed to the Chair of Chemistry and Metallurgy and Director of Laboratories at the Technical College, Manchester.

Metallurgical Lectures at the Royal School of Mines.—The course of lectures will begin early in November, as soon as Prof. Chandler Roberts returns from his visit to the Metallurgical districts of Colorado and Denver. He is also to examine the various Mints and Assay Offices of the United States. The Metallurgical Laboratory, to which a powerful testing machine has been added, opens in the first week of October.

Modern Mummies.—A Paper by Mr. Thomas Bayley, Consulting Chemist, of Birmingham, was among those communicated to the recent Social Science Congress. The author of the Paper points out that cremation immediately subsequent to burial, as at present advocated, would undoubtedly place facilities in the way of poisoners and other criminals. He proposes therefore to keep the body for a certain time after death, and treat it in such a manner as to avoid putrefaction. The bodies according to this method would be loosely but completely enveloped in cotton-wool, within air-tight cases of open construction which would be rivetted up. They would then be exposed in underground galleries lined with impervious cement to a current of cold and dry air, from which the germs capable of exciting putrefaction would be removed by filtration. The cooling would be effected by machinery working on the compressed air principle, and the air traversing the chambers would be dried by chemical agents, of which there are several suitable. At first thorough cooling would be necessary, but after a time the drying could be effected more rapidly at a higher temperature. The process would result in the formation of mummies with white integument similar to those produced by the most efficient and costly system of embalming in ancient Egypt. Attached to each dehydratorium, which is the name proposed for the building where the new process would be conducted, there might be established cool mortuary chambers for bodies awaiting inquest. After treatment the bodies might be cremated, or kept for an indefinite period in a dry place or in air-tight cases. It is certain that had this process been applied to the bodies now lying in Westminster Abbey, the authorities would not have had reason, as at present, to refuse further admissions on sanitary grounds.

NOTES AND QUERIES.

*Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Bones.—(Reply to L. Hundeshagen).—Bone manure was made at Aston, near Birmingham, on a small scale some years since by steeping bones in dilute muriatic acid, with excellent results, the fertility of the soil being greatly increased by this manure.—G. A. KETWORTH.

TO CORRESPONDENTS.

C. H. M. Mann.—In addition to Roscoe's "Organic Chemistry," you should consult Fownes's Chemistry, edited by Watts, and Miller's Chemistry, edited by Groves and Armstrong. There is also a very good elementary work by Armstrong in Longman's scientific series.

UNIVERSITY COLLEGE, LONDON.

ANALYTICAL CHEMISTRY.

The Laboratory of Analytical Chemistry, under the superintendence of Professor WILLIAMSON and Assistant Professor R. T. PLIMPTON, will re-open on Thursday, October 3rd.

For information as to other Courses on Chemistry, &c., apply to the Secretary of the College.

TALFOURD ELY M.A., Secretary.

UNIVERSITY COLLEGE, BRISTOL.

CHEMICAL DEPARTMENT.

PROFESSOR—W. RAMSAY, Ph.D.
LECTURER—SYDNEY YOUNG, D.Sc.

THE SESSION 1884-85 begins on 7th OCTOBER. Lectures on Inorganic, Organic, Advanced, and Technical Chemistry will be delivered during the Session. The Laboratories are fitted with the most recent improvements for the study of Practical Chemistry in all its branches. In the evening, Lectures on Inorganic Chemistry at reduced fees are delivered; and a Special Course of Lectures on Technical Chemistry is also given, with the co-operation of the Worshipful Company of Clothworkers. A Correspondence Class especially adapted for those engaged in the Clothworking and Dyeing Industries will begin in October. Several Scholarships are tenable at the College. Calendar, containing full information, price 1s. (by post 1s. 3d.) For prospectus and further information apply to the Registrar.

ANDERSON'S COLLEGE, GLASGOW.

THE CHEMICAL LABORATORY,

CONDUCTED BY

PROFESSOR W. DITTMAR, F.R.S.,

For the Technical Education of Young Chemists,

RE-OPENED ON THE FIRST OF SEPTEMBER.

Complete Syllabus on demand from the Laboratory.

THE CHEMICAL NEWS.

VOL. L. No. 1298.

A MEMOIR DETAILING SOME MINOR RESEARCHES ON THE ACTION OF FERROUS SULPHATE ON PLANT-LIFE.

By Dr. A. B. GRIFFITHS, F.C.S.,

Membre de la Société Chimique de Paris, Silver and Bronze Medallist in Chemistry and Botany.

As my investigations on the use of ferrous sulphate as a manure for certain crops are well known to chemists, this paper (which was the substance of a memoir of mine read before the Chemical Society on the 15th of May last, but contains additional notes, &c.), does not require to be supplemented by very many remarks concerning my former researches on this subject. I have already shown that ferrous sulphate is an excellent food for certain plants, particularly those developing a large amount of chlorophyll. My subsequent experiments prove that an excess of iron sulphate is fatal to plant-life. In fact it appears to be an analogous case to carbonic anhydride as a food for plants for MM. Déhéraïn and Maquenne (*Biedermann's Centralblatt f. Agricultur-chemie*, vol. xi., part 7; and *Annales Agronomiques*, 7, p. 385 to 406), have shown that vegetation derives a decided advantage in atmospheres rich in carbonic anhydride, and Dr. T. L. Phipson F.C.S., kindly informs me that in 1855, when at Brussels University, he first observed that an excess of this gas acts as a poison to plant-life: and this has since been confirmed by other chemists. Here I wish to detail some experiments I have made on plants growing in solutions containing varying amounts of ferrous sulphate.

I made up culture solutions containing the following ingredients:—

Water	100.00 grammes.
Potassium nitrate	0.10 "
Sodium chloride	0.05 "
Calcium carbonate	0.05 "
Magnesium carbonate	0.05 "
Calcium phosphate	0.05 "
Sodium silicate	0.05 "
	0.20 "
Ferrous sulphate	0.15 "
	0.10 "
	0.05 "

Four solutions were made with the above quantities of salts dissolved in 100 grammes of distilled water. The difference between them was in the amount of ferrous sulphate in each. No. I. solution contained 0.05 per cent, No. II. 0.1, No. III. 0.15, and No. IV. 0.2 per cent of ferrous sulphate. These solutions were poured into four dishes, and in each dish was placed a piece of flannel, and on each piece of flannel was sown the same number of mustard seeds. These were allowed to germinate and grow until nearly mature, and at stated intervals each set of plants was watered with its proper solution always of the same strength as the original solution. The plants growing in No. III. solution (*i.e.*, the solution containing 0.15 per cent of ferrous sulphate) were the largest and healthiest; and on submitting their ash to analysis the largest amount of ferric oxide was found therein.

The seeds placed in No. IV. solution (*i.e.*, the solution containing 0.2 per cent of ferrous sulphate), never germinated at all; in fact they withered and died. I have since repeated this several times with the same results. This proves that one-fifth per cent of ferrous sulphate proved fatal. The seeds growing in solutions Nos. I. and II. grew well, but not so well as No. III., which contained a larger amount of ferrous sulphate in solution. In passing

I may say that each set of plants was exposed to the same amount of sunlight, &c. From these experiments it will be seen that solutions containing a gradual increase in the percentage of iron sulphate is beneficial to plant-life up to a certain point; beyond this point, the plant declines and dies. In fact, as I stated at the commencement of this paper, it appears to be an analogous case to carbonic anhydride as a food for plants.

Again, when the roots of a young cabbage plant were placed in No. IV. (*i.e.*, the solution containing one-fifth per cent of iron sulphate); the plant in three days showed evidence of decreasing vitality; on taking it out of this solution, drying the roots with blotting-paper, and then placing them (the roots) in distilled water, the plant began to revive, and in a day or so was healthy again. On analysing the distilled water it was found to contain the excess of ferrous sulphate. From this experiment it appears that the plant growing in the one-fifth per cent solution of the salt of iron would have died (as a similar plant did when left in the solution for a week) if it had not been transferred to the distilled water. When the roots were placed in this new medium there was a "struggle for existence," so to speak, the excess of ferrous sulphate being passed back again into the water, and the plant recovered from the poisonous action of the excess of iron.

It will be seen from my previous researches that iron acts as a useful manure, but at the same time if given in excess proves fatal to plant-life, or, in the words of Liebig, "the most nutritious substances may cause death."

These experiments confirm those of Dr. Freytag, of Bonn, that plants are incapable of selecting from the soil the nutritious and rejecting the noxious ingredients. They absorb both indiscriminately; but as the experiments of Macaire-Princep and those of my own (described above) show that plants under certain conditions, and in narrow limits, are capable to a certain extent of excreting matters unnecessary to their existence; and when metallic salts are absorbed in excess, if circumstances, &c., are favourable, the plant returns in the form of an excrement the excess of a noxious salt.

To confirm this poisonous action of excess of ferrous sulphate, I examined, under the higher powers of the microscope, the little water plants *Spirogyra* and *Zygnema*. When these plants were placed in Nos. I., II., and III. solutions respectively, there was no change in colouring matters like eosin or magenta: thus showing that solutions containing 0.05, 0.1, 0.15 per cent of ferrous sulphate respectively, did not kill the little plants; on the contrary, the rotatory movement (*cyclosis*) of the protoplasm (when seen in *Anacharis alsinastrium*) was increased when the plants grew in the solution containing 0.15 per cent of iron sulphate. When the little plants were placed in solution No. IV. containing 0.2 per cent of ferrous sulphate, they died; for I was then capable of staining the protoplasm with eosin or magenta, which proved it was dead. These investigations show that these plants cannot live in a solution containing all the ingredients necessary for plant-life, if that solution contains as much as one-fifth per cent of ferrous sulphate, whereas a smaller amount is most beneficial, rendering the plants healthier and larger than if grown in a medium not containing this iron manure.

THE RELATION BETWEEN THE "WATT" AND "HORSE-POWER."

By W. H. PREECE, F.R.S.

THE most useful practical unit in use among electricians that has been derived from the C.G.S. system of absolute measurement is probably the watt, or the rate of doing work when a current of 1 ampère is maintained through a resistance of 1 ohm. The work done by an electric current

* A Paper read before the Montreal Meeting of the British Association

is thus brought into intimate relation with all other kinds of work. The common gravitation unit rate of working is the horse-power, which is 550 foot-pounds per second. The absolute C.G.S. unit is the erg per second, or the work done in 1 second in overcoming a force of 1 dyne through a distance of 1 centimetre. In any electrical measurement the electric motive force E in volts multiplied by the current C in amperes gives a product EC equivalent to so many 10^7 ergs per second, which is the watt. There are 746 watts in a horse-power: and hence EC is reduced to horse-power when it is divided by 746. The rate at which electrical energy is developed or expended in any part of any circuit is given in watts when we multiply the number of volts by the number of amperes. Strange mistakes are made in confusing the unit of power with the unit of work. No less an authority than Professor Adams, F.R.S., in his Inaugural Address as President of the Telegraph Engineers and Electricians, spoke of the watt as the unit of work.

The horse-power as a unit has all the defects of an arbitrary unscientific standard. It involves the use of coefficients; and it is not connected directly with the absolute system of measurement. It differs in different parts of the world; and its name is misleading. It could be changed both in value and name without any inconvenience except to those who are familiar with the existing coefficients and formulæ. If its value were raised 34 per cent it would become the kilowatt, and be connected directly with the C.G.S. system. It would thus become scientific, and diminish the use of coefficients. Even the present name could be retained and its value altered from 746 to 1000 watts; or from 33,000 to 44,233 foot-pounds per minute, without any serious inconvenience. Existing numbers expressing horse-power would simply have to be multiplied by 0.746 to bring them to the value of the new unit; or numbers on the new unit would have to be multiplied by 1.34 to express their value in the old system.

I cannot help thinking that the good work of the British Association Committee will not be complete until the C.G.S. system is authoritatively applied to work and power. The following table brings together nearly, if not all, the units in common use:—

Unit	Equivalent.
Horse-power	33,000 foot-pound per minute.
"	550 foot-pounds per second.
"	746×10^7 ergs per second.
"	7460 megergs per second.
"	75.9 kilogrammetres per second.
"	1.01385 force de cheval.
"	746 watts.
Force de cheval ..	75 kilogrammetres per second.
"	542.48 foot-pounds.
"	0.9863 horse-power.
"	736 watts.
Watt	0.0013405 horse-power.
"	10^7 ergs.
"	10 megergs.
"	$\frac{1}{9.81}$ kilogrammetres per second.
"	0.1029 kilogrammetres per second.
B. of T. unit	1000 watts per hour.
C.G.S. unit	erg per second.
Megerg	10^6 ergs per second.
Watt	10^7 ergs per second.

According to Professor Dewar, a standard sperm candle develops 240,000 foot-pounds per hour, or 4000 foot-pounds per minute. Now, since a watt is equivalent to 44.2 foot-pounds per minute, it follows that a standard candle develops 90 watts per minute. Again, according to the same authority, 5 cubic feet of coal-gas in London develops 2,500,000 foot-pounds per hour, or 41,666 foot-pounds per minute, or 2976 foot-pounds per candle per minute, which is equivalent to 67 watts per minute. A good glow lamp absorbs 2.5 watts per candle per

minute. Hence a glow lamp has an economy in energy of about 1-30th of a gas light, and 1-40th of a standard sperm candle. A man working very hard expends about 200 watts per minute; hence, if a man-power is equal to, say, 1 standard candle, it is equal to 1.34 gas candles and to 36 electric candles! What a field for economy in lighting, and how essential it is that gas should be applied to the production of power rather than to the production of light.

PARATOLUIDIN SULPHATE AS A REAGENT FOR NITRIC ACID.

By ANTONIO LONGI.

IF to a solution of paratoluidin in sulphuric acid nitric acid is added there appears first a blue colour, which changes into violet, red, and, lastly, into yellowish brown.

Rosenstiehl and Lauth used accordingly nitric acid for detecting paratoluidin in a solution of various aromatic bases in strong sulphuric acid. The author has studied this reaction with reference to the detection of nitric acid, and has obtained very good results.

If to a liquid containing nitrates there are added a few drops of a solution of paratoluidin sulphate, and if an equal volume of sulphuric acid is carefully added, so as to form two strata, there appears immediately, at the line of contact of the two liquids, a red colour, which after a considerable time passes into a dark yellow. If paratoluidin sulphate adds in a similar manner upon chlorates, bromates, iodates, chromates, or permanganates, there is formed instead of the red an intense blue colour, so strong that it completely masks the reaction of the nitrates if only a small quantity of one of the above-named salts is present.

The solution of aniline sulphate, if similarly used, gives no colour; but if a mixture of the salts of both bases is used, the reaction is more sensitive, and the red colour more intense. A solution of aniline oil in dilute sulphuric acid may therefore be advantageously used as a reagent instead of pure paratoluidin sulphate.

In order to ascertain the limits of the sensitiveness of this reaction the author has tried it with solutions containing different proportions of potassium nitrate. He succeeded in detecting the nitric acid in a liquid containing 1-32,000th.

By means of chrysanthine, as proposed by W. Hofmann, scarcely 1-1000th part can be detected. Ferrous sulphate is differently sensitive according to the manner in which it is used. If a strong solution of this salt is poured upon a cold mixture of 1 vol. of the liquid containing nitric acid and 1 vol. strong sulphuric acid, 1-2000th nitric acid may be detected. But if to the solution containing a nitrate there is added an equal volume of strong sulphuric acid so that the liquids do not mix, and if a few small crystals of good ferrous sulphate are dropped in, 1-8000th part of nitric acid may be detected.

By means of indigo 1-64,000th may be detected, and by means of the reaction with caustic potassa and zinc-powder, proposed by P. Tassinari and P. Piazza, 1-160,539th of nitric acid may be recognised.

Brucine has hitherto been regarded as the most sensitive reagent for nitric acid. Kersting, who used it in an aqueous solution (1:1000), succeeded in discovering 1-100,000th nitric acid. But if into a solution containing nitric acid there is poured sulphuric acid in which a small quantity of brucine has been dissolved, we obtain the well-known colouration even with liquids containing 1-256,000th nitric acid.

The sensitiveness of brucine is considerably surpassed by that of diphenylamin. It forms with nitric or nitrous acid dissolved in strong sulphuric or nitric acid, an oxidation-product of so intense a blue that even the minutest traces suffice to give a distinct colouration. E. Kopp

used this reaction for the detection of nitric and nitrous acids in commercial sulphuric acid, and asserts that it is at least as sensitive as that with ferrous sulphate. The author has examined whether diphenylamin can be used for the detection of nitric acid in aqueous solutions.

If the liquid containing nitric acid is mixed with a few drops of diphenylamin sulphate and a layer of strong sulphuric acid is then added, there is formed a very fine blue colouration which persists for a considerable time. By operating in the manner just described solutions of nitric acid containing 1-1,500,000th always give a distinct colouration. The reaction only begins to be doubtful with solutions containing 1-2,000,000th.

Though paratoluidin is not so sensitive as brucine and diphenylamin, it is nevertheless preferable because it does not give the reaction with chloric, chromic, and iodic acids, nor even with nitrous acid.

If a solution of paratoluidin sulphate is added to a liquid containing nitrous acid and then sulphuric acid as above, we obtain a yellowish brown colour if the solutions are strong, and if they are dilute, a yellow, which after a time turns to a red, as a part of the free nitrous acid is converted into nitric acid. The reagent may therefore serve to distinguish nitrates from nitrites. For this purpose the solution in question is diluted rather copiously, and it is noticed whether the reagent immediately gives the red colour which is characteristic of nitric acid. If it is required to detect nitric acid in presence of much nitrous acid the reaction is applicable, since the yellowish brown colouration of the latter completely masks the red of the nitric acid. In such cases, as Piccini proposed, the nitrous acid may be decomposed by means of urea. The author applies Piccini's method in a somewhat modified form. To the solution containing a nitrite he adds an excess of urea, and then, by degrees, acetic acid, until gas is no longer evolved in the cold. He then evaporates on the water-bath and tests the solution of the residue for nitric acid.—*Zeitschrift f. Analyt. Chemie.*

ALLOYS USED FOR COINAGE.*

By W. CHANDLER ROBERTS, F.R.S.

(Concluded from p. 162).

We have now to consider the means adopted to secure accuracy in the weight of coins issued from the Mint, and to examine the questions connected with the loss in weight sustained by coins during their circulation. Before the invention of coined money, the precious metals circulated by weight. Examples of such currency are presented by the gold and silver "talents" of the Schliemann collection, which bear a definite relation to the Babylonian "mina;" and so completely has the spirit of this method of circulation by weight been retained, that the best definition we possess of coins represents them as "ingots, of which the weight and fineness are certified by the integrity of the designs impressed upon the surfaces of the metal."[†]

Rice Vaughan,[‡] whom I have before quoted, has some interesting remarks on this point in the section of his little work devoted to the consideration "of coining moneys without distinction of weights." He says the proposition is, "that there should be coined no pieces of a certain [i.e. definite] weight, either of gold or silver, but that, the alloy being certain, the weight should remain uncertain; all money now current should be valued by a certain weight." For example, every ounce of silver should be valued at five shillings and every ounce of gold at such a proportion as shall be thought most equal. He points out that, among other incidental advantages, this plan would prevent the "culling, washing, and clipping," of

money, that is, its fraudulent reduction in weight; but on the other hand, the objection would be, as he says, "the extreme molestation which the people should receive in the practice of it, when every man should be bound to carry scales in his pocket, and upon every little payment be bound to weigh their money." Few people at the present day bear in mind that this is precisely what, in the case of the gold coin, the existing law requires them to do, for the Coinage Act of 1870, now in force, directs, in Section 7, that "where any gold coin of the realm is below the current weight provided by this Act, every person shall, by himself or others, cut, break, or deface such coin tendered to him in payment, and the person tendering the same shall bear the loss." Compliance with this demand would, of course, render it necessary for each individual, who has reason to expect the tender of a sovereign, to carry scales and weights, as well as shears to cut such pieces as should be found to be deficient in weight.

It will be well for us to examine—1st, what degree of accuracy as to weight the law requires in pieces issued by the Mint; and 2nd, how long gold coins may be expected to circulate without incurring the "extreme penalty of the law," which takes the same view of coins as is expressed in Butler's "Erewhon" with regard to humanity, and considers defective organisation and decrepitude in a coin to be criminal, and punishable by "cutting and defacing." Mr. John Biddulph Martin, whom I shall again have occasion to quote, well observes, "We are wont to speak of the life of a coin, but whereas the term 'life' is in all other cases associated with a period of growth, of maturity, and of decay, in this instance the process is one of degradation only."

The first schedule of the Coinage Act of 1870 prescribes the weight at which each coin shall be issued; it also defines the lowest weight at which the gold coins may be permitted to circulate, and it sets forth the "remedy" of weight—that is, the range above or below the exact standard within which the issue of coins would be legal. The silver and bronze coins, being merely tokens, have no "least current weight," but are withdrawn from circulation, and re-coined, when they become defaced by wear. The standard weight of a sovereign is 123.27447 grains, the remedy is ± 0.2 of a grain, and the least current weight 122.5 grains. In the case of the half-sovereign, the standard weight is 61.63723 grains, the "remedy" ± 0.1 , and the least current weight 61.125 grains. In order to ensure that the coins issued from the Mint shall be well within the remedy allowed by law, it is necessary to adopt in practice a still more minute margin, or allowance for unavoidable error. The "working remedy" adopted in the Mint in the case of the sovereign is therefore fixed at 0.17 of a grain, instead of the 0.20 which the law allows, and the weight which denotes whether a sovereign is or is not within the remedy is represented by a piece of wire of fine gold, 0.1355 inch in length, and 0.018 inch in diameter, and weighing 0.17 of a grain. It will be obvious that the possibility of restricting the weight of coin within such narrow limits entirely depends on the degree of accuracy which may be attained by the process of rolling the strips of metal from which the discs destined to form the finished coin are cut; and we have already seen, in the first lecture, that in the case of the fillet prepared for the manufacture of the half-sovereign, a variation of 100th of an inch above or below the accurate thickness, or a range of 1000th of an inch in the thickness of the fillet, would cause the rejection of the coin, on the ground of excess or deficiency of weight. The question then arises—Is it not possible to supplement the operation of rolling by some mechanical operation, conducted on the blanks themselves, in order to bring them within a closer approximation to the exact weight. The problem has long proved an attractive one in Mints, but the earliest suggestion I can find for securing absolute accuracy in weight occurs in the "Records of the Scotch Mint," from

* Cantor Lectures delivered before the Society of Arts.

† Stanley Jevons, "Money," p. 57. 1876.

‡ "A Discourse of Coin and Coinage," p. 214. 1675.

which it appears that J. Acheson claimed, in 1597, to have discovered a method of making coins so that none shall be "ane grane heavier or lighter nor another."

On the Continent it is very generally the practice to adjust blanks by the aid of a file, the weighing being performed by hand; the process is, however, open to the objection that the marks of the file are never quite obliterated when the blanks are struck into coin, and the same objection applies to most of the machines that remove a fine shaving of metal from the surface of the blank. An additional objection to such a mechanical adjustment of blanks arises from the tendency, in Mints where it is adopted, to produce "too heavy" blanks in the rolling and cutting departments, as it is impossible to adjust blanks which are too light. Some years ago, Mr. J. M. Napier* devised for the Indian Mints an automatic machine of great beauty, which first ascertains how much it is necessary to cut from each blank in order to reduce it to the standard weight, and then removes the necessary amount of metal and no more. The initial cost of such machinery is, however, considerable. Another machine, having the same object in view, has been devised by M. Seyss.†

Chemical aid has not been wanting in the attempt to solve the question of the adjustment of blanks. In 1849, M. Dierck, Director of the Mint in Paris, endeavoured to substitute a chemical for a mechanical treatment by submitting the heavy gold blanks to *aqua regia*, which, it was anticipated, would bring them within the prescribed limits of accuracy, by dissolving away metal. The results were not satisfactory, and the attempt was abandoned.

Having myself attacked the question in 1870, I may, perhaps, be permitted to refer to the results which attended my experiments. It was found that gold, alloyed with copper, might be removed from heavy blanks with singular regularity by means of a suitable solvent aided by a battery. The blanks were arranged in a frame of wood, and submitted to the action of a solution of cyanide of potassium, the heavy blanks forming the dissolving pole of the battery. The process was not used in the London Mint, as it became evident that it could not replace the present system, under which finished coins alone are weighed, and the manufacture of good coin only is paid for. The late M de Jacobi, one of the earliest workers in the field of electro-metallurgy, visited my laboratory while the first experiments were in progress, and we discussed the possibility of re-depositing the metal removed from the heavy blanks on those that were too light, the problem being to obtain a tenacious film.

I was greatly interested to find, long after my experiments were made, that an eminent firm of electrotypers had suggested officially that the worn gold coins in circulation could be restored to the legal weight by the electric deposition of a film of gold on the surfaces. The process was introduced into the Bombay Mint, in 1873, by the late Mr. L. G. Hines, who transferred the metal dissolved from the heavy blanks to blanks which are too light, the latter being by this means raised to the prescribed weight. Its importance in mints where its use is possible may be gathered from the fact that, in the Indian mints, no less than 1300 tons of silver were converted into coin in one year (1879), so that the saving effected by its use must be considerable.

Whether or not a method for adjusting the blanks be adopted, the finished coin must be weighed before it leaves the Mint, and this, as before stated, is the great obstacle to the introduction of the electro-chemical method into the English Mint. In former times the weighing was effected only in bulk, but more recently individual pieces have been weighed in this country. I have already pointed out that the weighing may be effected by hand, and this method is very generally adopted on the Continent

and in America, where each operator is provided with a delicate pair of scales.

In the Mint of this country, very beautiful automatic machines are used, for a full description of which reference may be made to the "Encyclopædia Britannica." [NOTE.—The general nature of the appliance was made clear by the aid of a model.] The balance was originally devised in 1851 by the late Mr. William Cotton, of the Bank of England, and has since been improved by the officers of the Mint, and by Mr. J. M. Napier, who has secured several patents in connection with this machine.

In the Vienna Mint, a balance devised by Herr Seyss is employed, which depends upon a somewhat different principle. The beam resembles that of an ordinary balance, with pans suspended from it; one pan contains the weight, and a slide brings forward the coin to the other pan; the depression of the beam produced by a heavy coin brings the balance pan opposite one of several slits, the lowest slit corresponding with the extreme depression of the beam produced by a very heavy coin. The pan is then momentarily fixed, and the coin is allowed to pass away into the slit against which it stands. If coin is very light, the pan which contains it will rise and stand opposite the highest of the series of slits.

The life of a coin, after it leaves the Mint, may now be traced, and it will be seen that the conditions of its existence are far less severe in modern than they were in ancient times. The actual wear to which coins are subjected may, no doubt, be rougher at the present day than in the past; but, on the other hand, they are not subject, to anything like the same extent, to ill-treatment from enemies in the shape of clippers and sweaters.

It is difficult to over-rate the importance of some system of protecting the edge of the coin against fraudulent treatment, and it is hardly less difficult to understand, at the present day, the extent to which the ill-shapen hammered coins were tampered with. The earliest protection seems to have been afforded by a circle or beaded ring on the surfaces of the coin, and that such circles have been used from early times is proved by the fact that many Greek coins bear them. Attention is specially directed to the outer circle in an enactment of King Henry VII., which provides that "every piece is to have a circle about the utter part thereof, and also that all manner of gold hereafter to be coined shall have the whole sculpture without lacking any part thereof, to the intent that the King's subjects might have perfect knowledge, by that circle or sculpture, when the coins were clipped or not." No protection, however, is as efficient as the addition of letterings or devices round the edge of the coins. I have already stated in the first lecture that the practice of marking the edges was adopted, for another reason, in Roman times in the case of the *Nummi Serrati*, mentioned by Tacitus.

Coins may be fraudulently reduced in weight by the action of a solvent aided by a battery, but there is reason to believe that the practice is only carried on to a very limited extent.

Removal of metal by drilling holes and filling them up by base metal has sometimes been resorted to, and the Mint Museum contains interesting examples of American coins which have been sawn so as to leave two thin flat discs, which have subsequently been soldered over a disc of base metal, the precious inside of the coin having been removed. It has been proposed to make the American gold double-eagle dish-shaped, in order to render the centre so thin as to prevent this method of falsification. In mediæval times, tampering with the coin caused the gravest anxiety, and was punished with dreadful severity.

In 1381, the first equivalent of the modern Royal Commission on the Coinage met, and the following was the evidence, or rather were the recommendations, of the individuals who took part in it. Richard Leyce advised that the practice of clipping the gold coin could only be checked by a proclamation directing individuals to weigh coins

* Patent, No. 108. 1866.

† *Dingler's Polytechnisches Journal*, cxxiv., 61; plate 6. 1882.

* Ninth edition, art. "Mint."

when they took them, and Richard Aylesbury, a goldsmith, also held that gold pieces which had been reduced by clipping should be universally weighed by those who received them.* I will take only a few more historical instances of instructions as to weighing the coins tendered to individuals. The Mint Records† contain a copy of a proclamation given in the 17th year of King James I., which states that the people, instead of refusing such light gold moneys as were without the remedies . . . do now for the most part accept in payments, indifferently and promiscuously, all such coins whatsoever tendered unto them, without weighing," which shows that the practice of weighing the coin had been adopted, and was falling into disuse. In 1619, the person who tendered the gold coin was instructed to give twopence for every grain the coin was light, and individuals were directed to brand every piece abnormally light by striking a hole through it, returning such pieces to the owners thereof, thus re-affirming a proclamation made in 1587 by Queen Elizabeth, which directed that the defective coins should be "stricken through and cut into pieces." In 1632, it is stated that "in and about London and Westminster, people carried scales in their pockets, to weigh gold on all occasions."‡ I mention these facts to show that the directions of the present law (Coinage Act, 1870) as to the cutting and defacing of worn coin rest on ancient precept.

The condition of the silver currency in the end of the 17th century may be gathered from the statement of Lowndes, who computed the amount of all the silver moneys coined in the reigns of Queen Elizabeth, James I., and Charles I., at £15,109,476. Writing in 1695, and allowing for the sums coined in the reign of Charles II., James II., and William and Mary, he did not consider that the silver circulation consisted of more than £5,600,000, of which only £1,600,000 was heavy;|| and he further pointed out, as the result of careful weighing of the coin in bulk, that the weight of "the moneys commonly current are diminished near one-half." Not, it must be remembered, merely by legitimate wear, but by the fraudulent practice of "clipping," from which, I believe, modern coinages suffer to a hardly appreciable extent.

It is now necessary to consider the conditions affecting the circulation of a metallic currency, more especially as regards its power of resisting legitimate wear. An experimental inquiry conducted by the officers of the Mint towards the close of the last century, showed that 78 $\frac{1}{2}$ of the shillings then in circulation were required to make a pound weight, which should have been represented by 62 shillings; eleven years later, 82 $\frac{1}{2}$ shillings weighed a pound. With regard to the gold coinage, the Mint officers found, in 1807, that 1,000 guineas withdrawn from circulation had lost 19s. per cent in value. Parcels of 300 sovereigns, coined in each of the years 1817-21-25-29, were weighed by the officers of the Mint in 1853, and the results proved that they had sustained an average rate of wear of 0.047 grain per annum.

The rate of wear, in the case of gold coins, is dealt with by Jacob;§ but we owe an authoritative determination of the annual rate of wear of the gold coin to the late Professor W. Stanley Jevons, F.R.S.—formerly assayer of the Sydney branch of the Royal Mint, and subsequently Professor of Political Economy at University College, London—who brought to the consideration of the question an acute intellect and perfect knowledge of the conditions which govern the metallic currency. He proved, as the result of an exhaustive enquiry, that "just about eighteen years' wear will reduce a sovereign below its point of legal currency"; and he shows conclusively

that the average rate of wear per annum of the sovereign is 0.043 grain, which led to the conclusion that, at the time he wrote, 1868, "31.5 per cent of the whole of the sovereigns in the kingdom are now no longer of legal currency." He estimated the annual average wear of the half-sovereign at 0.069 grain. Mr. Martin* has since repeated and extended Professor Jevons's inquiry. He has greatly added to the value of the work by bringing it down to the present time; and his researches, which deal with no less than 105,364 sovereigns, confirm, in a remarkable manner, the average rate of wear deduced by Professor Jevons, who adopted a different method of calculation. It may safely be assumed, therefore, that any sovereign which has been in circulation more than eighteen years has been reduced to a point at which it is not legally current, and should, therefore, be withdrawn from circulation, in order that it may be re-coined.

The questions now present themselves—Can this average rate of wear be diminished? Is the form of the coin well adapted to enable it to resist wear; and is it possible to adopt a more durable alloy for our gold coinage? First, with regard to the form; no doubt a sphere which contains the maximum weight in the smallest surface is better adapted than a disc to resist the abrading influence of friction, and it follows, therefore, that the Siamese money, which is nearly globular, will retain its weight longer than any other coin now in circulation.

A short cylinder is the geometrical form which, next to the sphere, presents the smallest surface for the greatest weight, and, consequently, in order to reduce the wear of coins to a minimum, their thickness should be equal to their diameter. Such a form would present many inconveniences; but, on the other hand, coins should not be made too thin, and much may be gained by even a small approach to theoretical requirements. A good practical rule for calculating the most useful diameter of a coin from its weight is given by the following formulæ:—

$$D = P \sqrt[3]{G}$$

D = Diameter in millimetres.

G = Weight in grammes.

P = A certain number found by experiment.

Take the cube root of the weight of the coin, multiply by the number for the particular coin, and this gives the most suitable diameter in millimetres. The value of P for all kinds of gold coins is 11.3.†

I have thought it advisable to make the above reference to the matter, although it is not likely that the form of our coins will ever be greatly modified. The mean thickness of the coin does not differ much from the initial thickness of the blank, because in virtue of the "flow" of metals, to which allusion has already been made, the portions of metal diminished in thickness are about balanced by the raised part of the device. Sharp new coins do not wear much more rapidly than old ones, as is shown by the experiments of Professor Jevons and Mr. Martin; that is, the rate of wear of coins at different periods of their career is fairly normal. There is no doubt that a coin in high relief becomes disfigured much sooner than one in low relief, as the unity of a design is greatly impaired by the loss of a prominent feature, and the lovely Renaissance works in low relief [now before you] present a much better appearance after prolonged circulation than their classical predecessors, which are almost lenticular in form. The power of the metal to resist, not wear, but deformation by impact, therefore demands attention, and from this point of view a soft metal is far less useful than a hard one. Coins of lead, for instance, have been found, in experiments to which reference will be made presently, to become rapidly defaced, and reduced to the state of mere blanks, when submitted to mutual action in a re-

volution drum. Coins of pure gold also become rapidly defaced, although their weight is but little reduced by such treatment. As has already been pointed out, the reason for using an alloy instead of pure metal is the greater durability of the former, and accurate experiments on this point have not been wanting. Their history may be briefly stated as follows:—In 1792, the unfortunate French Statesman Clavière* proposed that pure metals should be used for coinage, and that they should be current by weight. The Académie des Sciences was consulted on the subject, and experiments made by this distinguished body† showed that while the pure metals were rapidly reduced in weight by friction, the addition of even a small amount of base metal had a notable effect in enabling the metals to resist abrasion by wear. In 1798, the Privy Council appointed a committee "to take into consideration the state of the coins of this realm," and they directed Mr. Henry Cavendish, F.R.S., and Mr. Charles Hatchett, to ascertain experimentally whether the loss of gold coins by wear was "occasioned by any defect, either in the quality of the standard gold, or the figure or impression of the coins." The result was an elaborate investigation, conducted by Mr. Hatchett,‡ on the "comparative wear of gold," the results of which have since been frequently quoted, and have, in fact, become classical. Hatchett operated both on unstamped blanks, and on discs struck by dies, which produced small "rounded prominences, regularly disposed over the surface of the coin." Such blanks, or coined discs, were arranged in two frames, so that the flat surfaces of the metal could rub against each other when the frames were pressed together. Each frame was moved rapidly backwards and forwards by suitable mechanism, the path of each frame being at right angles to the other. The discs were in this way subjected to mutual friction, and the gearing was so devised that while one frame was moving with its greatest velocity, the other was at the extremity of its path, the result being that the coins were prevented from moving always in the same line. The numbers of "revolutions" or contacts of the pieces varied from 20,680 to 229,000. He also used a cubical box of eight inches, in the side, in which the coins were made to revolve; and the discs were also rubbed on a table covered with either flour, fine chalk, or metallic filings, fixed in isinglass. Hatchett's main conclusion was that the "extraordinary loss which the gold coin of the kingdom is stated to have sustained within a certain limited time, cannot, with even a shadow of probability, be attributed to any important defect in the composition or quality of the standard gold."§ He further observes "that the experiments on the various alloys of standard gold (that is gold standardised with various metals) concur with established practice and opinion to prove that only two of the metals, viz., silver and copper, are proper to be employed in the reduction of fine gold to standard for the purpose of coin."¶ Notwithstanding the care and skill employed by Hatchett in conducting his experiments, some of his deductions appear to demand confirmation. The subject possesses additional interest at the present time, because it is probable that much of the light gold coin now in circulation will soon be withdrawn; and it has therefore been considered advisable that Mr. R. A. Hill, Superintendent of the Operative Department, and myself should resume an investigation on the relative wear of coins of different metals and alloys, which was begun by one of us during the Mastership of the late Mr. Graham. After several preliminary experiments, in which a sliding motion was given to pieces of metal along a smooth surface of oak, we satisfied ourselves that revolving the pieces in a box represents more faithfully the kind of friction to which coins are subjected in the varying conditions of their circulation, and this view was fortified by the opinion of the late Professor Jevons. We addressed ourselves mainly to ascertaining whether

the alloy used for the British gold coin, the standard of which is 916·6, is, or is not, more durable than the alloy of 900 fine, which is so widely used by other nations; and we are satisfied that the experimental evidence proves, as regards rate of wear, that there is not much to choose between standards 916·6 and 900. On the other hand, differences in mechanical treatment, resulting from a heavy as compared with a light blow, or in thermal changes produced by annealing, exert greater influence on the rate of wear than the small variation in composition comprised between the limits 900 and 916·6. We agree with the view taken by M. Feer-Herzog* that differences of wear of coins of these two alloys is very slight.

Our experiments are in progress, but the results hitherto obtained are published in the Mint Report for last year.†

The use of aluminium has often been suggested for the manufacture of subsidiary coins, this metal being known to possess the great tenacity when equal volumes of it and other metals are compared. We have been much interested to observe that coins of aluminium, especially if they be alloyed with about 2 per cent of nickel, are very durable, as are also coins of pure nickel; but in one case the durability results from toughness, and in the other from hardness.

There is one other point in connection with the gold currency to which I would now direct your attention. The Coinage Act of 1870 fixes the remedy on each individual piece, and not, as was the case formerly, on the pound weight of the coin. The object of this provision is to prevent the "culling" of the heavy pieces, which would be a profitable transaction if the inequalities of weight were considerable. The heavy pieces so selected might either be exported or used in the arts, and the annals of the coinage abundantly indicate the extent to which the practice was carried on in former times. A notable case occurred in 1637,‡ when the Attorney-General charged several persons before the Star Chamber with "culling out the weightiest coins, and with melting down his Majesty's moneys into bullion;" and, on examination, it appeared "that between the years 1626-1631, one Timothy Eman culled £500,000 a year, which yielded £7000 or £8000 of heavy moneys yearly, and in five years he melted down £15,000, his profit therout amounting to £100." Another offender was Violet, whose name deserves mention. As his work "An Appeal to Cæsar" contains so much curious information as to the export of bullion.¶

I regret to say that the practice of culling is not absolutely unknown at the present day. Prof. Jevons stated, in 1868, that he "received overwhelming evidence that this picking and culling of the coinage, as it used to be called, is practised as an ordinary business transaction by all banks which need to make remittances to the Bank of England," in order, that is, to avoid the loss which would be entailed if light coin were sent to the Bank, where it would be cut and the deficiency charged for. "It will thus be apparent," Prof. Jevons adds, "that there exists a regular system, whereby the older coins are continually returned into the hands of the public, and the new heavy coins alone are returned to the Bank of England, or to those who would melt or export them."

The amount of gold actually in circulation is estimated to be £100,000,000, but the coinage returns show that the amount of sovereigns and half-sovereigns issued since 1816, when their coinage was begun, is £247,521,429. What, then, has become of the 147 millions not in circulation? The coinage returns show that between the years 1864-83 £57,492,842 in sovereigns were coined. A considerable proportion of these have been exported never to return. The following figures, which I offer with some hesitation as they may not be rigidly accurate, show that, while during the same period sovereigns were exported

¶ "An Appeal to Cæsar," by Thomas Violet, of London. 1660.

and imported, the excess of exports over imports was no less than £25,991,445, or a yearly average of £1,299,572.

With regard to the disappearance of gold coins from circulation, Prof. Jevons has some observations of extraordinary interest. He says it appears "that of the sovereigns coined in 1817-19, not more than one-fiftieth part remain in circulation; and the proportion rises until, between the years 1840-1858, it is about one-third." He suggests in his paper that these curves should be plotted graphically. In both cases there is an elevation in the period 1840-45, arising probably from the re-coining of the years 1841-43, when £14,000,000 of gold coin were called in and re-distributed in an unusual manner, so that more than a common proportion became fixed in the circulation. The most important peculiarity of the numbers is the very small increase which takes place in the proportion of sovereigns preserved between the years 1832 and 1854: this indicates that there is a residuum of coin which is no longer subject to be exported or withdrawn, like the rest of the circulation; for if the proportions of coins exported were taken indifferently, the curve would rise as rapidly as is the case with the half-sovereign curve, those coins not being liable to exportation.

It will be evident, therefore, that in tracing the analogy between the life of a coin and ordinary vital phenomena, we are abruptly checked by observing that the "fittest" coins are not those which survive as the fittest; that is, the heavy ones drop out of the struggle of active circulation they were created to sustain, and are either exported or exist as part of a "hoard" of coin. It may, of course, be urged on this ground that a full-weight coin, issued to the public without charge, is not the fittest to retain its place in circulation, and that a small amount of metal lost by wear really tends to its preservation.

With that Darwinian problem I must bring these lectures to a close.* You have seen the great change and depreciations through which the "alloys used for coinage" have passed in times gone by, but there is no probability that in this country similar changes will take place in the future, and I cannot find better words to offer you than a quotation from Professor Jevons, whose perfect grasp of the question of metallic currency enabled him to realise its difficulties in a way few of us are able to do. He points out that, in times past, the rulers of nations have been the most notorious false coiners and depreciators of the currency; but that now "the danger lies quite in the opposite direction—that popular governments will not venture upon the most obvious and necessary improvement of the monetary system without obtaining a concurrence of popular opinion in its favour; while the people, influenced by habit, and with little knowledge of the subject, will never be able to agree upon the best scheme."

I can say with Rice Vaughan that "my scope was not to render the reader able to find out the fittest course to govern this matter of money and coin, but able to judge of what should be propounded by others;" but we need no longer fear the state of things described by him when he says "that for want of that ability the wisest States and the greatest Councils of Christendom, for many ages, have been abused by mysterious names and perplexed subtleties of Mint-men."

NOTICES OF BOOKS.

Tables to Facilitate Chemical Calculations. Compiled by W. DITTMAR, F.R.S., with the assistance of J. MCARTHUR, A. KLING, and T. BARBOUR. Glasgow: Robert Maclehose, 1884.

The practical value of such a set of tables as is brought together in this little manual by Prof. Dittmar is un-

questionable, and the compiler's extensive experience as a teacher of chemistry has enabled him fully to appreciate the wants of analytical chemists and to make a judicious selection and arrangement of his materials that will render his book serviceable to analyst as well as student. Logarithms are presumed by the compiler to be employed by the chemist in his calculations, and to render the work complete a four-place table of these functions is given with a simple device in arranging the "proportional parts" by means of which a fifth unit may be obtained. By this means all the logarithms required in the vast majority of chemical calculations are condensed into a few pages; chemical operations unfortunately not having yet reached that degree of accuracy to require a student to wade through a treatise on Finite Differences, to understand and apply such an interpolation formula as that established by Lagrange or Euler to his logarithms. In some parts of the notes explanatory of the use of logarithms and the mode of manipulating the "proportional parts," we think the algebraical refinements will be apt to bewilder many chemists.

In the atomic weights the compiler takes Meyer and Seubert's calculations, but with O=16 and the ratio O:H equal to 15.96, thus leaving the chemist without a unit in these numbers. We might well ask, O is 16 what? A table of reciprocals is also given which must prove serviceable in many chemical calculations.

The tables for the calculation of chemical formulæ and for formula-values and analytical factors, will be appreciated by the analyst who has many of such calculations to perform. In the latter we notice such expressions as "6FeSO₄7H₂O" and "2FeSO₄7H₂O," which, without brackets, are liable to be confounded with something other than their true meaning. This, however, is of very slight consequence if the numerical factors attached are correct; when, however, we see the ratio of 3Li₂O:2LiPO₄ (*sic*) given as 0.3573 with the corresponding log, it is of more serious importance. How this result is obtained is difficult to see; if, however, instead of the usual molecular weight of Li₃PO₄ of 116.1 we take 126.1, the above factor may be obtained.

The "Rules of Gasometry" are given in a very general and concise manner, but we think it an omission not to have devoted a paragraph to the algebraical formulæ required for the calculations of the results of gas analyses by combustion. The density of water at different temperatures according to Rosetti's calculations, as well as the density of mercury, will be found useful in calibrating operations.

The coefficients of absorption of nitrogen, oxygen, and air by water that are given are taken from the compiler's "Mémorial on the Composition of Ocean Water" in the *Challenger* reports.

CORRESPONDENCE.

SALICYLIC ACID.

To the Editor of the Chemical News.

SIR,—I have seen in a local newspaper a grocer complaining of having found a quantity of salicylic acid in tinned salmon, lobsters, and tinned fruits, and in which he in writing seems to convey that it is a poison, but not regarded as such in this country. And he states that in France it is believed to be a poison, and is forbidden by legal statute to be used in any preparation of food or drink, under a heavy penalty.

And now as this article is used very largely in the preparation of tinned meats and fruits, and is looked upon as a poison by some, I should feel obliged if some fellow readers would kindly give their opinion on the subject of its poisonous or non-poisonous nature?

* Since the above was written I find that Mr. J. B. Martin incidentally pointed to this analogy in a paper read before the Institute of Bankers in March last.

In 1881 the French Minister of Commerce, it is stated, directed that an analysis of its properties should be made. The result of the investigation decided that salicylic acid was injurious to health by its direct action on the system, and its indirect action by permitting the fraudulent introduction into food of other deleterious, or at least unwholesome, substances. This action on the part of the Minister of Commerce led to great dissatisfaction on the part of most French pharmacists and analysts, as about that time salicylic acid was creating a perfect *furor* amongst the gout and rheumatic suffering public of France.

It is, I believe, becoming a practice to use this antiseptic in the preservation of fruit, as by doing so it may be preserved without boiling, and does not lose its flavour; the medicinal dose of salicylic acid, I believe, is from 10 to 30 grains, and as 15 grains would be enough to preserve a tin of fruit, or keep a tin of salmon or lobsters, if so used I do not see the danger—I am, &c.,

J. H. HEYWOOD.

Rochdale.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Zeitschrift für Analytische Chemie.
Vol. xxiii., Part 3, 1884.

A Contribution to the Chemistry of Wine.—R. Kayser.—The author's results are given in the form of tables and no not admit of useful abridgment.

Contributions to the Analysis of Wine.—Dr. J. Nessler and Dr. M. Barth.—In this portion of their treatise the authors treat of the quantitative determination of magenta in red wines, the determination of tannin, and the volatility of glycerin at 100° in presence of aqueous and alcoholic vapours.

Simple Process for the Approximate Determination of Carbonic Acid in the air of Inhabited Rooms and in other Gaseous Mixtures.—R. Blochmann.—A given quantity of lime-water of known strength is brought in contact with so much of the air in question that the carbonic acid present is exactly sufficient for its saturation. In order to detect the point of saturation there are added to the lime-water a few drops of a dilute solution of phenol phthalein, until it appears distinctly red. This colour remains as long as the liquid retains an alkaline reaction, but as soon as the conversion of the caustic lime into calcium carbonate is complete a very small excess of carbonic acid is sufficient for complete decolouration.

Remarks on a Communication by Prof. Clemens Winkler on an Absorption Apparatus for Elementary Analysis.—W. Mathesius.—This paper will be inserted in full.

Analysis of Antimony Alloys, such as Type-Metal, consisting of Lead, Antimony, and Tin.—Fr. Weil.—Inserted in full.

Paratoluidin Sulphate as a Reagent for Nitric Acid.—Antonio Longi.—(See page 168.)

Examination of Potable Water.—W. Bachmeyer.—Already inserted.

Determination of the Technical Value of Calcium Tartrate.—L. Weigert.—This paper will be reproduced in full at the earliest opportunity.

Remarks on Apparatus for Fractionated Distillation.—L. Weigert.—This memoir cannot be usefully abstracted without the accompanying illustration.

An Apparatus to Supersede Shaking up with Ether, Ligroine, &c.—Dr. H. Schwarz.

Apparatus for the Technical Determination of Carbonic Acid and Carbonates.—Prof. R. Baur.—

Platinum Filters.—A. Gawalovski.—These papers all require the accompanying illustrations.

Ether Capsules.—A. Gawalovski.—Analysts who have to evaporate ethereal extracts, especially those of fatty oils, find that the last traces of the water present in the ether are difficult to drive off, either on the water-bath or in the air-bath. The author overcomes this difficulty by the use of very flat capsules of glass or porcelain with a diametrical ridge or dam in the bottom.

Reply to Herr Kissling's Public Challenge.—Dr. Skalkweit.—This controversy is of too little general interest for reproduction in the CHEMICAL NEWS.

The Determination of Arsenic.—Carl Holthof.—This memoir will be reproduced at considerable length at the earliest opportunity.

Conclusions of the Commission Nominated by the Imperial Sanitary Office for Agreeing on Methods for the Examination of Wines.—This paper does not admit of abridgment.

The Dependence of the Boiling-Point on Atmospheric Pressure.—G. W. A. Kahlbaum.—The author refutes the common assumption that a reduction of pressure equal to 1 centimetre corresponds to a reduction of the boiling-point by 1°.

Tension of Mercurial Vapour at Low Temperatures.—H. McLeod and R. Warder.—From the CHEMICAL NEWS.

Apparatus for the Reduction of Measured Volumes of Gases to the Normal Condition.—U. Kreusler.—This paper requires the two accompanying figures.

A Thermo-regulator.—V. H. Veley.—From the *Journal of the Chemical Society*.

Improved Apparatus for Evaporating Liquids in a Vacuum.—H. McLeod.—From the *Journal of the Chemical Society*.

A Pressure-flask for the Saccharification of Starch.—F. Allihn.—This apparatus cannot be intelligibly described without the accompanying illustration.

Closing Absorption-Tubes.—R. Muencke.—The author uses ground glass stoppers which are hollow and have a lateral orifice. The arrangement is quite analogous to that proposed by Chancel for his apparatus for determining the specific gravity of gases.

Self-acting Apparatus for Filtration and Washing.—E. E. Robinson.—From the CHEMICAL NEWS.

An Improved Refrigerator.—F. Simand.—This apparatus can be used without alteration either in distilling or as a cohobator.

Preparation of Pure Hydrochloric Acid.—G. Giudice.—To the sulphuric acid used for liberating the hydrochloric gas is added a small quantity of an oxidising body (potassium dichromate or permanganate, pyrolusite, &c.), and the gas before absorbing it in water is washed in mercury. The object is to prevent the formation of sulphurous acid and to keep back bromine, iodine, and arsenic chloride.

Determination of Potassium and Sodium in the Ashes of Plants and in similar Substances.—C. Richardson.—The author shows that the method used for separating the alkaline chlorides from the ashes of plants does not yield them in such a state of purity that the respective proportions of sodium and potassium can be determined from the chlorine present. The alkaline chlorides are frequently accompanied by phosphoric acid and magnesia, which latter ingredient can be entirely removed only in the absence of the more energetic acids. To this end the author dissolves the ash in nitric acid, evaporates repeatedly with addition of nitric acid to expel all chlorine, takes up in water, adds a few grms. oxalic acid, evaporates again once or twice on the water-bath, and igni

The residue, consisting of carbonates, phosphates, and sulphates, is dissolved in water and filtered, through the smallest filter possible. The filtrate is then mixed with a slight excess of barium hydroxide, boiled up, and filtered. The solution then contains merely the alkalies as hydroxides and the excess of baryta. In order to remove with certainty any remaining traces of magnesia the solution is once more evaporated to dryness, the residue repeatedly extracted with small quantities of water, each not exceeding 5 c.c., and filtered through a filter of 7 centimetres in diameter. To the filtrate is added a boiling solution of ammonium carbonate; it is evaporated to dryness, redissolved in water, and filtered into a weighed platinum capsule. The carbonates are converted into chlorides by the addition of hydrochloric acid. If, after evaporation and gentle ignition, there appears a carbonaceous residue, it must be removed by filtration. The alkaline chlorides thus obtained are perfectly pure and fit for the determination of the chlorine. By means of this method the author found in the ashes of many plants far lower proportions of soda than had been obtained in former analyses. He justly ascribes this result to the circumstance that on determining the potassium as potassium-platinum chloride in impure alkaline chlorides all the impurities are calculated as soda.

Detection and Determination of Titanium.—A. Weller.—This paper will be inserted in full.

Electrolysis of Bismuth.—The electrolytic determination of bismuth, according to C. Luckow, A. Classen, M. A. von Reis, and Schucht, is attended with some difficulties, since the metal is not always separated in a compact state, and some peroxide is easily deposited at the positive electrode. To obviate these inconveniences H. W. Thomas and E. F. Smith perform the operation in the solution of the sulphate, in the alkaline solution of the citrate, or in the solution of the latter in presence of free citric acid. The authors employed a solution of bismuth sulphate containing in 10 c.c. 0.03 to 0.04 grm. bismuth and very little free sulphuric acid, and introduced it into a small platinum crucible surrounded by a strong copper wire in connection with the positive pole. The current is generated by a bichromate battery of three elements and the action lasted for three hours. On interrupting the circuit the liquid was without delay emptied out of the crucible, and the bismuth, which had been completely deposited in a compact form, was washed with water and alcohol, dried, and weighed. When larger volumes of liquid were used, such as 100 c.c. containing 0.03 to 0.04 grm., the authors placed the solution of bismuth sulphate in a beaker in which the platinum crucible connected with the negative pole was immersed, whilst a platinum wire connected with the positive pole was led under the crucible. The current was interrupted after five hours, when the entire bismuth was found deposited in a compact form on the outside of the crucible. Similarly successful results were obtained with solutions of bismuth citrate mixed either with soda-lye or with free citric acid. The application of heat does not accelerate the precipitation of bismuth. Peroxide was deposited only in a few cases when the current was too feeble, which, however, always disappeared again before it was interrupted.

Determination of Molybdenum.—Otto Baron von der Pfordten.

Determination of Phosphoric Acid.—Otto Baron von der Pfordten.—These two papers will be inserted at length.

Determination of Chlorine, Sulphuric Acid, and Chrome, in Presence of Organic Matter.—O. T. Pomeroy.—The determination of chrome in presence of organic matter is practicable only if such matter is destroyed by fusion with sodium carbonate and saltpetre. But as a part of the nitrate is thus converted into nitrite, after acidifying a part of the chromic acid is reduced and chromium chloride is formed, which interferes with the determination of chlorine by means of silver nitrate. The

determination of sulphuric acid is also inaccurate in presence of chromic acid. It is therefore necessary after the destruction of the organic matter to convert the chromic acid entirely into chromium oxide, and to remove it before determining the chlorine and the sulphuric acid. The authors effect this reduction by means of nitric acid and a nitrite. The watery solution of the melt is mixed with potassium, sodium, or ammonium nitrite, and with an excess of nitric acid. After standing for about twelve hours in the cold the mixture is supersaturated with ammonia, boiled, and the precipitated chromium hydroxide is determined as usual. After the filtrate has been again acidified with nitric acid the sulphuric acid is precipitated with barium nitrate. It is necessary to purify the barium sulphate by fusion with sodium carbonate and to re-precipitate the sulphate. In the filtrate the chlorine is then determined in the ordinary manner. If only sulphuric acid and chrome have to be determined the reduction of the chromic acid by means of a nitrite and nitric acid can be effected at a boil, and takes place then immediately. The author recommends this method also for the examination of commercial chrome-yellow. The lead, even though present as sulphate or chloride, dissolves perfectly after adding a sufficiency of sodium nitrite and nitric acid and boiling the mixture. The author prepares pure sodium nitrite, free from sulphates and chlorides by heating pure saltpetre for some time to a red heat in a closed iron vessel, dissolving the mass in water and filtering. He purifies crude sodium nitrite by dissolving in water, filtering, precipitating sulphuric acid if present with barium nitrate, removing the latter with sodium carbonate, acidifying the filtrate with nitric acid, and heating with the occasional addition of small quantities of the latter acid until the liquid is free from chlorine. It is then neutralised with sodium carbonate and allowed to crystallise.

A Reaction for Alcohol.—It has been proposed to bring the substance in question into contact with a solution of molybdic acid in strong sulphuric acid, when the presence of alcohol is indicated by a fine blue colouration. Messrs. Gladstone and Tribe have shown that this reaction is inconclusive, since a series of other reducing agents produce the same effect.

A New Colour Reaction of Amylic Alcohol.—M. Vitali.—Equal volumes of amylic alcohol and sulphuric acid produce at common temperatures a dirty red colouration. If the quantity of amylic alcohol is doubled, the colour becomes cherry-red and then violet. Five to six additional volumes of amylic alcohol give an azure blue colour, and larger proportions of amylic alcohol produce a green. An addition of ether makes the colours more brilliant. If the green liquid is evaporated it takes again a blue and a violet colour, especially on the sides of the capsule. If upon a small quantity of sulphuric acid there is poured amylic alcohol, and if the acid is cautiously stirred with a glass rod the colours appear in the same order as more and more amylic alcohol mixes with the sulphuric acid. In this manner the reaction can be used in testing alcohol for fusel oil in Betelli's method to demonstrate that the residue obtained by shaking up with chloroform is really a mylic alcohol.

Detection of Glycerin and Lignine.—C. Reichl.—The author utilises the colours which these substances give when treated with pyrogalllic acid and stannic chloride. If a little of the substance supposed to contain glycerin is boiled with a little pyrogalllic acid, a few drops of sulphuric acid, previously diluted with an equal volume of water, if the smallest quantity of glycerin is present, there appears a distinct red colouration, which turns to a fine violet-red on the addition of a solution of stannic chloride. Carbohydrates and certain alcohols must not be present, as they produce similar colourations. Lignine takes a fine violet colour colour if boiled with pyrogalllic acid and stannic chloride. Pure cellulose remains colourless.

Bettel's Process for the Determination of Nitrogen.—H. Bungener and L. Fries.—These authors have modified Bettel's apparatus in a manner which Fresenius does not think advantageous.

Colorimetric Determination of Grape Sugar in Presence of Cane-Sugar.—A. Vivien.—The author dissolves 10 grms. of the sample in 200 c.c. water, adds 10 c.c. of a copper solution for the reduction of which 10 milligrams of grape sugar are required, and boils. Complete decoloration occurs only if at least 10 milligrams, i.e., 0.1 per cent of grape sugar is present. If only smaller quantities exist in the mixture the colour of the liquid is compared with that of 10 liquids similarly treated, containing respectively 0, 1, 2, &c., milligrams of grape sugar.

Determination of Tannin.—E. Johanson.—The precipitation of tannin by a solution of gelatin is effected more completely and in a better condition for filtration, if, besides ammonium chloride, as proposed by Schulze and Lehmann, there is also added a small quantity of chromium sulphate or of chrome-alum. The author proceeds in the same manner as Lehmann, but he adds to 100 c.c. of the solution containing sal-ammoniac from 5 to 8 drops of a solution containing 1 part chromium sulphate in 25 parts of water. In order to ascertain the end of the reaction he filters small quantities into two test glasses of equal width, adds to the one a few drops of a solution of gelatin, observing if the two liquids, when held up against a sheet of black glazed paper, appear opaque or transparent. As long as a precipitate is formed these portions and the washings of the little filters are poured back to the main quantity. If acetic or tartaric acid is present the liquid should be neutralised before proceeding to the determination. Johanson points out that though this method gives good results with the tannin of galls and of oak-bark, an extract of coffee gives no precipitate with solution of gelatin, so that cafeeo-tannic acid cannot be determined in this manner. This shows that only quantities of tannin of one and the same kind can be compared with each other.

Analysis of Milk.—J. Uffelmann.—Fuchs had previously shown that the presence of nitric acid in milk indicates the previous addition of an impure water contaminated with nitric acid. Uffelmann has further worked out this method so as to take cognisance of ammonia and nitrous acid. He mixes 350 c.c. of milk with dilute acetic acid until the casein is entirely thrown down; 100 c.c. of the filtrate are mixed with three drops of hydrochloric acid, boiled up, let cool, and filtered. Of this new filtrate 50 c.c. are rendered faintly alkaline with pure potassa-lye, filtered, distilled, and the distillate is tested with Nessler's reagent. To the remaining 50 c.c. are added sodium hydroxide and carbonate, the mixture is filtered, and tested with Nessler's reagent. The residue of the liquid filtered from the acetic acid precipitate is boiled and filtered. 30 c.c. are tested with meta-phenylen-diamine (diamidobenzol) another 30 c.c. with zinc-iodide-starch paste for nitrous acid. The remainder is utilised for detecting nitrates by means of diphenylamin. A little crystalline diphenylamin is dissolved in a white capsule in about 1.5 c.c. of pure sulphuric acid (full strength) and 3 to 4 drops of the milk filtrate are added. In presence of much nitric acid there is formed almost instantly a blue zone, which quickly extends. If there is little nitric acid, the colour appears only after some time. If the blue colour does not appear the experiment is successively repeated with portions of the milk-filtrate, concentrated respectively to one-third, one-seventh, and one-tenth of the original volume. Neither ammonia, nitric nor nitrous acid, is present in normal milk, but all three may be introduced by sophistication with impure well-water.

Examination of Confectionery and Fruit Syrups.—E. Johanson.—In mixtures obtained by boiling down acid liquids with cane-sugar the author found that 15 to 20 per

cent and even more of the saccharose was converted into reducing sugars.

Cocoa and Chocolate.—M. Boussingault.—This paper contains nothing new from an analytical point of view.

Examination of Beer.—E. Johanson.—The author maintains that the consumption of recent beer is injurious to health. He states that such beer is scarcely rendered turbid by potassium mercuric iodide, whilst beers which have remained in store for three months give flocculent precipitates with the same reagent.

Examination of Lubricating Oils.—W. Fox.—From the *Analyst*.

Genuine Cod-liver Oil.—H. Meyer.—The author mixes in a stoppered glass 10 parts of the sample with exactly 1 part of a mixture of equal parts of strong sulphuric and nitric acids. The pure oil of *Gadus morhua* turns to a fiery rose, and then quickly to a lemon-yellow. That of the "haak-jaerring" turns also to a rose, but then to a brownish violet. The oils of the remaining *Gadida* turn also yellowish, but of a less pure tone. This reaction is to be applied with caution, as all colour reactions of oils are modified by a variety of circumstances.

Contributions to the Chemistry of Lignification.—C. F. Cross and E. J. Bevan.—From the *Journal of the Chemical Society*.

Determination of Phosphoric Acid in Arable Soils.—P. de Gasparin.—Already noticed under *Comptes Rendus*.

Determination of Reverted Phosphoric Acid.—Brief mention of a number of memoirs.

Azotometric Examination of Ammoniacal Manures.—Marek Massalski.—Noticed under *Bulletin de la Soc. Chimique de Paris*.

Detection of Arsenic in Ferrum Pulveratum.—H. Beckurtz and O. Schlickum.—No particulars are given.

Examination of Potassium Bromide.—G. Vulpis.—The author proceeds iodometrically: 0.10 gm. of the sample and 2 grms. potassium iodide are dissolved in 5 grms. hot water in a beaker; 10 grms. cold distilled water and 15 grms. of pure hydrochloric acid at 25 per cent are added, and finally the iodine liberated is either titrated directly with sodium hyposulphite or an excess of the latter is added and titrated back with iodine and starch.

Examination of Tartaric and Citric Acid.—R. Otto.—The presence of gypsum in tartaric acid is more distinctly shown by means of ammonium oxalate if the acid has been approximately neutralised with ammonia. With citric acid the reverse holds good. Sulphuric acid is more readily detected by means of barium nitrate, both in tartaric and citric acids if they have not been neutralised. For the detection of tartaric acid in citric acid Push beats 1 gm. of the pulverised sample with 10 grms. pure sulphuric acid in a dry test-tube for an hour. The tube is placed in a water-bath heated almost to a boil. The sample melts to a lemon-yellow liquid, and if pure retains this colour for an hour. If even half per cent tartaric acid is present the liquid becomes brownish in thirty minutes, and in an hour reddish brown.

Valuation of Radix Belladonnæ.—Prof. Redwood.—From the *Pharmaceutical Journal and Transactions*.

Detection and Determination of Iodine in Urine.—E. Harnack.—For the detection of iodine in urine the author recommends a combination of the starch and the carbon disulphide methods. In case of minute traces of iodine, where the simple starch tests gives no colouration, if carbon disulphide is simultaneously present, there is gradually formed a narrow ring of colour where the two liquids come in contact.

Alkaline Bismuth Solution as a Reagent for Starch Sugar in Urine.—E. Nylander.—The author dissolves 2 grms. basic bismuth nitrate and 4 grms. Seignette salt in 100 grms. of a soda-lye containing 8 per cent sodium

oxide, filtering off any undissolved bismuth salt. One part of this reagent must be added to 10 parts of the urine.

Robert's Process for Determining Starch-Sugar in Urine.—W. Müller.—In this process the sugar is calculated from the decrease of density in the urine after fermentation with yeast. Müller finds that by this process the sugar can be determined to 0.5 per cent. The specific gravity must be determined by means of the pycnometer.

Detection of Morphine in Animal Tissues and Excretions.—In some cases morphine is converted in the living animal into oxy-dimorphine, a more poisonous substance, which produces symptoms differing from those of morphine, and resembling rather those met with in arsenical poisoning.

Determination of Albumenoids in Human Milk.—E. Pfeiffer.—The author's researches relate to the precipitation of caseine by acids, and to the determination of the total albumenoids according to the methods hitherto proposed.

Determination of Chloroform in the Blood of Animals which have been subjected to Anæsthesia.—MM. Gréhan and Quinquaud.—From the *Comptes Rendus*.

Examination of Blood-spots.—C. Husson.—From the *Comptes Rendus*.

On Ptomaines.—A collection of references to the *Comptes Rendus* and the *Berichte der Deutsch Chem. Gesellschaft*.

Bulletin de la Société Chimique de Paris.
Vol. xlii., No. 3, August 5, 1884.

New Method for the Synthesis of Nitrogenous Organic Compounds: Synthesis of Xanthine and Methyl-xanthine.—M. Arm. Gautier.—In order to produce xanthine and methyl-xanthine the author heats a mixture of hydrocyanic acid, water, and acetic acid, the last body in such quantity that the liquid may not become alkaline, it being merely requisite to saturate the ammonia which tends to form. When the operation has succeeded, the contents of the tubes are maroon or reddish brown, and is composed of two portions. The one, soluble in cold water, contains aldehydic acids of a very interesting constitution, which the author is examining, and a yellow matter soluble in alcohol, which becoming oxidised in the air gives a slate-blue substance, the potassic solution of which stains paper a splendid indigo-blue. This same solution, if made in the cold and treated with hydrochloric acid in excess, deposits gradually on exposure to the air a compound in purple microscopic crystals with a golden-green reflection. This is a feeble acid, probably diatomic. The portion insoluble in cold water is taken up in boiling water acidulated with acetic acid. On cooling there is formed a precipitate which is boiled, re-dissolved in hydrochloric acid, neutralised with ammonia, filtered to separate impurities, and finally treated with copper acetate. On boiling there is deposited a mixture of copper xanthate and methyl-xanthate. If in the reaction above described there are substituted for water the mono-atomic or poly-atomic alcohols, the acetones, aldehydes, phenols, &c., or if in turn there are substituted for hydrocyanic acid the various carbylamines we obtain an almost indefinite series of new bodies, basic, acid, or neutral. The author considers that the mechanism of the syntheses of which a sketch has been given appears very similar to, if not identical with, that which takes place in vegetables.

Sterilisation of Fermentible Liquids in the Cold.—A. Gautier.—After pointing out the inconveniences of sterilisation by heat, the author proposes filters made of porcelain, deprived of its glaze, or of earthenware in the form of bottles with long, narrow neck. The bottom of the filter-bottle has the shape of an inverted cone. A thick glass tube penetrates by the neck down to the bottom;

above the neck it is bent at a right angle, and ends in a conical point ground with emery. The tube is cemented to the neck of the bottle by a lead boro-silicate, consisting of crystalline boric acid 8 parts, silica 2 parts, red lead 12 parts. These substances are melted together, pulverised finely, worked up with oil of turpentine, applied with a brush to the part which is to be cemented, and heated to redness. The bottle, when thus connected and thoroughly "flambée" on Pasteur's method, is exhausted of air and plunged into the liquid to be filtered, which passes from without inwards. The properties of various organic fluids are much modified after filtration. We may hence infer the alterations which the plasmas of the organic economy must undergo after filtration by endosmosis through animal or vegetal membranes.

A New Alcohol, extracted from Bird-lime.—J. Personne.—The new compound, illicic alcohol, has the composition $C_{50}H_{44}O_2$. It is insoluble in cold water, slightly soluble in dilute ethylic alcohol, soluble in almost all proportions in ethylic alcohol at 90° per cent; fuses at 175°, and boils at 350°.

In a few days, with Lithographic Plates and Wood Engravings,
8vo., 24s.

INORGANIC CHEMISTRY.

BY

EDWARD FRANKLAND, Ph.D., D.C.L., LL.D., F.R.S.

Professor of Chemistry in the Normal School of Science.

AND

FRANCIS R. JAPP, M.A., Ph.D., F.I.C.

Assistant Professor of Chemistry in the Normal School of Science.

London: J. and A. CHURCHILL, 11, New Burlington Street.

CHEAP PHYSICAL APPARATUS.

Elementary Instruction in the Experimental Sciences.

Teachers in want of Apparatus for performing experiments to illustrate the Principles of the Physical Sciences, are referred for information to GRIFFIN'S CATALOGUE for Schools and Colleges.

PRICE 3d., POST FREE.

Sixth Edition, entirely Re-written, and prices reduced to date.

JOHN J. GRIFFIN & SONS, 22, GARRICK STREET, W.C.

UNIVERSITY COLLEGE, BRISTOL.

CHEMICAL DEPARTMENT.

PROFESSOR—W. RAMSAY, Ph.D.
LECTURER—SYDNEY YOUNG, D.Sc.

The SESSION 1884-85 begins on 7th OCTOBER. Lectures on Inorganic, Organic, Advanced, and Technical Chemistry will be delivered during the Session. The Laboratories are fitted with the most recent improvements for the study of Practical Chemistry in all its branches. In the evening, Lectures on Inorganic Chemistry at reduced fees are delivered; and a Special Course of Lectures on Technical Chemistry is also given, with the co-operation of the Worshipful Company of Clothworkers. A Correspondence Class especially adapted for those engaged in the Clothworking and Dyeing Industries will begin in October. Several Scholarships are tenable at the College. Calendar, containing full information, price 1s. (by post 1s. 3d.) For prospectus and further information apply to the Registrar.

UNIVERSITY COLLEGE, DUNDEE.

THE WINTER SESSION will BEGIN on
MONDAY, 13TH OCTOBER.

All Departments, comprising both Day and Evening Classes, are Open to Both Sexes on the Same Terms. The Laboratories are equipped with every requisite for Study and Research; and special Facilities are offered for Instruction in Electrical Engineering.

The College is recognised by the University of Edinburgh for Graduation in Science to the extent of Two out of the Three Years' Course required. The various Courses are suitable for the Degree Examinations of the University of London, and for the L.L.B. Certificate of St. Andrews.

The Calendar, containing Full Information, may be had from the BOOKSELLERS, or from the Undersigned, price 1s. by post.

SHIELL & SONS, Secretaries.

THE "YOUNG" CHAIR OF TECHNICAL CHEMISTRY, ANDERSON'S COLLEGE, GLASGOW.

PROFESSOR EDMUND J. MILLS, D.SC. (LOND.), F.R.S.

SESSION 1884-85.

This Chair has for its object the instruction of Students in Chemistry as applied to the various branches of industry in Chemical and other works, Metallurgy, Agriculture, &c.

Lectures.—Principal Course.—A Course of Twenty-five Lectures will be delivered on Mondays, Tuesdays, and Wednesdays, at 10 a.m., commencing on November 3rd. These Lectures mainly relate to the applications of Higher Chemistry in General Chemical Technology. Fee, One Guinea.

Subsidiary Course.—A subsequent Course of Thirty Lectures will be delivered on Mondays, Tuesdays, and Wednesdays, at Ten a.m. These Lectures are more particularly intended for Dyers, Colour Manufacturers, Brewers and Distillers, Tar Rectifiers, Drysalts, and others interested in a knowledge of TECHNICAL ORGANIC CHEMISTRY. Fee, Two Guineas.

Evening Courses.—Professor MILLS will deliver a special Evening Course of Twenty-five Lectures on OILS, PAINTS, and VARNISHES. Fee, One Guinea. For further particulars see special Prospectuses.

Popular Industrial Lectures.—A short set of Industrial Lectures, each on a special subject, is in course of arrangement. These Lectures are for Working Men only. Fee, 6d. Full Press Announcements will duly be made.

EVENING PRACTICAL CLASSES.—There will be Practical Evening Classes in the following subjects, viz.:—OILS, PAINTS AND VARNISHES; BLEACHING, DYEING, AND PRINTING; IRON AND STEEL; and WATER SUPPLY AND SEWAGE. The assistance of this Chair is placed at the disposal of all classes of Students of Technical Chemistry; and any person will be eligible for the Practical Evening Class who is desirous of learning, of improving his learning, or of perfecting some invention in any branch of Technical Chemistry. Time, 6.30–9 p.m., on October 16, and following Thursdays. Fee for the Course of Twelve Lessons, Two Guineas.

LABORATORIES.—The Laboratories are open daily throughout the year from 10 to 4, and on Saturday from 10 to 1 o'clock, for practical working by the Students, under the superintendence of the Professor and his Assistants. The Fee for attending the Laboratories is £20 per Session of Nine Months, £14 10s. for Six Months, £7 10s. for Three Months, or £2 10s. per Month. Students must have a fair acquaintance with Elementary Chemistry.

The Trustees, having had under consideration the requirements of Inventors, Patentees, and others whose investigations require isolation and privacy, as well as professional advice, have included in the arrangements Five Private Laboratories, which have met a demand not previously supplied in this country. Electric Cable has been laid to these Laboratories for the supply, if required, of adequate power.

Further Information may be obtained of the Professor, at the Laboratory, Anderson's College, 60, John Street.

Assistant.—Mr. C. ELLIS, F.C.S.

Glasgow, 128, Hope Street,
September, 1884.

ALEX. MOORE, C.A.,
Secretary.

VOL. L. No. 1299.

ON THE BOILING-POINT OF HYDROGEN.

By EDMUND J. MILLS, D.Sc., F.R.S.

In a recent memoir (*Phil. Mag.*, [5] xvii., 173) I showed that the boiling-point y of any member of a homologous series is related as follows to the coefficient x of C in its formula,—

$$y = \frac{\beta(x-c)}{1+\gamma(x-c)},$$

c being the value of x to which zero Centigrade corresponds, and β , γ constants depending on pressure and other conditions. Thus, the equation to the series of olefines in which x is even is—

$$y = \frac{40.709(x-4.228)}{1+0.060123(x-4.228)}$$

Putting $x = 2$, $y = -104.7^\circ$, the calculated boiling-point, at the ordinary pressure, of common olefiant gas. Olzewski (*Comptes Rendus*, xcix., 133) has since found that olefiant gas boils at -103° under a pressure of 750 m.m.

The satisfactory character of this result has induced me to calculate the boiling-point of hydrogen. It is perfectly clear, and has been long since supposed, that hydrogen (H_2) is, or may be, the "origin" of the series of paraffins, C_nH_{2n+2} . In the memoir referred to, the boiling-points of the normal paraffins were discussed, and equations found for them. There are in all four series to deal with, viz., the even and odd series under ordinary pressure, and the same series under a pressure of 15 m.m., the latter having been worked out by Krafft.

The equation for the even series is—

$$y = \frac{39.315(x-3.94)}{1+0.070753(x-3.94)}$$

and for the odd series,—

$$y = \frac{38.992(x-3.92)}{1+0.070564(x-3.92)}$$

Under 15 m.m., the equation to the even series is—

$$y = \frac{23.154(x-7.1)}{1+0.035484(x-7.1)},$$

and to the odd series—

$$y = \frac{21.685(x-6.77)}{1+0.030437(x-6.77)},$$

When in each of these four equations we put $x=0$, the results are—

	y .
Even	-214.77
Odd.	211.29
Even (15 m.m.) ..	219.76
Odd (15 m.m.) ..	184.91

The discordance between the results for the odd series, as compared with those of the even series, shows that hydrogen is certainly not the origin of the odd series of paraffins. The two results, however, for the even series amply support each other, and show the boiling-point of hydrogen to be about -215° C.

Messrs. Wroblewski and Olzewski are understood to be separately engaged in the investigation of this subject. According to the former (*Comptes Rendus*, xcvi., 952) oxygen and nitrogen boil respectively at -184° and -193°

under the ordinary pressure, and the temperature at which hydrogen liquefies is not greatly distant from -184° . These temperatures were measured thermo-electrically. Olzewski, who uses a hydrogen thermometer, has also liquefied hydrogen, and alleges that he has measured a temperature of -213° C. (*ibid.*, xcix., 134.)

The question will probably be settled at an early date; but it is clear that the experimental number is not likely to differ greatly from -215° C.

Glasgow, Sept. 29, 1884.

ESTIMATION OF TANNIC ACID BY CARBONATE OF LEAD.

By ROBERT JACKSON, F.C.S.

AN easy and satisfactory method of determining the amount of tannin in the materials used in the manufacture of leather, or in the liquors in operation in tanneries, not having been yet devised, I beg to submit the results of a few experiments on the subject, which may be of use to tanners and others not sufficiently skilled to obtain satisfactory results by Lowenthal's method.

50 grms. of English oak-bark were exhausted by four successive boilings in distilled water, and the extract made up to a litre at 60° F.: the density was 1003.86. Dry powdered carbonate of lead was then added, and the liquid shaken occasionally for two or three hours: the density of the clear filtrate was 1001.52, giving a loss of density of 2.34.

Previous experiments showed that 1 per cent of tannic acid in distilled water at 60° F. gave a density of 1003.8, and higher and lower amounts proportional densities.

Taking the loss of density of the bark extract 2.34, dividing by 3.8, and multiplying by 20, shows 12.30 per cent removed by carbonate of lead. A sample of good Irish oak-bark similarly treated gave a density of 1004.70, before the addition of the carbonate of lead, and 1001.68 after, showing a loss of 3.02.

$$\frac{3.02}{3.8} \times 20.0 = 15.88 \text{ per cent}$$

The following are the results obtained on treating various other samples by the same process.

The solutions are all of 5 per cent strength, with the exception of the tan liquors, which were tried as received.

Material.	Density.	After Lead.	Per cent.
Valonia	1009.08	1003.33	30.2
Sumach	1008.25	1003.61	24.4
"	1009.61	1005.08	23.8
Oakwood extract, 27 B...	1007.33	1003.15	21.9
" " 29 B...	1007.20	1002.47	24.8
" " 29 B...	1007.66	1002.80	25.5
Chestnut extract, 20 B...	1006.06	1002.48	18.8
" " 26 B...	1007.68	1003.12	24.0
Tan liquor	1019.16	1012.86	1.65
"	1019.15	1012.52	1.74
"	1019.20	1012.32	1.81
"	1007.26	1005.06	0.57

The insoluble matter in the oakwood extracts varies from 6 to 9 per cent.

18, Harrington St., Dublin.

The Antiseptic Properties of Carbon Disulphide.—Ckiani Bey.—Carbon disulphide is soluble in water to the extent of 0.50 gm. per litre. The solution arrests all fermentations and kills microbes. During twenty years' experience the author has never known a case of paralysis among the workmen constantly exposed to the fumes.—*Comptes Rendus*.

PROPOSALS FOR UNIFORM METHODS FOR THE DETERMINATION OF NITROGEN.

Translated and Contributed by H. H. SHEPHERD.

At the instance of the German Manure Manufacturers' Association a General Meeting of Chemists was held in Wiesbaden at the end of last May under the presidency of Prof. Fresenius, to consider the proposals for uniform methods for nitrogen determination brought forward by the Commission appointed at the Hamburg Meeting of German Manure Manufacturers. The report was laid before the meeting by Dr. O. Pieper, of Hamburg, and the proposals were accepted in the following terms:—

A. Preparation of the Samples.

The entire sample is to be reduced to as fine a degree as possible and carefully mixed. Dry samples to be so finely powdered that they will completely pass through a sieve of 1 m.m. meshes. Damp samples, such as sulphate of ammonia, nitrate of soda, &c., which cannot be sifted are to be simply rubbed fine in a mortar and well mixed up. The unused portion of the sample to be kept in a well-closed glass bottle for eventual reference.

If the material is coarse and irregular, 400 grms. at the least must be sent for analysis, and, if fine and uniform, at

nia by means of calcined magnesia. The apparatus shown in the following sketch serves for this purpose.

In using the apparatus the following precautions must be observed: (1). That the steam containing the ammonia be condensed by cooling as it passes over; (2). That the tube of the condenser does not dip beneath the sulphuric acid in the flask; and (3). That the complete absorption of the ammonia be secured by the use of a small U-tube.

Ten grms. are dissolved in a half litre of water free from ammonia. The normal acid coloured with cochineal is introduced into the two receivers in the proportion of about 18 c.c. in the flask to 2 c.c. in the U-tube. The receivers are then tightly fixed to the apparatus, and two grms. of calcined magnesia, 25 c.c. of water, and 50 c.c. of the prepared solution = 1 gm. of substance introduced into the distilling flask. (Solution of soda is on no account to be used for distilling off the ammonia). The flask being then tightly fixed to the apparatus, its contents are heated to boiling by a lamp placed underneath and distilled nearly to dryness. During the distillation a slow stream of cold water is allowed to flow through the condenser. The distillation proceeds regularly without any bumping and needs no further attention. At the conclusion the stopcock of the distilling flask is opened and a slow stream

least 200 grms. Should, however, a still larger sample be sent, it is to be carefully mixed and either 400 grms. or 200 grms. taken as the case may require.

B. Determination of Nitrogen.

Nitrogen is usually determined by conversion into ammonia and titration. For the acid, normal or half-normal sulphuric acid is recommended, and for the alkali, a half-normal soda solution, an ammonia solution, or baryta water. The two last-named solutions must, however, in no case be stronger than half-normal.

For the indicator we recommend tincture of cochineal, which is best prepared in the following manner: six grms. of cochineal are finely powdered and digested for several hours at the ordinary temperature with half a litre of a mixture of 300 c.c. water and 200 c.c. alcohol. The solution is then filtered through a Swedish filter and preserved in well-stoppered bottles.

I. Sulphate of Ammonia.

This determination is effected by distilling off the ammo-

of air drawn through the apparatus by suction from the U tube.

(a). The determination can also be made by means of the azotometer.

(b). Further, the method of combustion with soda-lime with the addition of sugar in a tube 34 c.m. long is thoroughly trustworthy if care be taken with the manipulation.

II. Organic Nitrogen, e.g. Blood, Horn, &c.

The determination is effected by combustion with soda-lime in the usual combustion-tubes of hard glass.

A few grms. of the sample prepared according to the instructions given in A are rubbed to the finest powder in an agate mortar. Of this, 0.7 gm. if the substance be rich in nitrogen, or 1 gm. if poor in nitrogen is accurately weighed out.

The combustion-tube may conveniently have a length of 41 c.m. and an internal diameter of 1.1 c.m. It is filled as follows:—Sufficient finely powdered soda-lime to form a layer 10 c.m. long is first introduced, then the weighed

portion of the substance for analysis followed by more fine soda-lime sufficient to form a layer about 4 c.m. long. The soda-lime and substance are then intimately mixed together by means of a clean copper wire, taking care that a layer of pure soda-lime about 5 c.m. long remains undisturbed at the end of the tube. The mixture of substance and soda-lime ought only to occupy a length of from 8 to 10 c.m. in the tube. The tube is then filled up with coarsely ground soda-lime, a loose plug of ignited asbestos is inserted, and the U-shaped receiver containing about 14 c.c. of normal sulphuric acid attached to the glass tube by means of a caoutchouc cork. The combustion is to proceed slowly and from the front part of the tube to the end. When the coarse soda-lime in the front part of the tube thoroughly glows, the heating of the substance is commenced gradually, whilst at the same time a few small flames are lighted underneath the turned-up point of the tube. The combustion is to be conducted so that the bubbles pass through the sulphuric acid at regular intervals. It ought not to be prolonged beyond an hour. When properly carried out the sulphuric acid in the U-tube is never coloured. When the acid begins to recede the jets of flame are turned out, the point of the tube broken off, and air is sucked through the combustion-tube.

(a). The method of Kjeldahl (*Zeit. f. Analyt. Chemie*, 22, p. 366, *Chemiker Zeitung*, viii., No. 25) is also worth recommending, though further experience of it is needed.

(b). The use of iron combustion tubes cannot be generally recommended. They are only allowable with the modifications described by Prof. Paul Wagner (*Chemiker Zeitung*, viii., No. 37).

III. Determination of Nitric Nitrogen.

(a). Determination by difference. The technical method used for nitrate of soda.

The moisture is determined by drying at 120° C., the murate by titration with a decinormal silver solution, the sulphate of soda and any insoluble residue by gravimetric analysis. The difference gives the nitrate of soda.

(b). By expelling the nitric acid by fusion with silica or acid chromate of potash.

The nitre is first thoroughly dried at a temperature of 120° C., and the loss in weight (=moisture) ascertained. One grm. of the dried nitre is then intimately mixed with six grms. of ignited sand or eight grms. of fused bichromate of potash and the crucible and its contents accurately weighed. It is then heated for 30 minutes, but in such a manner that only a third part of the bottom of the crucible becomes red-hot. After cooling, the crucible and its contents are again weighed, the loss in weight corresponding to the amount of nitric anhydride contained in the nitre. It is, however, absolutely necessary to take the precaution of repeating the fusion and weighing.

(c). Siewert's method, depending upon the conversion of nitric acid into ammonia.

The apparatus recommended for the determination of ammonia is used. The two receivers are arranged as directed in I. Into the distilling flask are introduced four grms. of iron filings, 10 grms. of zinc powder, 12 grms. of sodic hydrate, 100 c.c. of 90% alcohol, and 50 c.c. of the solution of nitre—one grm. substance. The disengagement of hydrogen begins at once at the ordinary temperature; when, however, it commences to flag, the flask is to be warmed by a small flame, so that a uniform disengagement of gas takes place. When all the alcohol has distilled over, 20 c.c. more is to be run in through the funnel tube and likewise distilled off. To ascertain when the distillation is complete, the caoutchouc cork is loosened from the distilling flask and a strip of moistened red litmus paper squeezed in between the cork and the neck of the flask, observing if it still becomes blue. Should this be the case, 20 c.c. alcohol are again to be introduced and the distillation repeated.

(d). The Schlöesing-Grandeau method, modified and

simplified by Prof. Paul Wagner (*Chemiker Zeitung*, vii., 1710, and viii., 650).

This method depends upon the reduction of the nitric acid to nitric oxide by a hydrochloric acid solution of ferrous chloride, and calculating the nitrogen from the volume of gas obtained. The determination, when performed in the manner described by Prof. Wagner, superseding the use of mercury, and avoiding the necessity of regarding temperature and pressure, is not only rapid, but exact and accurate and much to be recommended.

IV. Ammoniacal and Organic Nitrogen.

The determination of the total nitrogen is accomplished by the method described under II. with this modification, that (especially with substances rich in ammonia) a much shorter combustion-tube (about 34 c.m. long) is used, and the substance is mixed with half a grain of finely powdered sugar. The combustion is to be accelerated as much as possible and can be finished in half an hour.

In ammoniated superphosphates the nitrogen is always to be determined in this way, not according to I.

Should separate determinations be required of the amount of nitrogen present as ready formed ammonia and that present as organic nitrogen, the former may be determined according to the method I., and the latter in the residue from the ammoniacal nitrogen determination by method II., after evaporation of the residue with sulphuric acid.

V. Nitric and Ammoniacal Nitrogen.

In mixtures containing both nitric and ammoniacal nitrogen, the ammoniacal nitrogen is first determined by distillation according to method I. The receivers are then re-arranged, iron filings, zinc powder, &c., added, and the nitric nitrogen determined by conversion into ammonia according to method III., C.

Or the ammoniacal nitrogen may be determined in one portion of the sample and the nitric acid in a separate portion by the process III., D.

VI. Organic Nitrogen in the presence of small quantities of Nitric Acid.

For this determination Ruffie's method is most to be recommended. The nitro-compounds are reduced and converted into ammonia by a mixture of wood charcoal, sulphur, and hyposulphite of soda (sodium thiosulphate). The process is conducted as follows:—Finely powdered soda-lime is intimately mixed with an equal weight of dry hyposulphite of soda; this mixture is held in readiness. The weighed portion of the substance for analysis is mixed with an equal weight of a mixture of equal parts of finely powdered wood charcoal and sulphur. Sufficient of the mixture of soda-lime and hyposulphite is first poured into the combustion-tube to form a layer of about 20 c.m. in length, this is followed by the mixture of substance, wood charcoal and sulphur, and lastly by some more of the mixture of soda-lime and hyposulphite sufficient to form a layer a few c.m. long in the tube. The whole is then well mixed together by means of a spiral copper wire in such a way that about 5 c.m. remains undisturbed at the beginning of the tube. The tube is then filled up with coarsely ground soda-lime. The combustion is conducted in the usual way. As the reagents used may easily contain some nitrogen it is necessary to make a "blank" combustion to ascertain the amount of the error due to this. The amount of the error to be deducted from the determination.

ACROLEIN-UREA.

By ALBERT R. LEEDS.

In the *Annalen der Chemie und Pharmacie* for 1869 (vol. lxxv., p. 203), Hugo Schiff has described, under the name of acroleinurea, a condensation product formed by the union of two molecules of urea with one of acrolein, in accordance with the reaction—

Without being aware of Schiff's labours, and whilst studying the aldehyd compounds with quite different objects than those followed by Schiff, I obtained the same compound, but had assigned to it a quite different formula. The explanation of these differences becomes apparent on studying the method by which Schiff prepared the compound, since this method did not and could not yield the substance in question. He mixed a concentrated aqueous solution of urea with acrolein, and after his acrylureid had gradually precipitated as small white needles (?) he washed it merely with ether and water, and dried *in vacuo*. He likewise states that powdered urea unites with acrolein directly. "The mixture swells up, and is converted into a white brittle mass, which in some places has an entirely crystalline appearance. By far the greatest portion is intimately mixed with a white porcelain-like product, formed by decomposition of the acrolein." The analysis of this body gave, as might readily have been expected, no satisfactory results. Schiff further states that in various preparations, some of which were prepared at ordinary and others at higher temperatures, he obtained carbon varying between 44 and 47 per cent, and hydrogen between 6.9 and 7.1 per cent. The formula of diacryltriureid requires 42.2 per cent carbon and 6.3 per cent hydrogen. That of acryldiureid, which Schiff adopted, but 38 per cent carbon and 6.3 per cent hydrogen.

Throughout his investigation Schiff worked upon impure substances, and in that way obtained not only varying results, but results which would support no rational formula, the one which he finally adopted—that of diacryltriureid—being altogether erroneous.

In the first experiment made by the author, the acrolein obtained by heating anhydrous glycerin with potassic bisulphate was allowed to distil over directly into an alcoholic solution of urea. A precipitate formed at once, and after a time a considerable amount was obtained, the urea, however, being still in excess. The filtrate was of a reddish colour, and on evaporation yielded a resinous or gummy mass, which could neither be sublimed nor crystallised from solvents. The precipitate left on the filter was of a yellow-white colour, but after repeated treatment with alcohol became quite white, and lost all of the gummy or thick oily substance at first adhering to it.

Its analysis showed that it had been formed by the union, not of two, but of one molecule of urea, with one of acrolein, a molecule of water being eliminated, and the resulting compound having the formula $\text{C}_4\text{H}_6\text{N}_2\text{O}$ or $\text{CO}(\text{NH})_2\text{C}_3\text{H}_4$.

	Found.	Theory.
Carbon	49.01	48.98
Hydrogen	6.3	6.12

Not only as originally prepared by repeated purification with alcohol, but also after treatment with carbon disulphide, chloroform, and ether, in all of which it is only slightly soluble, every attempt to obtain it in a crystallised condition was unsuccessful. It did not melt nor sublime, and when strongly heated underwent decomposition. It is readily attracted by nitric acid, but the products of the decomposition were not studied. From its solution in alcohol no precipitate was obtained on the addition of bromine. On treatment with hydrochloric, tartaric, and acetic acids no salts were formed.

The alcoholic extracts were collected, and yielded, after

successive solutions in alcohol and precipitation with water, a white substance similar to that above described, and having a melting-point of 185° . Since sufficient of this material could not be obtained to admit of its satisfactory purification and analysis, a much larger amount of urea in alcoholic solution than that used in the foregoing experiments (40 grms.) was treated with acrolein in successive portions in a closed vessel, until after long-continued warming the odour of acrolein ceased to disappear. In this case, unlike the foregoing, no precipitate was formed, nor did any take place until after the addition of water, when a very abundant white amorphous substance was thrown down. This was boiled with alcohol a great many times, each extract affording a white precipitate when diluted with water, and the portion of pure material obtained eventually was not more than that procured in the first instance, when but a small amount of urea was used and the acrolein was not added in excess. The composition of the substance thus obtained was—

and it was identical in all respects with the substance formed in the first case. From the alcoholic extracts no other substance could be obtained, and the explanation of the small yield of the pure acrolein-urea in the second case was eventually found to be due to the presence of the oily or gummy substance formed as a by-product. The amount of this by-product was apparently much greater in the second case, and explained the non-precipitation of the acrolein-urea until after the addition of water to the original solution of the urea in alcohol. And the tenacity with which it adhered to the acrolein-urea on precipitation with water, and carried it into solution again on each successive boiling with alcohol, explains the very small eventual yield of the pure material. It was also due to the small adherent traces of this oil that the second body, the one soluble in alcohol, had a melting-point of 185° , and was supposed to be something else than the acrolein-urea.

The presence of this oil, which I was unable to isolate, explains all the above difficulties and the erroneous results obtained by Schiff. In conclusion it may be safely stated that, besides the small amount of this oily by-product, the only compound formed by the action of acrolein on urea was that containing the residue from one molecule of urea, the compound $\text{CO}(\text{NH})_2 \cdot \text{C}_3\text{H}_4$.—*Journ. Am. Chem. Soc.*

ANALYSIS OF DRINKING-WATER FOR AMMONIA.*

By Dr. G. GORE, F.R.S.

1. THE object of this research was to render clear, by means of experiment, several points in the analysis of drinking-water. The water employed in the experiments was ordinary potable water of average quality, such as is usually supplied by the Birmingham Corporation Water Department. An analysis of it was made to determine the amount of organic matter in it, according to the method employed by Wanklyn and Chapman,† and the quantities of ammonia obtained were, "free" 0.026, and "albumenoid" 0.138 milligramme per litre or parts per million. (In each of the experiments of distillation described in this paper, small cubes of hard and highly-purified gas-carbon, of close texture, and previously ignited, were added to the water to prevent "bumping" during the process of boiling, and were found very efficacious and durable).

2. As the ammonia, termed "free" in the above process, was obtained by distilling the water after addition of carbonate of sodium, I distilled half a litre of the sample without such addition until fifty cubic centimetres had

* Read before the Birmingham Philosophical Society, June, 1884.
† See "Water Analysis," 5th edition, chapter IV.

passed over. I then added 2.0 c.c. of sensitive "Nessler's reagent" to the distillate, and stood the mixture twelve hours; only a mere trace of opacity or deposit occurred, showing that only a trace, not exceeding 0.002 m.grm. of ammonia, had distilled over.

3. To determine whether, if present in small quantity, ammonia uncombined with acids would come over freely in the first part of the distillate, I added to half a litre of the sample of water aqueous ammonia containing 0.5 m.grm. of absolute ammonia (H_3N), and distilled over 25 c.c., and found in the distillate 0.11 m.grm. of ammonia, showing that about two-tenths of the total amount of ammonia added had come over in the first one-twentieth part of the water. I also added to another half litre of the sample 0.05 m.grm. of ammonia, and distilled over 25 c.c. and tested; the distillate contained 0.019 m.grm. of ammonia, showing that with the more dilute solution about four-tenths of the ammonia had come over in the same proportionate amount of the water. I conclude, therefore, that if the water contains free ammonia (i.e., uncombined with an acid), a large portion of it comes over in the first one-twentieth part distilled, especially with very weak solutions, and that one part of free ammonia in ten million parts of water (and probably in 100 million parts) may be readily found by such means.

4. To determinate whether carbonate of ammonia, if present in the water in minute quantity, would yield free ammonia by simple distillation, I added to half a litre of the sample of water 0.10 m.grm. of transparent carbonate of ammonia (=0.0288 m.grm. of absolute ammonia), and distilled over 25 c.c. and tested; the distillate contained about 0.019 m.grm. of ammonia, or about two-thirds of the total amount added.

5. I also took half a litre of the original sample, distilled over 25 c.c., added Nessler's reagent, and stood six hours; scarcely a trace of ammonia was found. Meanwhile I added 4.0 c.c. of a solution of sal-ammoniac in perfectly pure water (see paragraph 7), containing exactly 0.01 m.grm. of ammonia per c.c., and distilled over 25 c.c. and tested; found 0.024 m.grm. of ammonia, or about three-fifths of the total amount added. Half a litre of the sample, to which had been added 0.10 m.grm. of sulphate of ammonium (=0.02575 m.grm. of ammonia), was treated in an exactly similar way, and gave 0.0125 m.grm. of ammonia, or about one-half the total amount added. And half a litre to which I had added 0.10 m.grm. of phosphate of ammonium (=0.02568 m.grms. of ammonia) gave by the same process 0.0120 m.grm. of ammonia, or half of the total amount added. The following table shows these results more clearly:—

M.grms. of absolute ammonia added.		M.grms. of am. distilled over.	Fracntl. part of total am. added.
0.5	as aqueous. am.	gave 0.11	=0.2
0.05	as "	" 0.019	=0.4
0.028	as carb. ammonm.	" 0.019	=0.66
0.04	as chloride "	" 0.024	=0.6
0.02575	as sulphate "	" 0.0125	=0.5
0.02568	as phos. "	" 0.0120	=0.5

6. The liberation of ammonia from these salts cannot be explained upon the assumption that the water contained in solution a small amount of alkaline carbonate, or of free alkali, because if such had been present the water would have yielded its ammonia by simple distillation without requiring a previous addition of carbonate of sodium (see paragraphs 1 and 2). It follows also from these results that any ammonia which comes over by simple distillation of such water may be derived either from ammonia or ammoniacal salts dissolved in the water.

7. To determine whether the ammoniacal salts added to the water were dissociated by the heat, I took some ordinary distilled water which I knew contained traces of ammonia, added a few drops of "pure" sulphuric acid to it, and distilled over a considerable quantity, which on

testing I found perfectly free from ammonia.* To one-fourth of a litre of this pure water in a retort I added 0.05 m.grm. of sulphate of ammonium (=0.01287 m.grm. of ammonia), and distilled over 25 c.c. and tested it with one 1.0 c.c. of Nessler's reagent; it gave 0.009 m.grm. of ammonia, or nearly three-fourths of the total amount added. I conclude from this result that the ammoniacal salt in this case was dissociated.

8. I subsequently found some compounds containing ammonia, the aqueous solutions of which did not yield ammonia by simple distillation. A solution of chloride of aluminium in pure water gave on distillation not a trace of ammonia, but on distilling it after addition of pure carbonate of sodium it yielded ammonia freely. Also a solution of sulphate of aluminium, or of purified potash-alum, yielded no ammonia on distillation, but gave it freely by distillation after addition of a solution of potash (quite free from ammonia), added in sufficient quantity to re-dissolve all the precipitate. In the "pure" hydrochloric and sulphuric acids of commerce, especially the latter, I also found ammonia freely, and it was not removed from the former acid by distillation with a small quantity, either of sulphuric acid or ignited alumina. As drinking-water does not often contain soluble salts of alumina it follows from the various results obtained that a more correct way of ascertaining if "free" and "saline" ammonia is in it, is by distilling a portion of the water alone.

9. As I found after various trials that chloride or sulphate of aluminium, or potassic alum, perfectly free from ammonia, was not readily obtainable by purchase, I made a nearly saturated solution of crystallised potash-alum, by dissolving 5 grains of it in 60 grains of water free from ammonia, the mixture occupying 65 c.c., and determined the amount of ammonia in it by distilling 10 c.c. of this solution with 10 c.c. of a saturated solution of ammonia, some free sodic carbonate, and 30 c.c. of pure water, until 25 c.c. had passed over. The 10 c.c. yielded 0.25 m.grm. of ammonia, or 0.325 part ammonia per one million parts of the alum.

10. As ammoniacal salts, whether neutral or alkaline, when dissolved in water, yielded a large proportion of their ammonia by simple distillation, and as the sample of drinking-water gave scarcely a trace of ammonia by such treatment, it appears that the drinking-water did not contain either ammonia or ammoniacal salts, and that the ammonia liberated from such water by distillation with carbonate of sodium was probably due to the action of the alkaline carbonate either upon nitrogenous organic matter or upon double salts of ammonia and alumina; as, however, a trace of alum made the water cloudy, that substance was not present. The ammonia, therefore, obtained by distilling ordinary drinking-water with carbonate of sodium is not necessarily either "free" or "saline," but may be of the kind termed "albumenoid."

11. To ascertain how much of the ammonia of neutral ammoniacal salts which might be contained in drinking-water would be obtained by distillation with carbonate of sodium, as in the process described in "Water Analysis," I added 1.0 m.grm. of chloride of ammonium (=0.648 m.grms. of ammonia) to one litre of the same sample of water, then added 10 c.c. of a saturated solution of carbonate of sodium, perfectly free from ammonia, to half a litre of the mixture in a retort, and distilled over 50 c.c. and tested it. The distillate contained 0.25 m.grm. of ammonia, to which if one-third be added as directed in the book referred to the result equals 0.666 m.grm. of ammonia per litre; =0.648 m.grm. from the sal-ammoniac, and 0.026 m.grm. (see paragraph 1) from the action of the alkaline carbonate upon nitrogenous matter. From this result it appears that two-thirds of what may be termed the "saline" ammonia came over in the first tenth part of the distillate, as in the experiment where no alkaline

* Water prepared in this way was employed for making all the comparison tests liquid used in this investigation.

† I have generally found one-third too large a proportion to be added; I have also found the proportion variable.

carbonate was added (see paragraph 5). I further continued the distillation, throwing away the next 150 c.c. of distillate; then added 50 c.c. of a solution composed of 4 grammes of crystals of permanganate of potassium and 100 grammes of pure hydrate of potash, dissolved in pure water to form 500 c.c. by measure, the solution being perfectly free from ammonia, and distilled over three successive 50 c.c. and tested them; they yielded 0.083 m.grm. of ammonia, or 0.166 m.grm. per litre. The amount of ammonia obtained from the same sample by means of alkaline permanganate without addition of chloride of ammonium was 0.138 m.grm. per litre, as stated above.

12. To ascertain whether the amount of ammonia yielded by distillation of the ordinary water with the alkaline solution of permanganate only was less than the united amounts obtained by distillation with the carbonate and that solution in succession, I distilled half a litre of the sample with the permanganate only, and obtained exactly the same amount, viz., 0.164 m.grm. of ammonia per litre, as the united amounts obtained by distillation with the two substances (see paragraph 1). I also distilled a third similar quantity with the carbonate and permanganate solutions mixed together, and obtained nearly the same total amount of ammonia, viz., 0.156 m.grm. per litre. These and the previous results show that the carbonate of sodium may be dispensed with.

13. To determine whether the amount of ammonia obtained by distillation of the water with the caustic potash and permanganate of potassium solutions mixed together beforehand was less than if the potassic hydrate was used first, I took half a litre of the water, distilled 50 c.c., then added the 10 c.c. of carbonate of sodium solution, and distilled over 150 c.c., then added a solution (perfectly free from ammonia) of 10 grammes of pure hydrate of potassium in 50 c.c. of pure water to the residue in the retort, and distilled over three successive 50 c.c.; the two first of these gave a total of 0.028 m.grm. of ammonia per litre, and the third gave none. I now added 0.4 gramme of crystals of the permanganate, and distilled over three more 50 c.c. They gave respectively, after correction for a trace of ammonia contained in the permanganate, 0.146, 0.012, and 0.016 m.grm. of ammonia per litre. Rejecting the last of these because the liquid had become concentrated, the total amount of ammonia yielded by the potash and permanganate when separate was 0.166 m.grm. per litre, whilst it was only 0.138 m.grm. when those substances were mixed (see paragraph 1). This result shows that the mixture of those substances at the outset diminished their united yield of ammonia.

14. To ascertain whether the permanganate, in the state in which it was purchased, was free from ammonia, I added some to a solution of pure potassic hydrate, and distilled over 25 cc. The amount of ammonia found was about 0.01 m.grm. in 0.4 gramme of the salt.

15. In order to ascertain whether the method of analysing potable water by distilling it with carbonate of sodium and alkaline permanganate of potassium in succession converts into ammonia any portion of the urea which may be in the water, I dissolved 0.5 m.grm. of colourless, odourless, and dry crystals of urea (= 0.283 m.grm. of ammonia) in half a litre of water, and distilled it with those substances in the usual manner, and obtained the following amounts of ammonia:—With carbonate of sodium, 0.0214 m.grm. per litre; with alkaline permanganate, 0.164 m.grm. per litre, = total 0.185 m.grm. per litre. The urea, therefore, did not increase the amount of ammonia obtained by distillation with carbonate of sodium. I also distilled a second half litre containing the same amount of urea, with the solution of alkaline permanganate only, and obtained 3.200 m.grm. of ammonia per litre. And I further distilled a third half litre of the same mixture of urea and water with the carbonate and alkaline permanganate solutions mixed together, and obtained 0.196 m.grm. of ammonia per litre. As the same sample of water without the addition of urea, distilled in the usual way, gave 0.026 m.grm. of ammonia per litre, by distillation with the

carbonate, and 0.138 m.grm. with the alkaline permanganate, equal to a total of 0.164 m.grm. per litre, the addition of the urea increased the total amount of ammonia from 0.164 m.grm. to 0.185 m.grm. per litre, or about 1.13.5 part of the total quantity of ammonia which the urea was capable of forming. If, therefore, ordinary drinking water contains 0.5 m.grm. of urea per litre, and is analysed by the process referred to, a small portion of the urea is converted into ammonia.

16. To ascertain whether a small quantity of urea in drinking-water is more completely converted into ammonia by distilling the water with the caustic potash and permanganate solutions separately than with them mixed together, I took half a litre of the water containing the same proportion of urea, distilled over 50 c.c., then added 10 c.c. of the carbonate of sodium solution and distilled over 100 c.c. Next added 50 c.c. of pure water, containing 10 grammes of pure potash, free from ammonia, distilled over three successive portions of 50 c.c. each, and obtained a total of 0.116 m.grm. of ammonia per litre. I then added 0.4 gramme of crystals of permanganate of potassium, and distilled over three more volumes of 50 c.c. each, and after correction for the small amount of ammonia in the permanganate, obtained 0.206 m.grm. of ammonia per litre. The total amount of ammonia obtained by distillation with the potash and permanganate separately was therefore = 0.322 m.grm. per litre, and included more than one-third of the total amount of ammonia which the urea was capable of yielding, whilst in the previous experiment with them mixed together it was only 0.185 m.grm. per litre, and included only about 1.13.5 part of the amount of ammonia the urea was capable of forming. Neither of these methods, therefore, shows the amount of urea in drinking-water.

17. By distilling over a further portion of 50 c.c., and two portions of 25 c.c. each, until the residue in the retort was only semi-fluid, 0.036, 0.160, and 0.200 m.grm. = a total of 0.396 m.grm. of additional ammonia per litre was obtained, shewing that a further amount of nitrogenous matter (besides that due in the present case to the portion of urea still undecomposed) remained in the water after stopping the distillation at the usual period in the process referred to.

18. I also took one-fourth of a litre of the same sample of water, added to it 25 c.c. of a solution, perfectly free from ammonia, of 100 grammes of pure potash in 500 grammes of pure water, and distilled over five successive portions of 50 c.c. each, and tested them. The first 50 c.c. gave 0.144 m.grm. of ammonia per litre, the second gave about 0.002, and the others none. I then transferred, by the aid of some pure water, the semi-fluid residue to a small tube retort of the annexed form, of thick refractory

glass, and evaporated it to perfect dryness, and heated it partly to redness; the tube then cracked. The distillate thus obtained gave about 0.32 m.grm. of ammonia per litre of the water, but the exact amount could not be determined because the colour produced on adding the test was a clear golden-yellow like that yielded by dilute aqueous methylamin. The total amount of "albumenoid" ammonia therefore obtained was about 0.466 m.grm. per litre, or 0.146 by distillation and 0.32 by ignition, whilst by the ordinary process of distillation only, as recommended in "Water Analysis," it was 0.164 m.grm. (see paragraph 1), or about one-third of that amount.

19. Although ignition greatly increased the yield of ammonia, it does not prove that the water was proportionately unwholesome. The nitrogenous compounds in river water are derived not only from animal substances but also from vegetable ones, such as vegetable albumen, legumin, casein, gluten, a great number of vegetable bases and bitter extracts, the green colouring-matter of leaves,

alkaloidal principles, &c., extracted or otherwise derived from living and dead plants of many kinds by the influence of rain, streams, and rivers; various observers have also found considerable quantities of "free" and "albumenoid" ammonia in rain-water collected in the atmosphere of the open country (see Dr. Angus Smith on "Air and Rain," pp. 235-286, &c.) Many different kinds of plants also when soaked in water yield a more or less different kind of nitrogenous organic matter. The ammonia, therefore, obtained from river-water, both by distillation with alkalis and by ignition of its residue, is probably derived from a considerable number and variety of nitrogenous compounds, some being noxious and others not so. As it is not yet clearly known which of these nitrogenous substances, especially when in such minute proportions, are unhealthful and which are not, it is probable that the albumenoid ammonia obtained by distillation with a strongly alkaline solution of permanganate, or the "organic nitrogen" obtained by a combustion analysis, affords a very inaccurate estimate of the unwholesomeness of water, because it is derived from and represents the harmless as well as the noxious nitrogenous ingredients. As also "albumenoid ammonia" and "organic nitrogen" are continually being carried to the earth by rain, it is certain that they do not afford a true measure of what is termed "previous or recent sewage contamination."

20. The sample of water operated upon in all these experiments was of a greenish colour when viewed through a depth of it equal to one metre. The colour was not due to salts of iron, but to vegetable matter; it was not affected by a drop of sulphide of ammonium, nor diminished by filtration, nor by addition of carbonate of sodium (which produced a cloud), and filtration, even if warmed or boiled after addition of that salt; but by adding a little alum (which also produced a cloud), and then filtering, the green colour was almost entirely removed. To ascertain, therefore, approximately, how much of the "albumenoid" ammonia capable of being obtained from the water was due to the green vegetable matter, I added 5 c.c. of a strong solution of chloride of aluminium to a litre of the water, then added 20 c.c. of the saturated solution of carbonate of sodium, allowed the precipitate to subside, and put half a litre of the perfectly clear liquid into the retort, and distilled it in the usual manner. The 200 c.c. of distillate obtained with the carbonate of sodium was disregarded, because the chloride of aluminium was found to contain a small quantity of ammonia (see paragraph 8). The distillate obtained with alkaline permanganate yielded 0.067 m.grm. of ammonia per litre of the water, or about one-half of that obtained when the green colouring matter was not previously removed (see paragraph 1). This diminution was not due to the alumina salt uniting with a salt of ammonia, because there was but little, if any, of the latter substance in the water (see paragraph 10). In consequence of these results I propose this method of using a salt of alumina in connection with Nessler's reagent as a means of determining approximately the amount of "albumenoid" ammonia derivable from the green vegetable colouring matter contained in samples of drinking-water.

21. After all liberation of ammonia by the alkaline permanganate in the foregoing experiment had ceased, the distillation was continued until the residue was of small bulk; the last 25 c.c. of distillate yielded 0.03 m.grm. of ammonia or 0.06 m.grm. per litre. The residue was then washed by the aid of pure water into a small glass bulb, distilled to dryness, and heated to redness; by these means 0.08 m.grm. more of ammonia per litre was obtained. The total yield of ammonia, therefore, by distillation and ignition with the alkaline permanganate, after precipitation of the green matter, was 0.207 m.grm. per litre (or 0.067 by distillation, and 0.14 by ignition), whilst in the immediately preceding experiment with caustic potash solution (see paragraph 18), and without previous precipitation of the vegetable colouring matter,

it was 0.466 m.grm. per litre, or 0.146 by distillation and 0.32 by ignition. In each case also, whether the colouring matter was previously precipitated or not, the ignition yielded about twice as much ammonia as the distillation. As a solution of an acid salt of alumina perfectly free from ammonia was not readily obtained, I did not prosecute this part of the investigation farther.

22. In order to ascertain the effect on the yield of "free" and "albumenoid" ammonia of prolonged heating of the water previous to distillation, about two litres of ordinary town water was heated in a large carefully-cleaned flask, placed in a bath of water almost at the boiling point, a clean condensing apparatus being fitted in the mouth of the flask to prevent loss of vapour. Two experiments were made; in the first the water was heated during seven hours, and in the second during two. The following are the results expressed in parts per million:—

	Free ammonia.	Albumenoid ammonia.
Heated for seven hours ..	0.025 ..	0.160
" two ..	0.026 ..	0.160
Not previously heated ..	0.010 ..	0.130

23. From these results it will be seen that previously heating the water during two hours increased the yield of free ammonia by simple distillation without sodic carbonate about 2½ times, and of albumenoid ammonia about 1½ times, but that the further heating of the water during five hours had scarcely any effect.

24. Every precaution having been taken to exclude extraneous impurities in these experiments, it is evident that the increase in the amount of ammonia after heating was due to oxidation of some of the organic matter (see paragraph 19). And as it was simply heating the water alone for a longer time which caused this result, the rate at which the ordinary process of distillation is conducted must to some extent influence the amount of ammonia obtained. Water thus treated would on analysis appear to be less pure, whilst in reality it would be more wholesome on account of the oxidation of some of its organic impurity.

25. The effect of prolonged agitation with air, upon the yield of ammonia by distillation with potassic permanganate was also ascertained. About 1 litre of water was continuously shaken during five hours in a closed bottle of 2½ litres capacity, and a portion of it analysed; the remainder was then similarly shaken during a second five hours, and also analysed. The following amounts of ammonia, in milligrammes per litre, were found:—

Water.	Free.	Albumenoid.	Total.
Not shaken ..	0.0050	0.140	0.145
Shaken five hours ..	0.0050	0.195	0.200
Shaken ten hours ..	0.0100	0.185	0.195

26. Similar and sufficient portions of the unshaken water, and of that which had been shaken, were evaporated to equally small bulks; the former was slightly the most alkaline.

27. These results indicate that, by the agitation, the nitrogenous matter in the water was so altered as to enable it to yield considerably more ammonia both by simple distillation without sodic carbonate and by the permanganate process. They also show that a sample of water which, by thorough contact with atmospheric air, is probably rendered more fit for drinking, might by the permanganate process be indicated as being less pure.

28. In order to ascertain whether the growth of vegetable matter in the water altered the proportion of ammonia or purified the water, another sample of the same town water was taken, a portion of it at once analysed for ammonia by the permanganate process, and the remainder exposed during eighteen days in a very large closed flask to the influence of sunlight, assisted by occasional gentle warmth, until the bottom of the glass became green with vegetable growth, and the amount of vegetable matter appeared to cease increasing; the amount of ammonia

in it was then determined. The following are the results:—

Water.	Free.	Albumenoid.	Total.
Unexposed	0.020	0.110	0.130
Exposed	0.030	0.130	0.160

29. From these results I conclude that the action of sunlight and warmth converted some of the nitrogenous matter into such a state that it yielded ammonia by simple distillation without sodic carbonate, and by the permanganate process; and by comparing them with previous results, that the effect in this respect was exactly the same as that of heating the water to a much higher temperature during two hours; and also similar to, but less in amount than, that of agitating the water in contact with air during five hours. Further, that the formation of vegetable growth caused the water to appear more impure when tested by the permanganate process, and that the nitrogen of the green vegetable matter was probably derived chiefly from impurities which would not yield ammonia by that process.

Conclusions and Summary of Results.—Returning to the retort, the distillate obtained with carbonate of sodium in the ordinary process of water analysis for ammonia and re-distilling it gave a slightly larger amount of "free" ammonia, and, mixing the alkaline carbonate with the sample of water twelve hours before distilling, gave a still larger increase. Permanganate of potassium solution, to which had been added pure caustic soda, acted apparently quite as well as that to which had been added hydrate of potassium.

Water containing even a very small amount of ammonia or its salts yielded much of its ammonia by simple distillation (see paragraphs 3 to 7), and did not require the aid of carbonate of sodium to liberate it unless salts of alumina were present (see paragraphs 8, 9, and 11). The production of ammonia by distillation with carbonate of sodium appeared to be due to the carbonate acting upon nitrogenous matter (see paragraph 10). Drinking water distilled with an alkaline solution of permanganate of potassium alone yielded as large a total quantity of ammonia as when previously distilled with sodic carbonate, or with a mixture of that substance and alkaline permanganate (see paragraph 12). Such water, distilled first with caustic potash and then with the permanganate alone, yielded more ammonia than when distilled with those two substances mixed together (see paragraph 13). Ordinary permanganate of potassium was found to contain ammonia (see paragraph 14). A very dilute solution of urea in the water was not converted into ammonia by distillation with carbonate of sodium, and only to a small extent by distillation with alkaline permanganate of potassium, and to about one-third only by distillation, first with caustic potash and then with permanganate (paragraphs 15 and 16). The residue left in the retort after the completion of the usual process of water analysis for ammonia yields a large additional amount of ammonia by heating to redness (paragraph 17); the usual permanganate process gave only about one-third (paragraph 18). Previous precipitation of the dissolved green vegetable matter in drinking water by means of salts of alumina diminished the amount of ammonia obtained by the subsequent distillation of the clear portion of the water with a solution of alkaline permanganate of potassium, and may be employed as a means of determining the approximate amount of ammonia due to such vegetable matter (paragraph 20). The effect of heating the water nearly to boiling (paragraph 22), or of exposing it to sunlight and warmth (paragraph 28), or of agitating it with atmospheric air (paragraph 25), and especially the latter, was to increase the proportions both of free and albumenoid ammonia yielded by the permanganate process, and whilst purifying the water render it apparently less pure according to this test.

If the object in water analysis is to obtain the largest amount of ammonia, it appears to be best effected by

distilling the water first with a solution of caustic potash, then adding a solution of permanganate of potassium, distilling to dryness, and igniting the residue to redness.

CORRESPONDENCE.

DETERMINATION OF POTASH.

To the Editor of the Chemical News.

SIR,—A goodly number of samples of commercial muriate and sulphate of potash come under my notice, and recently a very serious discrepancy in my results as compared with those of a well-known Continental manufacturer came to light. This not only occurred once, but repeatedly, and strange to say the seller was the lowest. A sample testing 94.01 by seller's test, 95.8 and 95.9 by mine, was sent for control to a well-known analyst, whose potash determinations are a speciality. To my astonishment he returned it as containing 96.04 per cent, the mean of two determinations, and 95.87 as that of a third. It was quite manifest that there was some serious error vitiating our results, as it was very unlikely that a furnace sulphate of potash which, in addition to the inevitable soda salts present, always contains very notable quantities of sulphuric acid as bisulphate, ferric sulphate, calcic and magnesian sulphate, &c., would contain 96 per cent potassic sulphate.

I first of all examined my reagents. The bichloride of platinum evaporated with the addition of HCl nearly to dryness, and alcohol added, remained perfectly clear. But on the addition of a little pure sulphuric acid a decided turbidity appeared. When filtered off, washed with platinum solution, then with alcohol, it presented the appearance of a white powder, not showing any appearance of the yellow potash precipitate under the microscope.

Another experiment was made in which the usual quantity of bichloride of platinum for a determination received a few grains of pure sodium sulphate, and was then evaporated on the water-bath, when a crystalline deposit gradually separated. This was washed twice with platinum solution, then with methylated spirit, precisely as in a potash determination, and dried. It weighed 0.2 grain, equal to 0.71 per cent of potassic sulphate, and was found to be calcic sulphate. Here I had at least a partial solution of the discrepancies. There can be no doubt that in the recovery of the platinum precipitates and washings, if reduced by alcohol in an alkaline solution (as is generally the case), it is very probable that the separation of lime in the after operations may be not quite complete, and this neglect may be aggravated by slight impurities in the acids sold as "pure."

It seems to me, at any rate, imperative that those who make potash determinations by this very accurate platinum method should satisfy themselves by evaporating a definite quantity of their platinum tetrachloride with a few drops of pure sulphuric acid, or sodic sulphate, nearly to dryness, dilute with alcohol, &c., and weigh any precipitate thus obtained. This weight ought to be deducted from that of every potash precipitate before calculating to percentage.

In recovering my platinum solutions and washings, I found it best to add a small quantity of pure sulphuric acid to the aqua regia used for dissolving the platinum, and, after evaporating tolerably low, dilute largely with pure spirits of wine. After standing some time, filter from the sediment, wash with alcohol, evaporate on the water-bath, add a little nitric acid to re-oxidise any reduced platinum tetrachloride, and so on.

Using this purified solution on a pure sulphate of potash (made by calcining cream of tartar, under neutralising with pure sulphuric acid, filtering, and crystallising), I obtained 99.93 per cent K_2SO_4 , multiplying the weight of the precipitate by 0.35687.

Much has been written on the subject of the determina-

tion of potash in sulphates, and in order to convert the sulphate of potash into muriate the addition of chloride of sodium has even been recommended. I have never viewed this proposal with favour, introducing as it does a comparatively large quantity of fixed salts which have to be removed in solution in a small amount of solvent, in addition to the other impurities naturally present. My personal experience of it has quite corroborated my prepossessions, and, further, I have not found it at all necessary to revert to this method. My plan is to add a liberal excess of pure hydrochloric acid before evaporation, and a few drops after. As compared with the results of others, mine have not certainly come out too low.—I am, &c.,

KALIUM.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 12, September 22, 1884.

General Progress of Vegetation in Annual Plants: *Amaranthaceæ*.—MM. Berthelot and André.—The relative and absolute preponderance of lignine is shown more and more as vegetation increases, just as in borage. The soluble matters increase less rapidly, their proportion falling from equality to one-seventh. The albumenoids increase also in absolute weight, but their relative proportion reaches its maximum at the beginning of the time of flowering, and then diminishes greatly. The salts of potash which represent the organic acids and nitric acid, and consequently the phenomena of oxidation, increase continually in absolute weight. Their relative maximum coincides with that of the soluble principles and the albumenoids at the beginning of inflorescence.

Bulletin de la Société Chimique de Paris.
Vol. xlii., No. 3, August 5, 1884.

Action of Phosphorus Perchloride upon the Aromatic Ethers.—A. Colson.—Not adapted for abstraction.

On Various Colloids.—E. Grimaux.—The author's researches extend to Schweitzer's liquid, the condensed pyruvic ureides, the amido-aspartic colloid, and soluble silica.

On Propenyl-glycolic Acid.—C. A. Lobry de Bruyn.—This acid consists of $\text{CH}_2\text{CH}=\text{CHCHOH.COOH}$.

Action of Hydrocyanic Acid and Dilute Sulphuric Acid upon Aldol.—C. A. Lobry de Bruyn.—The product obtained is cyanhydrine, formed of two mols. of aldol and 1 mol. of hydrocyanic acid.

Detection of Coal-Tar Products in Wines by means of Amylic Alcohol and Ammonia.—M. Jay.—The author adds to 100 c.c. of the suspected wine 2 or 3 c.c. of ammonia, and then 3 to 4 c.c. of amylic alcohol. After shaking up the amylic alcohol floats on the top, taking a rose colour more or less distinct if a foreign colouring matter is present. If the colour is indistinct the amylic alcohol is decanted off, and evaporated in contact with a small piece of white silk, which takes up the colour.

Action of Tellurous and Telluric Acids upon the Paratungstates.—D. Klein.—The action of tellurous acid upon the paratungstates gives rise not to well crystallised salts, but to pulverulent deposits in which the presence of tellurous and telluric acids seems marked. By the action of telluric acid there is produced a crystalline compound containing potassium and the tungstic and telluric acids.

Substance Employed in Spain for Colouring Wines (Tintura por los Vinos).—M. Jay.—This colour is composed of Biebrich red, a smaller quantity of a red of the rosaniline group, and arsenious acid to the extent of 1.62 per cent!

Action of Benzoyl Chloride upon Isoduroil in Presence of Aluminium Chloride.—MM. Essner and Gossin.—The principal product obtained is benzoyl-isoduroil.

Potassium and Barium Glyoxal Bisulphites.—M. de Forcrand.—Not adapted for useful abridgment.

Decomposition of Pyridic Ammonium Iodides by the Alkalies.—Oechsner de Coninck.—The author has studied certain new colouring-matters resulting from this reaction, derived from β -lutidine, from α and β -collidine (obtained from brucine and cinchonine), from α -picoline and γ -lutidine (of coal tar).

Bulletin de la Société d'Encouragement pour l'Industrie Nationale. 3e Série. Tome xi., June, 1884.

Report on M. Clemandot's Process for Tempering Steel by Compression.—Ad. Carnot.—The process consists in heating the metal to make it acquire a sufficient ductility, and submitting it during cooling to very energetic pressure.

Revue Universelle des Mines, de la Metallurgie, &c.,
July and August, 1884.

Analysis of the Copper Ore of Stolzembourg, in the Grand Duchy of Luxembourg.—This ore, a copper pyrites, contains 28.5 per cent of copper and 34.3 of sulphur, and is free from arsenic and antimony.

Cosmos les Mondes.
No. 18, August 30, 1884.

This issue contains no chemical matter.

No. 1, September 11, 1884.

A paragraph here inserted states that the poisonous properties of the aniline colours do not, as commonly supposed, depend on the presence of arsenical compounds. According to MM. Poincaré and Nassias, they are dangerous even in a state of absolute purity. The least dangerous of all is magenta. [This opinion does not agree with the prolonged observations of Dr. Grandhomme, conducted at the Works of Meister, Lucius, and Brünig.]

No. 2, September 18, 1884.

The quantity of domestic refuse produced at Paris is about 2500 cubic metres daily, whilst the sewage amounts to 300,000 metres daily.

Death by Electricity.—Dr. Gariel has just published in the *Electricien* a report on the death of two young men who were killed as far back as August 6, 1882, by having incautiously or accidentally touched with both hands one of the wires conveying an alternating current of about 500 volts to supply 12 Siemens lamps in the gardens of the Tuilleries. The immediate cause of death seems to have been stoppage of the action of the heart.

No. 3, September 27, 1884.

This number contains no chemical matter.

Journal de Pharmacie et de Chimie.
Series 5, Vol. ix., May, 1884.

Characters distinguishing Chloroform and Methylene Chloride from a Physiological Point of View.—MM. J. Regnaud and Villejean.—This paper has no chemical bearing.

Extemporaneous Gelatinous Calcium Phosphate.—C. Tanret.—A pharmaceutical memoir.

Powders of Meat.—M. Yvon.—Thoroughly cooked meat, when sufficiently comminuted, is as readily attacked by the gastric secretions as raw meat.

Observations on the Tincture of Iodine.—A. Lambert.—A solution of iodine in methylated alcohol gives off a volatile product of an odour resembling that of acrolein. This reaction is due to the presence of acetone, which forms with the iodine an iodised acetone and acrolein.

On Digestive Ferments and their Pharmaceutical Preparation.—M. Pierre Vigier.—A purely pharmaceutical paper.

New Reactions characteristic of Codeine and of Esculine.—L. Raby.—To the codeine placed in a watch-glass are added two drops of the common solution of chloride of soda, the alkaloid is stirred up, and four drops of undiluted sulphuric acid are added. The whole is then mixed up with a glass rod, when there appears a splendid and persistent blue colouration. If bromine water is substituted for chloride of soda, this colouration does not appear. Bromine water, if used alone, becomes turbid in contact with codeine. On stirring, the liquid clears up and becomes perfectly colourless, but after a few seconds there appears a violet colouration, not very intense, but quite distinct. On experimenting with some thirty of the commonest alkaloids, the author obtained in no instance a colour which could be mistaken for the fine blue above mentioned. On the other hand, chloride of soda and strong sulphuric acid—if applied in a slightly different manner—give a fine violet colour with esculine. The author adds to the esculine four drops of sulphuric acid: to the slightly coloured liquid resulting from this mixture there is added gradually a solution of chloride of soda, stirring continually. When sufficient has been added the liquid takes an intense violet colour, which fades gradually, and disappears entirely in about an hour. On operating in an inverse manner the colouration is not obtained. If bromine water is substituted for chloride of soda there is formed a precipitate of the colour of dregs of wine: this reaction is less fine and less certain than that with chloride of soda.

Preparation of Pure Hydrochloric Acid.—M. Giudice.—The sulphuric acid employed is mixed with a small quantity of potassium permanganate, and the hydrochloric gas before being absorbed in water is passed into a bulb-tube containing mercury. The permanganate prevents the formation of sulphurous acid, and the mercury absorbs free chlorine and decomposes arsenic chloride.

Purification of Hydrochloric Acid.—M. Bensemann.—The commercial acid may be obtained free from arsenic and sulphurous acid if it is diluted to 1·12 sp. gr., and distilled over a little potassium chlorate.

Antimony Penta-Iodide.—M. Pendleton.—From the CHEMICAL NEWS.

Sodium Hypobromite as Reagent for Gum-Ammoniac.—P. C. Plugge.—Sodium hypobromite produces a fine reddish violet colouration in an alkaline solution of gum-ammoniac. Plugge dissolves 30 grms. sodium hydroxide in distilled water, adds 20 grms. bromine and makes up to 1 litre. A few drops of this reagent added to an ethereal solution of the gum-resin give the reaction immediately.

On Carvol.—A. Beyer.—The carvols obtained from caraway and from aniseed resemble each other exceedingly in their optical properties. That of *Mentha crispata* deflects the plane of polarisation to the left as much as the other carvols turn it to the right.

Glucoside from *Viola arvensis*.—K. Mandelin.—The alcoholic extract of *Viola tricolor* (variety *arvensis*) is taken up in water and shaken with benzol to remove salicylic acid. The aqueous solution deposits light yellow crystalline needles, violaquercitrin, $C_{84}H_{42}O_{48}$. This

compound, on treatment with dilute mineral acids, is split up into quercitrin and a fermentable sugar.

Researches on Solubility.—Edmond Dupuy.—The author recommends that the sample of the solution for analysis should be taken very rapidly, as it may otherwise suffer less from crystallisation or evaporation.

June, 1884.

Scale of Temperatures, and on Molecular Weights.—M. Berthelot.—Already noticed.

The Digestive Ferments and their Pharmaceutical Preparations.—Pierre Vigier.—This paper is of no chemical interest.

Note on *Abrus precatorius*.—G. Patein.—An examination of the state in which iron occurs in the seeds of this plant.

Sophistication of Flour.—M. Balland.—A hydrated calcium sulphate in fine powder has lately been offered to millers for mixing with flour in the proportions of 1 to 1·5 per cent. If the weight of the ash of a flour decidedly exceeds 0·6 per cent the analyst should determine lime and sulphuric acid. In a genuine flour there is very little lime and a mere trace of sulphuric acid.

Official Mercuric Oxides.—P. Carles.—A pharmaceutical paper.

Gum of *Grevillea Robusta*.—M. G. Fleury.—This gum, which is now produced in Algeria, closely resembles gum-arabic in its reactions.

Titration of Cinchonas.—M. Huguet.—The author approves of the process of Proliis Petit, but points out that the powder of the sample operated upon should be equally fine in every case. Heat should be avoided as much as possible during the process of extraction. The rotatory power of the mixed alkaloids should be determined, and then that of the crystalline quinine sulphate.

Production of Zinc Formiate in Cisterns containing Oil of Turpentine.—M. Schlagdenhauffen.—The sides of the zinc cistern were coated with a deposit of zinc formiate. Lead formiate has been formerly discovered in lead cisterns used for the same purpose.

The Tannin of Alder Bark.—M. Lamasse.—The amount of tannin in this bark has been very variously estimated at from 3 to 20 per cent. The tannin in question belongs to the same series as that of the oak, being a methyl-tannin. With ferrous acetate it gives a reddish-blue precipitate; with ferrous sulphate an olive-green; it is precipitated by solution of gum, but is not affected by tartar emetic.

Reaction of Gallic Acid.—S. Young.—If a solution of gallic acid is shaken up with a solution of potassium cyanide there is produced a fine red colour, which disappears on standing. If the liquid is shaken up the redness reappears in the entire mass of the liquid, but is permanent only on the surface if the mixture is left at rest. In this manner the red colour may be made to appear and disappear for fifteen to twenty times in succession. Finally the liquid becomes of a permanent brown. In this manner gallic acid may be detected in the tannins of commerce.

New Reaction of Atropine and of the Mydriatic Alkaloids.—A. W. Gerrard.—From the *Pharmaceutical Journal*.

New Reaction for Distinguishing Nepaline from Aconitine.—M. Mandelin.—These two bodies behave in a different manner with nitric acid and with an alcoholic solution of potassa. If nepaline is evaporated with a few drops of fuming nitric acid we obtain a residue with an odour of musk, which when brought in contact with a few drops of a solution of potassium hydroxide in absolute alcohol produces a carmine or purple colour. Aconitine behaves quite differently. This reaction is still distinctly appreciable with 0·01 of nepaline.

July, 1884.

Dissociation, appreciated by J. B. Dumas.—A portion of the *éloge* of H. Sainte-Claire Deville read by M. Bertrand after the death of the author.

Analysis of the Oily Seeds of *Symphonia Fasciculata*.—MM. J. Regnaud and Villejean.—The proportion of the fatty principles in this seed is 56 percent. They contain no substance capable of modifying their bland flavour, and they are further remarkable from the nature of their glycerides, which render them strikingly analogous to the fats of mammalian animals used as food. The stringent matters isolated closely resemble the principles of the same kind found in the cinchonas.

Digestive Ferments and their Pharmaceutical Preparations.—Pierre Vigier.—Continued from the last number.

A Geological and Hydrological Study of the Valley of the Agly (Eastern Pyrenees).—J. L. Soubeiran.—A notice of the general character of the potable waters of the district.

Remarks on the Determination of the Alkaloids by the Optical Method.—G. Fleury.—The author contends that an exact analysis cannot be made of mixtures, e.g., of quinine and quinidine. When these salts are mixed in water they influence each other mutually, as experiment proves. The difficulty of always operating at $+17^\circ$ is a further argument against using polarising apparatus in quantitative analysis.

Studies on *Conrallaria Maialis*.—A. Langlebert.—A pharmaceutical paper.

Mineral Springs of Bourbon-l'Archambault.—E. Willm.—This paper may possibly have some medical interest.

Aseptol, a Soluble Substitute for Phenic and Salicylic Acids.—M. Annensens.—Aseptol or orthoxy-phenylsulphurous acid, $\text{C}_6\text{H}_4\text{OH}(\text{SO}_2\text{OH}_2)$, is an energetic acid, perfectly soluble in water. It is said to possess the same anti-putrescent powers as salicylic acid, but to be free from irritant or poisonous properties.

The Physiological and Therapeutic Action of Cotoine.—M. Albertoni.—This paper has no chemical interest.

On Vanillism.—Dr. A. Layet.—An account of certain morbid symptoms with which persons who work with vanilla are liable to be affected.

Coal-Gas and Carbon Monoxide.—Dr. E. Richard.—The author discusses the dangers due to an escape of coal-gas from the mains through the soil. The poisonous effects of carbon monoxide are very distinct at 0.4 per cent. Exposure to such a mixture is fatal in from thirty to sixty minutes. As coal-gas contains about 10 per cent of carbon monoxide the presence of such gas in the proportion of 4 to 6 per cent will become fatal. When coal-gas traverses a layer of soil before entering a house the danger is greatest, since it is then deodorised and its presence may remain undetected.

Manufacture of Wood-Pulp by means of Sulphurous Acid at a Low Temperature.—Raoul Pidet.—The author treats the comminuted wood or other vegetable matter with concentrated solution of sulphurous acid and water under a pressure of 5 atmospheres and at temperatures ranging from 75° to 80° .

Justus Liebig's Annalen der Chemie,
Vol. 224, Part 3.

Communications from the Chemical Laboratory of the Technical High School of Stuttgart.—These consist of a paper of Fr. Nafzger on the acids of bees-wax. In the portion of wax which is soluble in alcohol—cerine—the author finds cerotic acid. In myricine, the por-

tion insoluble in alcohol, there occur palmitic acid and an oleic acid which the author did not succeed in obtaining in a state of purity.

Comparative Researches on the Methods of Fractionated Distillation.—Dr. Hans Kreis.—The author remarks that the apparatus for fractionated distillation on the large scale is far more perfect and satisfactory than that for laboratory experiments, where the entire quantity to be operated upon does not exceed 50 grms. He gives the preference to Hempel's tube, filled with glass beads, which is figured in the original.

Communications from the Chemical Laboratory of the University of Jena.—These consist of a memoir by Dr. Oscar Froelich on the products formed on treating bromine with nitric oxide gas, and a paper by Professor A. Geuther on a new phosphoric ether.

Communication from the Central Chemical Laboratory of the University of Tübingen.—This is a memoir by Paul Spindler on the nitration of the benzol derivatives, which does not admit of useful abstraction.

Communications from the Laboratory of the University of Halle.—These include a paper by G. Baumert on the action of acetyl chloride and acetic anhydride upon lupinine, in which the author proves the existence in that base of two hydroxyl groups of an alcoholic character. Another paper by the same author treats of the liquid alkaloid of *Lupinus luteus*.

Action of Dimethyl-para-toluidine and Dimethylaniline upon Ethylen Bromide.—H. Hübner, A. Tölle, and W. Athenstadt.—This paper does not admit of useful abstraction.

Action of Ferric Chloride upon Ortho-phenylenediamine.—F. Wiesinger.—The product, a salt crystallising in long needles of a ruby-red colour, is the hydrochlorate of a new base.

AMMONIACAL LIQUOR.**TENDERS.**

The Directors of the Alliance and Consumers' Gas Company are prepared to receive Tenders for the Ammoniacal Liquor produced at their several Works during a period of 5 or 7 years, to commence in January next. The quantities of Coal and Cannel carbonised are estimated to be as under, but the same cannot be guaranteed, and may be more or less. The Liquor produced at the Bray Works will be delivered by the Company into the Kingstown Works, free of cartage.

The Dublin Works 114,400 tons.
The Kingstown Works 10,900 "

The tenders may be for the whole, or for one or more Works separately.

The Contractors must give security to remove the Liquor as it accumulates, to pay for the same monthly, and generally for the due fulfilment of the contract.

The form of agreement to be signed can be seen at the Company's Offices on application to the Engineer.

Tenders, sealed and endorsed "Tenders for Ammoniacal Liquor," to be delivered here not later than the 3rd November next.

The Directors reserve to themselves the right to accept any tender in part or in whole, and do not bind themselves to accept the highest or any Tender.

By order of the Board,

W. F. COLTON.
Secretary and Manager.

Alliance and Dublin Consumers' Gas Co.,
24, Collier Street.

BAILEY'S HYDRAULIC MOTORS.

BAILEY'S WATER MOTORS.

silver Medal, Manchester, 1879; Blackburn, 1881.

WHAT THEY ARE DOING:—

The Water Motor blows Blacksmiths' Fires at Penmaenmawr.

The 2-horse Water Motor daily works Waggon up an incline at Edge Hill Collieries, Bolton, with success.

The *Brighton Guardian* is regularly printed by these Motors, giving the highest satisfaction.

The Lifts are in Hotels and Warehouses of Manchester, Dublin, Liverpool, Lancaster, &c.

The "Thirlmere" drives a Grindstone at Bristol.

The 4-horse Water-Motor is at work Cutting Timber, by circular saw, 5 inches thick.

A 20-horse Water Motor, pumping for H. Vivian, Esq., M.P.

A 12-horse Water Motor, pumping at the Mine of G. N. Newdegate, Esq., M.P.

TESTIMONIALS.

June 22, 1881.—From H. H. Vivian, Esq., M.P.—"I have just heard that the Water Motor sent out last year is doing well."

Lord Salisbury's Clerk of Works writes:—"I am much pleased with the Water Motor, for it is most compact and useful."

From Messrs. Seed Brothers, Leather Merchants, Halifax:—"The Water Motor is doing its work well and quietly, and bids fair to answer our highest expectations."

From Lever Edge Coal Company, Bolton:—"The Water Engine you have supplied does its work well."

ON A

MODIFICATION OF DUMAS'S METHOD FOR THE QUANTITATIVE ESTIMATION OF NITROGEN.

By G. STILLINGFLEET JOHNSON.

HAVING occasion recently to make a complete quantitative analysis of the platinum salt of a nitrogenous base, I was desirous of securing as many platinum determinations as possible, and my efforts to economise the samples of substance employed for nitrogen determinations for this purpose resulted in the following process, which may prove serviceable to others.

A long combustion-tube is selected, and drawn out at one extremity in the form shown in the figure. Freshly reduced metallic copper is packed into the front of the tube as usual; behind this is a layer of cupric oxide, preferably granulated oxide; whilst at the extreme back of the tube a porcelain boat, which may be from 4 to 5 inches in length, is introduced. The front half of this boat contains the substance to be analysed, whilst the remainder is filled with pure *potassium chlorate*, which has been previously just fused and then powdered. If the operator deems it advisable the chlorate may be separated from the substance by a small plug of ignited asbestos.

The analysis is conducted as follows:—Air is expelled from the cold apparatus by a stream of pure carbon di-

stance under analysis having been duly arranged so that the drawn out extremity of the combustion-tube fits under the open extremity of the graduated gas tube, the heat is gradually extended backwards towards the porcelain boat, a slow stream of carbon dioxide being still kept passing. It will be found very easy to effect a slow destructive distillation of the substance by means of hot tiles, &c., without bringing about any expulsion of oxygen from the potassium chlorate. As soon as the evolution of nitrogen, which results from the destructive distillation of the substance, has ceased, as shown by the volume of permanent gas above the caustic potash in the receiving-tube remaining unaltered, the heat is allowed to spread to the further extremity of the boat, which contains the potassium chlorate. Evolution of oxygen gas of course follows, during which the stream of CO_2 may be somewhat slowed. The more or less nitrogenous charcoal left in the boat is now rapidly consumed, and an addition is made to the volume of the gas in the receiving-tube.

The remainder of the analysis is simple. The passage of the CO_2 is continued as long as any permanent gas escapes absorption by the potash, and the volume of the nitrogen is then read as usual.

The advantages of the process I have described are as follows:—

1. The expulsion of air from the copper oxide is certainly more rapidly, and probably more completely, effected at a red-heat than it is at the ordinary temperature by a stream of CO_2 .
2. In burning platinum, gold, or silver salts, these metals are retained in the boat, and may be weighed after simply washing out the potassium chloride adhering to them.
3. Much valuable insight into the constitution of nitrogenous compounds may be gained by observing the

oxide, which is best delivered from a Kipp's constant-generating apparatus.

After the CO_2 has been passed in the cold for about ten minutes, heat is applied to the whole of the front part of the tube, which is laid upon the combustion-furnace, up to within an inch of the boat containing the substance, the operator taking the usual precautions to avoid overheating of the tube and its contents in the immediate neighbourhood of the boat.

The front part of the tube having been kept at a low red-heat whilst the CO_2 has been continuously passing through it for a quarter of an hour, a sample of the gas is collected as it issues from the tube, by displacement of water or mercury in the usual way, and on examination is usually found to be perfectly free from nitrogen. If anything of consequence remains unabsorbed by strong solution of potash the process is continued till the issuing gas is pure carbon dioxide.

When complete expulsion of nitrogen from the ignited copper oxide has been ensured the receiving apparatus for the nitrogen of the substance under analysis is adjusted according to the taste of the operator. I have myself employed with much advantage Dumas's original apparatus,—a mercurial trough and a graduated glass tube about one-third full of strong potash solution, and the remaining two-thirds containing mercury.

The receiving apparatus for the nitrogen of the sub-

stance under analysis having been duly arranged so that the drawn out extremity of the combustion-tube fits under the open extremity of the graduated gas tube, the heat is gradually extended backwards towards the porcelain boat, a slow stream of carbon dioxide being still kept passing. It will be found very easy to effect a slow destructive distillation of the substance by means of hot tiles, &c., without bringing about any expulsion of oxygen from the potassium chlorate. As soon as the evolution of nitrogen, which results from the destructive distillation of the substance, has ceased, as shown by the volume of permanent gas above the caustic potash in the receiving-tube remaining unaltered, the heat is allowed to spread to the further extremity of the boat, which contains the potassium chlorate. Evolution of oxygen gas of course follows, during which the stream of CO_2 may be somewhat slowed. The more or less nitrogenous charcoal left in the boat is now rapidly consumed, and an addition is made to the volume of the gas in the receiving-tube.

This is thrown out as a hint to future observers, but I may state, in illustration of the possible importance of the data which may be obtained, that the ratio of nitrogen in stage one to N of stage two in the case of an organic base was as 1 to 3, whilst in the case of a cyanogen compound it was as 6 to 1.

If any doubt be entertained as to the efficacy of the metallic copper in front of the tube in absorbing excess of oxygen gas from the chlorate of potash, the measured nitrogen may be shaken up with a little solution of alkaline pyrogalline and again measured.

The Decomposition of Benzo-nitrile by means of Fuming Sulphuric Acid.—Fr. Gumpert criticises the researches of Pinner and Klein, and regards their dibenz-imido-oxide and benzimido-benzoate respectively as benzimido-benzamide and dibenzamide.—*Journal für Praktische Chemie*.

RESULTS OF SOME EXAMINATIONS OF
BUTTER.

By HENRY LEFFMANN, M.D.

I SUBMIT the following as an example of the quality of the butter sold in Philadelphia, the samples having been purchased at random in the course of an investigation for the Pennsylvania State Board of Agriculture. I tried various methods of analysis, and finally fixed on that in which the amount of alkali necessary to saponify the fat is determined. Just as the work was completed I saw a notice of Mr. Wanklyn's suggestion that when true butter is heated with alcoholic soda butyric ether is given off. I tried this test on all of the samples, and, as will be seen, it gives good results. In the table subjoined the term "acid equiv." refers to the amount of standard acid to which 1 gramme of the fat is equivalent in action on alkali; the column "Odour with Alcoholic Soda" shows the effect with Wanklyn's test. As matters of some interest I give the price per pound, the title under which the article was sold, and a judgment based on the analytical results.

Nos. 1, 18, and 19 were known to be genuine; No. 20 was sent by a friend; No. 21 is a sample of tallow introduced for comparison. The figures obtained show that the saponification process is very satisfactory.

metric method of boiling the ammoniacal liquid with a definite volume of alkaline solution and titrating the residual alkali naturally suggested itself. This method, which I have used for some considerable time, gives results closely agreeing and often identical with those obtained by distillation, but with a much smaller expenditure of time and attention. It is well suited for the testing of gas water and bone-liquor, which are nearly constant in constitution if not in percentage composition. The alkaline solution used for the boiling off of the total ammonia is a decinormal one of carbonate of soda. Sod. carbonate I find more suitable than the hydrate (which has been recommended), as caustic soda is apt to form with the ammoniac sulphide sometimes present sodic sulphide, which gets oxidised to sulphate and so yields a slightly too high result.

The following examples out of many will serve to show how the method is carried out and agrees with the distillation process:—

(1.) 5 c.c. bone-liquor distilled with caustic soda into 50 c.c. normal HCl solution neutralised 25.5 c.c.

$25.5 \times 20 \times 0.017 = 8.67$ per cent total ammonia.

5 c.c. same liquor titrated with normal HCl and methyl-orange indicator = 25 c.c. normal acid.

$25 \times 20 \times 0.017 = 8.5$ per cent free ammonia.

THE RAPID DETERMINATION OF FIXED
AMMONIA.

By J. W. PRATT, F.C.S.

WHEN free and combined ammonia exist together in the same solution the former is usually estimated by direct titration and the latter by distillation with caustic alkali and absorption in acid, also of known strength. The difference between the first and the latter result is set down as fixed or non-volatile ammonia as distinguished from the carbonates, sulphides, &c., of ammonia which neutralise acid and are volatilised on boiling.

The process of distillation for the determination of the fixed or total ammonia is often very troublesome, owing to the frothing caused by the action of the alkali on organic matter present, and requires frequently a large amount of time and attention for its successful accomplishment. For this and other reasons, where a large number of determinations of free and fixed ammonia have to be performed daily, the distillation process becomes specially inapplicable. Being placed in such a position some shorter method became necessary, and the volu-

25 c.c. of liquor boiled and evaporated to dryness with 25 c.c. N/10th Na_2CO_3 , ignited to get rid of organic matter, and treated with water. The solution took 3.2 c.c. normal HCl for neutralisation = 16 c.c. N/10th Na_2CO_3 .
25 c.c. — 16 c.c. = 9 c.c. N/10th Na_2CO_3 consumed.
 $9 \times 4 \times 0.0034 = 0.1224$ per cent fixed ammonia.

Adding to this amount of ammonia the amount found by direct titration (8.5 per cent) we have 8.6224 per cent, as against 8.67 NH_3 obtained by distillation.

(2.) 50 c.c. gas-water distilled with NaHO solution neutralised 39.2 c.c. normal HCl.

$39.2 \times 2 \times 0.017 = 1.3328$ per cent total NH_3 .

50 c.c. same sample titrated directly with normal HCl = 32.1 c.c. HCl.

$32.1 \times 2 \times 0.017 = 1.0914$ per cent free NH_3 .

25 c.c. evaporated to dryness with 25 c.c. N/10th Na_2CO_3 , taken up with water and titrated required 1.5 c.c. normal HCl = 7.5 c.c. N/10th Na_2CO_3 solution.

25 c.c. — 7.5 c.c. = 17.5 c.c. N/10th Na_2CO_3 consumed.
 $17.5 \times 4 \times 0.0034 = 0.2380$ fixed NH_3 .

Adding to amount of free ammonia (1.0914 per cent) the fixed ammonia as above, 0.2380 per cent NH_3 , we have

1.3294 per cent total ammonia, as compared with 1.3328 per cent total NH_3 by distillation.

It is well before applying this method to test the reaction of the sample to litmus-paper before and after boiling a small portion of it. If the liquor remains alkaline after expulsion of the ammonia by boiling it is obvious the method is not suitable without such correction or modification as may be left to the discrimination of the analyst.

A NOTE ON SOME PHYSIOLOGICAL EXPERIMENTS WITH IRON SULPHATE ON PLANTS.

By Dr. A. B. GRIFFITHS, F.C.S.,

Membre de la Société Chimique de Paris, Lecturer on Chemistry
and Physics, Technical College, Manchester, &c.

CONCERNING the researches I have been engaged upon for the last three years on the use of ferrous sulphate as a manure for certain plants, I am desirous of informing chemists that I have found when plants are grown with this manure an excess of it is injurious, as I have shown in my paper (CHEMICAL NEWS, vol. 1., p. 167, and *Chemiker-Zeitung*, 1884, p. 757) on this subject. But, further than this, all my researches on iron as a manure go to show that when the amount of *ferric oxide* in the ashes of all the plants I have grown with this new manure has reached 10 per cent the plant died. So it is quite impossible for the plants I have examined in these researches to live when any one of them is capable of yielding after incineration *ten per cent* of Fe_2O_3 in their ashes.

I intend next month to present a long memoir to the Chemical Society detailing some important results on the subject.

ON THE COLOUR OF CHEMICAL COMPOUNDS REGARDED PRINCIPALLY AS A FUNCTION OF THE ATOMIC WEIGHTS OF THEIR CONSTITUENT ELEMENTS.

By THOMAS CARNELLEY.

THE colour of chemical compounds depends on at least three conditions, *i.e.* (1) the temperature; (2) the quantity of the electro-negative element; and (3) the atomic weights of the constituent elements.

Of these three conditions the two former have been especially studied by Mr. Ackroyd (CHEMICAL NEWS, vol. xxiv., p. 76). The author therefore wishes to direct attention mainly to the third point. He gives, however, a brief summary of Mr. Ackroyd's results concerning the two former conditions.

1. All the chrome compounds change their colour in a definite serial order, and indeed in that of the spectral colours, in such a manner that as the temperature rises the colour approximates more and more to the red end of the spectrum, and ultimately, at a sufficiently high temperature passes into brown and black. Most frequently the transition of colour is direct from white to a pale yellow, whilst violet, indigo, blue, and green are passed over as transition stages.

2. In binary compounds an increase of the quantity of the electro-negative element involves a change of colour to the red end of the spectrum, and ultimately into brown and black. Thus PbO is yellow, Pb_2O_3 red, and PbO_2 brown.

3. Influence of the atomic weight: in some series of compounds, Ax , Ry ; Bx , Ry ; Cx , Ry ; &c., in which R is an element or a group of elements, whilst A, B, C, &c., signify elements belonging to the same subordinate group in Mendeleeff's table of the natural classification of the

elements, the colour passes either entirely or partially through the following scale:—White or colourless, violet, indigo, blue, green, yellow, orange, red, brown, black, with the increasing atomic weight of the elements A, B, C, &c. Or, in other words, the higher the atomic weight of the elements A, B, C rises, the more the colour of the compound approaches the red end of the spectrum, and passes in certain cases into brown and black.

It must be remarked that the above rule applies only to cases in which A, B, C, &c., are elements belonging to the same sub-group, but not to cases in which they belong to different sub-groups. Thus, oxides cannot be directly compared with the corresponding sulphides, selenides, and tellurides; in like manner fluorides cannot be compared with the corresponding chlorides, bromides, and iodides, since fluorine and oxygen belong to even series, whilst chlorine, bromine, iodine and sulphur, selenium, and tellurium belong to odd series. The author then gives tables showing the influence of the atomic weight on the colour of the compounds.

In these tables the colours of every compound is given as laid down in the usual manuals. If two authorities state different colours both are mentioned. Some compounds exist in two allotropic conditions of different colours: in this case both colours are quoted. It must not be forgotten that the above rule applies in strictness only to compounds in the solid state; and, further, that the colour in the solid state may, to a certain extent, change in accordance with the state of aggregation.

Besides the 426 cases in which the author found the above rule applicable, there appeared 14 exceptions.

Four of these, DiCl_3 , V_2O_3 , CrO_3 , and CdO , do not admit of any satisfactory explanation.

Theoretic Explanation.

In the discovery of the following explanation of the phenomenon in question the author acknowledges the assistance received from his colleague Mr. J. W. Capstick.

1. *Influence of the Atomic Weight (a).*—In a solid body the molecules vibrate as entireties in certain mean positions. If the conditions are in other respects alike (*e.g.*, the temperature) the period of vibration will be the smaller the less dense the mass of the molecule. If the time of the vibration of the molecules is so small that it coincides with any vibration beyond the violet end of the spectrum no visible vibration can be absorbed and the colour must appear white. This condition must persist until (by chemical substitutions, &c.) the molecular mass becomes so large that its period of vibration falls above the violet extremity, when the violet rays are absorbed, and the compound appears of the complementary colour of violet, *i.e.*, greenish yellow. If the mass of the molecule becomes still greater, the period of their vibrations increases more and more, and the blue rays begin to be absorbed, whilst the unabsorbed light is yellow. Next the green rays are absorbed, and the result is orange. Then the yellow is extinguished, leaving only red. Finally the red is absorbed, and the substance becomes black.

(b.) If we may conclude from the observation of colours it seems an almost invariable rule that in case the period of vibration is long enough to extinguish any given colour it annihilates all those colours which have a shorter wavelength; thus if yellow is extinguished blue and green disappear also. Otherwise, the colours would pass from orange to a purple-red; and if red were obliterated without the simultaneous disappearance of blue, green, and yellow, the colour would appear greenish instead of the ordinary black. The exceptional green colour of Au_2O , AuI_3 , WCl_4 , Wl_2 , UCl_5 , and UCl_4 may thus be explained.

2. *Influence of Temperature.*—In case of a solid body in which the molecules vibrate in certain mean positions, an increase of temperature occasions a greater amplitude of vibration, but not a longer period. In connection herewith a rise of temperature diminishes the cohesion between the molecules and thus enfeebles the power of recuperation, since the molecules are thus induced to vibrate more

slowly and thus to bring about the same changes of colour which were observed as the mass of the molecules increases.—The above theory seems to me a satisfactory explanation of the otherwise paradoxical fact that an increase of molecular weight on the one hand, and on the other a rise of temperature, should occasion exactly the same changes of colour.

That in certain binary compounds an increase of the proportion of the electro-negative element occasions a change of colour towards the red extremity of the spectrum may probably be due to the circumstance that with an increased quantity of the electro-negative element an increase of the molecular weight follows. The phenomenon may then be readily explained by the theory given above. However, to render this explanation universally available it would be necessary in certain cases, *e.g.* the oxides of copper, lead, and chrome to double or treble the generally received formulæ for some of their grades of combination. Thus:—

Cu_2O , red; Cu_2O_2 , black.

PbO or Pb_2O_3 , yellow; Pb_3O_4 , red; Pb_5O_6 , brown.

Cr_2O_3 , green; Cr_2O_6 , red.

Lastly, there appear certain indications that the colour of compounds is a periodic function of their atomic weights. This is best seen if we consider the normal iodides. If we construct a curve in which the ordinates represent the atomic weights of the positive elements and the abscissæ a scale of colours rising from black through brown, red, orange, yellow, green, &c., up to white, the curve resembles in form Lothar Meyer's well-known curve of the elements.

The author purposes extending his researches to the colours of organic compounds.—*Berichte der Deutschen Chemischen Gesellschaft.*

DECOMPOSITION AND ANALYSIS OF SLAGS.

By MALVERN W. ILES, Ph.D.

SEVERAL years ago, in the columns of the *Engineering and Mining Journal* (vol. xxxi., p. 58), I described a method for the decomposition of slags, for analytical purposes. This method, briefly stated, was to fuse the finely-powdered slag with caustic potash in a silver crucible.

Since then I have found the method to be applicable to a large class of ores and furnace products; and that for estimating sulphur in slags and minerals by such fusions, and the subsequent use of bromine water, the method is also capable of wide application.

The chief objection to this method arises from the fact that in the fusion the silver crucible is more or less attacked by the caustic alkali, and that inasmuch as argentic chloride is quite soluble in a hot solution of potassium chloride, the silver will give trouble in the subsequent analytical determinations. To obviate this difficulty, W. Bettel advocates* the use of gold lined or plated platinum crucibles for such fusions with potassium hydrate.

This is a most valuable suggestion, and the method as originally detailed,† together with this modification, becomes applicable to the decomposition of nearly all silicates, and to the estimation of sulphur in nearly all inorganic as well as organic bodies.

I now find it is not necessary to make a fusion of any slag I have ever seen produced in connection with the lead-silver industry.

About two years ago, I learned from Mr. Hermann Schlapp, that he was using a "glassy" sample for analytical purposes, and that the slag he produced was decomposed with hydrochloric acid. I found to my surprise that if the hot flowing slag is allowed to run upon an iron rod, and while the slag is still hot, the rod is plunged into

cold water, not only the physical, but the chemical, properties of the slag are so changed that upon drying the sample, it becomes completely decomposed by concentrated hydrochloric acid. The slag samples so taken are also readily attacked by most of the other inorganic acids, and are more or less decomposed by many of the organic acids.

Tartaric acid partially decomposes the slag, at a boiling temperature, giving rise to formation of much gelatinous silica.

Acetic acid very slightly attacks the slag on boiling and using strong acid (sp. gr. 1.055); and by filtration and the addition of ammonia some iron is precipitated, and the filtrate from the iron shows a small amount of lime.

A strong solution of sodium hydrate when boiled with the slag gives an intense green solution of sodium manganate (when manganese is present). Upon adding boiling water to this green solution, the manganese is precipitated.

Bromine water added to the finely-divided slag attacks it very vigorously, giving hydrated oxides of iron and manganese; if now a few drops of strong sulphuric acid be added, the iron and manganese are of course readily dissolved, leaving practically pure hydrated silicic acid. Inasmuch as the silicic acid so obtained does not filter well, no practical use of this very curious reaction can be made in the laboratory.

The above mentioned simple tests very plainly indicate, that by rapid cooling the slag is markedly changed in its chemical properties. If one closely examines a pot of newly drawn slag there will be observed on the outer edges a very fine shell or plate of glassy looking slag, varying in thickness from $\frac{1}{8}$ to $\frac{1}{4}$ of an inch—and also, where the slag has come in contact with the upper rim of the pot, there will be an appearance of a glassy or siliceous slag; this will be noted even when the slags are quite basic. All of these glassy surfaces or portions of the slag are generally completely soluble in hydrochloric acid, whilst if we allow the slag to cool slowly, alkaline fusions, or treatment with hydrofluoric acid, or heating with some strong acid in sealed glass tubes, is necessary to effect decomposition.

My method of taking the laboratory samples at these works is to use an ordinary tapping bar, and after there begins to form a very thin crust upon the newly drawn pot of slag, to throw aside this crust with one end of the bar, and immerse the other end into the pot of slag about four inches; then very quickly withdraw and plunge into a bucket of water. This mode of taking the sample is applicable for both the assay and laboratory determinations; more care, however, is used in taking the laboratory sample, in order to secure a thin crust or shell, and also to lose no time in plunging into water.

In cases where much matte is formed, I think the method just detailed is the fairest by which the sample can be taken; that is, when due care is taken to save and rework the matte (or lead regulus). I have several times had the laboratory samples accidentally contaminated with plates of iron rust, scaling off from the iron pans in drying the sample; therefore I have procured porcelain or "granite" lined cups (shaped like the ordinary tin cups), and find they are admirably adapted for this purpose.

In order that my mode of procedure may be clearly understood, I will state very briefly the routine operations, viz.:—Allow the flowing slag to run upon the end of a steel bar, or dip the bar into the newly drawn pot of slag; plunge into water, dry the sample upon the slag pot, powder and pass through an 80-mesh sieve: now grind a small portion in an agate mortar for two or three minutes, and then weigh out the desired amount for analysis. It is generally unnecessary even to powder in an agate mortar, for the estimation of silica, iron, and lime; and only in making complete analysis of the slag, or where unusual care is required, is this operation performed.

After using the above method for over two years, I find that all slags containing an amount of silica varying from

* CHEMICAL NEWS, xliii., 94; see Note *Amer. Chem. Journ.*, 1881, vol. iv., No. 1., p. 57.

† *Scientific American Supplement*, No. 126, June 1, 1878.

30 to 42 per cent are entirely decomposed by hydrochloric acid.

I am led to the belief that the slags produced by the iron smelting industry will also be soluble in strong hydrochloric acid. I will be glad to hear from some of the iron smelters upon this point.

One of the main distinguishing features of a singulo-silicate slag in contradistinction from the bi-silicate (also the so-called "mixed" or sesqui-silicate), is that the singulo-silicate is soluble (generally) in strong hydrochloric acid, whilst the bi-silicate is only imperfectly soluble. I am inclined to the belief that almost all slags are soluble in concentrated hydrochloric acid, if we use the precaution to take a very thin crust or scale upon a steel bar, and immediately plunge into cold water. I do not find that by taking the samples in this manner, the chemical composition is materially changed,—certainly, it is not perceptible, so far as the silica, iron, lime, and manganese are concerned; and for practical working of the furnaces these are the main ingredients which the metallurgist desires to know. It would be reasonable to suppose that part of the sulphur, and perhaps a minute trace of arsenic, antimony, and phosphorus, would be eliminated in combination with hydrogen.

Before leaving this part of the subject, I will state that I see no reason why many slags could not be made a source for a number of inorganic salts; such as iron, lime, manganese, vanadium, &c.; perhaps a portion of the lead and silver could be saved; also the (gelatinous) silica. Nor is it unreasonable, in view of the above facts, to utilise even basic slags for the manufacture of building and paving brick.

Analysis of Slags.

After taking the slag sample, as previously indicated, weigh out from $\frac{1}{2}$ to 1 grm., transfer to a covered casserole, add from the wash bottle a few drops of water, stir well, add concentrated hydrochloric acid, again stir, and digest over a free flame for a few minutes. The addition of water and the stirring prevents the slag from clotting or caking upon the bottom of the vessel.

Now add a few drops of nitric acid, both to ensure the oxidation of the iron and also to decompose a few specks of lead sulphide which are apt to form during the first addition of hydrochloric acid, and rise upon the sides of the vessel. Evaporate to dryness upon the water-bath; this is not a long operation if the analyst will use a minimum quantity of hydrochloric acid (say 6 to 8 c.c.). After the evaporation is completed, add a few drops of water, just sufficient to moisten the mass, and evaporate the second time. Now add a slight excess of concentrated hydrochloric acid, warm, dilute, and filter, washing the silicic acid with boiling water, and drop a small amount of hydrochloric acid around the edges of the paper; wash again with water. The moist residue, with filter-paper, is transferred directly to either a porcelain or platinum crucible, placed in an ordinary scorification cup, and dried before the assay muffle until the paper begins to carbonise. It is then placed in the muffle for about five minutes, removed, and allowed to cool, and the silica then weighed. The silica will be found perfectly white, not even tinted with iron, and the determination is as accurate as if a fusion had been performed.

For the determination of the iron it is advisable to take a second portion of $\frac{1}{2}$ grm., boil with hydrochloric acid to complete decomposition in a casserole; then dilute with water and add a small piece of unamalgamated zinc, directly into the covered vessel. After a few minutes the cover is removed, washed, and the contents of the casserole are cautiously transferred by decantation to a large beaker, and diluted up to 500 c.c.; now add rather a large amount of concentrated sulphuric acid (say 25 c.c.), and titrate the iron with a standard solution of potassium permanganate.

It will be noted that it is entirely unnecessary to remove the silica in order to determine the iron, and furthermore, time is saved by reducing the iron by unamalgamated zinc

directly in the vessel in which the decomposition of the slag is effected.

While the above mode of procedure may seem somewhat crude, yet it can be shown that all the precautions are taken to secure accuracy in estimating iron in a hydrochloric acid solution. Zimmermann proved that the addition of manganese sulphate allowed an accurate estimation of iron by potassium permanganate in a hydrochloric acid solution; and quite recently J. Krutzwig and A. Cochetex showed* that manganese sulphate might be omitted by taking the precaution to use:—1, as little hydrochloric acid as possible for the solution of iron; 2, to reduce with zinc in a hydrochloric acid solution; 3, to use twice as much sulphuric as hydrochloric acid; 4, to dilute largely and use a dilute solution of permanganate of potassium.

For commercial work, a solution of permanganate about $\frac{1}{10}$ normal (6.5 grms. per litre), is recommended.

For the estimation of lime, two methods are used according to the accuracy to be attained. If for quick work, we wish to ascertain the percentage of lime, we use the filtrate from the silica as follows: heat this filtrate, add ammonia to slight alkaline reaction; then add a saturated solution of oxalic acid to dissolve the iron; boil for a few minutes, allow to stand twenty-five minutes, filter hot, wash well, and transfer to a casserole; add some hot water, and sufficient hydrochloric acid to dissolve the calcium oxalate, filter, and dilute with cold water. Now add rather a large amount of sulphuric acid; heat to boiling, and titrate with a solution of permanganate.

If a greater degree of accuracy is desired, the iron and alumina are removed as basic acetates, then manganese is separated by bromine water, the zinc removed by sulphurated hydrogen, and the filtrate treated according to the usual method. Some manganese will invariably pass into the filtrate, when the iron is precipitated by ammonia, and will come down with the lime, introducing thereby an error to the extent of its presence. Where, however, the amount of manganese is small in comparison to the amount of iron, we can often use the first mentioned method with a great saving of time. For the manganese determination, take 1 to 2 grms. of the finely-powdered slag, according to the amount of manganese present, and treat in a casserole with concentrated hydrochloric acid, with the addition of a small amount of nitric acid in order to convert all the iron into the ferric form. Now boil, and add sulphuric acid, gradually replacing all of the nitric and hydrochloric acids; the success of the operation depends upon the entire removal of the hydrochloric acid. Dilute to about 150 c.c. and boil; add an emulsion of zinc oxide in large excess, by which the iron is precipitated as ferric hydrate; filter off the silica, oxides of zinc and iron, and dilute up to 500 c.c. Some writers recommend, before the addition of zinc oxide, to neutralise with sodium carbonate and then clear up the solution with a few drops of nitric acid; this in practice we have found to be unnecessary.

Draw off from the diluted liquid, after thorough mixing, an aliquot part, say 100 c.c., transfer to a casserole, heat to boiling, and titrate with frequent stirring, with a normal solution of potassium permanganate, until the first rose tint is obtained. Calculate the per cent of iron corresponding to the permanganate used, and multiply this per cent found by 0.2946 = per cent, Mn.†

The manganese scheme as above stated is highly recommended, both for rapidity and accuracy; in fact there is no known method which we think will compare with it for technical and scientific work.

Occasionally arsenic determinations are required upon the slags; for this determination the writer thinks there is no known method which will compare with that of Prof. Pearce, as detailed by Mr. O. J. Frost in the columns of

* *Berichte der Deutschen Chemischen Gesellschaft*, 16, 1534. See note in *Amer. Chem. Jour.*, vol. v., No. 6, p. 459.
† See original article, *Zeit. f. Anal. Chem.*, 20th year, p. 271; also recent articles by Williams, Stone, and others in the *Trans. Amer. Inst. Min. Eng.*

the *Engineering and Mining Journal* (see vol. xxxv., p. 256). The method is a general one, and is applicable to ores, furnace products, &c.

—The sulphur is determined by the "Fahlberg-Hes" method as follows:—

1. Fuse from 1 to 2 grms. finely-powdered slag in a silver or platinum gold-lined crucible, with 25 grms. potassium hydrate for twenty minutes, cool, dissolve in water, filter off hydrated oxide of iron, &c.; now add 30 c.c. bromine water, and then concentrated hydrochloric acid to acid reaction; boil off excess of bromine, filter if necessary, add barium chloride, and proceed as usual for the treatment of barium sulphate.

Mr. Walter T. Page, chemist to these works, has kindly favoured me with the scheme for zinc determinations, which he is using with good success. I will take this opportunity to acknowledge my indebtedness to Mr. Page for much valuable aid throughout the entire preparation of this paper.

Zinc Scheme.

Treat 1 grm. of substance with 10 c.c. HCl + 5 grms. HNO_3 + 4 grms. H_2SO_4 ; acids concentrated and added in the above given order. Digest over a free flame to perfect decomposition, until thick fumes of H_2SO_4 appear; cool, dilute to 150 c.c., and filter; wash with hot water—now add 2 c.c. HCl and pass a rapid stream of H_2S to saturation; filter, and wash; boil filtrate, and oxidise with KClO_3 . Precipitate iron and alumina with ammonia, using large excess; filter and wash. (If the percentage of zinc is large, it is best to re-dissolve and re-precipitate, and combine filtrates).

Add now HCl to decided acid reaction. Transfer to $\frac{1}{2}$ litre flask—fill to mark, mix thoroughly, and draw off an aliquot part. Titrate this directly with a standard solution of potassium ferrocyanide,* using uranium acetate as the indicator. The ferrocyanide solution is made up with about 43 grms. K_4FeCy_6 per litre. Ammonium chloride interferes slightly with the accurate determination of zinc by this method; therefore we use the same amount of reagents, and correct for the ammonium chloride in each case. Manganese, nickel, and cobalt interfere—hence they are to be removed before titration.

The results of the fire assays for lead and silver are generally all that is necessary; if, however, a complete analysis of slags is to be made, the lead is estimated as a sulphate in the usual manner.

Some writers on metallurgy, and certain metallurgists, I am inclined to think, seem to over-estimate the importance of using wet methods for lead and silver. Dr. Percy is inclined to the belief "that the dry method of assaying must always be resorted to as the only direct, accurate, and practical method" for commercial determinations of both lead and silver. The writer, after having used a number of proposed methods to facilitate the above determinations, has come to the same conclusion. There are, however, two wet methods, that deserve special mention; one of these is the method used at Bleiberg,† where lead sulphate is digested for one hour with sodium carbonate, the resulting lead carbonate dissolved in acetic or nitric acid, and the lead precipitated from this solution as a sulphate, in which form it is weighed.

The other method is the one proposed by A. E. Haswell,‡ and was subsequently altered by H. v. Jupner.§ This method, very briefly stated, is:—

Use a nitric acid solution of the substance to be determined, add an emulsion of zinc oxide, titrate in the cold to slight rose tint with a decinormal solution of permanganate, warm, and add a few drops of permanganate until the second tint is observed.

My experience with the foregoing method is, that the other substances mentioned by von Jupner, which may re-

place the zinc oxide, as potassium and ammonium hydrates, sodium and ammonium carbonates and also quicklime, do not give entire satisfaction, while by the use of zinc oxide, the results are exceedingly good. I, therefore, have come to the conclusion, that if one can only succeed in getting all the lead into solution as a nitrate, the method is an accurate one. Inasmuch as many lead ores contain lead sulphate and lead in other forms which are liable to tenaciously resist the ordinary solvents, the method should only be used with great discretion. In cases where lead sulphate is present, perhaps it could be advantageously removed from the siliceous residue by digestion with sodium carbonate, or the lead sulphate could be easily decomposed by metallic zinc in a hydrochloric acid solution. The difficulty of obtaining zinc which is free from lead would militate against this mode of procedure. The volumetric estimation of lead by potassium dichromate is not used at any of the western metallurgical works, and, I think, for good reasons, as the method is valueless.

Volhard's method for the volumetric estimation of silver by ammonium sulphocyanide is a most excellent one, where it can be applied.

These are all of the ingredients the chemist will ordinarily be called upon to determine in connection with the lead-silver smelting industry. Slags, however, may and generally do contain any one or several of the following elements: Ba, Cu, Ni, Co, V, Sb, P, K, and Na. If any of these are to be determined, the methods as given by Fresenius, Rose, Sutton, Cairns, or Hart are followed.

In conclusion I will state that the above methods we also use daily for ores and furnace products, and we regard them for the performance of our work as invaluable.—*The School of Mines Quarterly*.

REPORT ON GLUCOSE.†

THIS Report contains a great deal of useful information in regard to the manufacture of starch-sugar and the nature of the products obtained. There are twenty-nine factories in the United States, using, as nearly as can be estimated, 43,000 bushels of corn per day. The products are of various grades, which appear in commerce under the following names:—(a) The liquid varieties: glucose, mixing-glucose, mixing-syrup, corn-syrup, jelly-glucose, confectioners' crystal glucose. (b) The solid varieties: solid grape-sugar, clipped grape-sugar, granulated grape-sugar, powdered grape-sugar, confectioners' grape-sugar, brewers' grape-sugar.

The most general purposes for which starch-sugar is used are:—(1) For the manufacture of table-syrup; (2) A substitute for barley-malt in the brewing of ale or beer; (3) As a substitute for cane-sugar in confectionery; (4) For the adulteration of cane-sugar, to which it is added to the extent of 20, or more, per cent; (5) For the manufacture of artificial honey; 6. For the manufacture of vinegar.

The transformation of the starch into dextrose is effected in most of the factories by means of sulphuric acid, though in some oxalic is used, and the use of phosphoric acid has been suggested. The normal products of the transformation by means of these acids are, as is well known, dextrose, maltose, and dextrin. The commercial products consist of these substances in different proportions, the liquid products containing more dextrin and maltose than the solid products. In the latter the analyses showed the presence of from 72 to 73.4 per cent of dextrose, and from 4.2 to 9.1 per cent of dextrin. In the "glucoses" or liquid products analysed the amount of

† Prepared by the National Academy of Sciences, in response to a request made by the Commissioner of Internal Revenue. Washington: Government Printing Office. 1884.

dextrose was found to vary from 34·3 to 42·8 per cent, and the amount of dextrin from 29·8 to 45·3 per cent. The mineral constituents were found to be present only in insignificant quantities, and to be of harmless nature.

In the fourth sub-division of the report the subject of the relation of starch-sugar to health is discussed. The question, "Is the use of 'glucose,' or 'grape-sugar,' injurious to health?" is asked, and the report then proceeds:

"This is certainly one of the most important questions that can be asked regarding the substance under consideration. It has been discussed very freely, but on a very insufficient basis of facts. Indeed, so far as the products made from corn-starch are concerned, it appears that no experiments have ever been made with reference to their effects upon the system. It is essential in a discussion of this subject to keep clearly in mind the fact, that while it is undoubtedly true that the pure chemical substances, dextrose, maltose, and dextrin, are not injurious, there may be other substances present in small quantities in the commercial products, and that these are capable of producing injurious effects; or it may be true that when the commercial products are changed by fermentation substances of injurious character are formed or left unfermented.

"In Germany, where large quantities of dextrose are made from potato-starch, experiments bearing upon the question of the presence of injurious constituents have been made with the commercial products. Some of the results obtained indicate that after fermentation of potato-sugar there are left substances which are injurious, while others indicate that this is not true. Among those who have experimented on the subject A. Schmitz, Nessler, and Freiherr von Mering should be specially mentioned. Schmitz* fermented potato-sugar, and, evaporating the products down to small volumes, administered known quantities of the residues to cats and dogs, and in a few cases to human beings. The results obtained were uniform, and showed that the substance caused sickness, as headache, sweating, and loss of appetite.

"Later, Nessler† undertook similar experiments, and obtained similar results. He experimented upon his assistant and himself. One of his experiments is here described. He allowed a 20 per cent solution of potato-sugar to ferment after the addition of a small quantity of hops. After the fermentation was over the liquid was filtered, a litre evaporated down to a syrup, and then diluted up to 100 c.c. This solution had a disagreeable bitter taste. Nessler took 50 c.c. of it at 7 a.m., and the same quantity at 10 a.m., each portion corresponding to 100 grms. of potato-sugar. Toward noon he began to feel uncomfortable, but not so much so that he could positively attribute his condition to the beer extract. At 2 p.m. the residue from 100 grms. potato-sugar was again taken, and now in about an hour there followed profuse perspiration and violent headache, both of which continued until night. A few days later his assistant took the residue from 90 grms. of sugar, the fermented liquor having been evaporated down to two-fifths its original volume. He soon experienced difficulty in breathing, and broke out in a cold sweat; at dinner he had no appetite, and was obliged to throw up the little soup he did take. In the afternoon he had a violent headache, which continued until evening.

"Nessler concludes his paper with these words:—'It is hence beyond a doubt true that in the liquid obtained in the fermentation of potato-sugar there are substances injurious to health. If the question is asked whether this is true of all commercial potato-sugars, as well as of the sugar examined, we cannot give a definite answer.

"In the case of all varieties of potato-sugar thus far examined there remains after evaporation of the fermented liquid a bitter tasting extract, which turns the plane of

polarisation to the right, and it is very probable that all of them may act injuriously upon the health, in varying degrees, according to the greater or less purity.

"As in buying the sugars it is not possible to determine whether the harmful substances are present or not, potato sugar should not be used for the preparation of beverages,* until it can be prepared in perfectly pure form.'

"Directly opposed to the results of Schmitz and Nessler are those obtained by Freiherr von Mering.†

"This writer experimented upon dogs, cats, rabbits, and human beings, in much the same way as Schmitz and Nessler had done, and he concludes that the unfermentable residues from potato-sugar are not at all objectionable.

"Later, Schmitz‡ replied to Von Mering, upholding his first results.

"It hence appears doubtful whether there are injurious substances in potato-sugar, and it is highly desirable that the experiments on this subject should be repeated by those who have not thus far taken active part in the discussion. Even though it should eventually be shown that potato-sugar is or is not objectionable, it would not necessarily follow that the same is also true of maize-sugar.

"As, so far as we know, no experiments had been made upon starch-sugar, we carefully repeated the experiments described above, using several of the samples of glucose and grape-sugar, the analyses of which are given in the preceding part of this report.

"We were fortunate in securing for this work the assistance of Dr. J. R. Duggan, of the Johns Hopkins University, who has for some time past been occupied in experiments upon fermentation, and who is hence fully familiar with all the precautions necessary to secure reliable results. The fermentations were carried on in a new cellar, which fortunately chanced to be available, so that the danger of abnormal fermentation was reduced to a minimum.

"Pure glucose cannot be fermented by the simple addition of yeast in small quantity; for yeast, like all living matter, requires certain nitrogenous and inorganic materials for its own nourishment. As has been shown by Pasteur, this want may be supplied by the addition of certain salts, such as ammonium tartrate, calcium phosphate, &c.; but as these cannot be added in exactly the necessary proportions, some would be likely to remain in the solution after fermentation was complete, and, if taken into the stomach along with the glucose residue, would probably produce an effect of its own which might be attributed to the glucose.

"It is not easy to obtain in sufficient quantity a liquid furnishing a proper medium for the growth of yeast which does not also contain glucose; and, for this reason, it was first necessary to determine the effect, if any, of the unfermentable residue from this glucose.

"Experiments Nos. 1, 2, and 3 were made for this purpose. The nutrient liquid used was barley-wort, on account of the fact that it is most commonly used in brewing for commercial purposes.

"This liquid contains much more nitrogenous matter than is necessary to support the yeast during its fermentation, and therefore it still forms a good medium for the growth and development of yeast after it is considerably diluted with a solution of glucose.

"The method of experimenting was as follows: The barley-wort, of the concentration usually employed for making beer, was mixed with the glucose solution, and the whole heated to boiling by passing steam through a coil of block-tin tubing placed in the tub. The tube was then connected with the hydrant, and water passed through it until the solution was well-cooled. It was then allowed to flow slowly over a wide board, for the purpose of thoroughly aerating it. The temperature was reduced to about 10° C., and about a pint of yeast added. Ferment-

‡ Ibid., 481.

tation was carried on in a cool vault, and was allowed to continue until very little sugar was left in the solution and the yeast had all settled to the bottom of the tubs. A sufficient quantity of beer was then syphoned off and evaporated slowly over the water-bath to about one-tenth its volume. The residue consisted principally of dextrin, nitrogenous matter from the wort, glycerin, succinic acid, and probably other products of fermentation in very small quantities. It formed a thick, dark-coloured syrup, of very disagreeable taste, especially when wort containing hops had been used. For this reason, sweet-wort was used in most of the experiments. All of the fermentations were carried on by the low process—that is, with bottom yeast at a temperature of from 8° to 10° C.

"Two experiments were tried with the high process, but it was found to be impracticable on the small scale, on account of the development of bacteria, due to the higher temperature. As the difference in the two processes is essentially one of temperature only, there is no reason to suppose that they could in any way give different results.

"The amount of yeast added to each tub was about one-half litre. This was carefully examined with the microscope, both before and after fermentation, to guard against the presence of foreign ferments that might produce injurious products. The glucoses used were of the various manufactures already mentioned, and embraced the different grades of solid and liquid products.

"The extracts were taken at different hours of the day, both before and after meals. The quantity usually taken contained the residue from 125 grms. of glucose; but in experiment No. 8 this quantity was increased so as to correspond to 200 grms. It seems useless to try still larger quantities, for it is probable that if much more was taken the normal products of fermentation, such as succinic acid, would produce some effect.

"*Experiments 1 and 2.*—Thirty litres of sweet-wort and the same quantity of hopped wort were separately fermented, the process lasting, in each case, one week. Five litres of the resulting liquid were evaporated to 750 c.c., and 300 c.c. of the extract taken internally. The same experiment was tried by two individuals, but no effect was produced. The amount of extract taken corresponded to two litres of the beer.

"*Experiment 3.*—In this experiment there were used 15 litres of sweet-wort, to which were added 15 litres of a 12.5 per cent solution of cane-sugar. Five litres of the liquid were evaporated to 500 c.c., and 200 c.c. of the extract taken, with no effect. The amount of extract taken represented 125 grms. of cane-sugar.

"*Experiment 4.*—Fermented 15 litres sweet-wort and 15 litres of a 12.5 per cent solution of grape-sugar. (Sample No. 12.) Five litres of the liquid were evaporated to 500 c.c., and 200 c.c. taken. No effect was produced. On the following day, the same amount of residue was taken, and with no effect. The amount of extract taken corresponded to 125 grms. of glucose in each experiment.

"*Experiment 5.*—Fifteen litres of sweet-wort and 15 litres of a 12.5 per cent solution of grape-sugar (Sample No. 7) were fermented. The same amount of extract was taken as in the last experiment, with the same results.

"*Experiment 6.*—The details of this experiment were exactly the same as those of the last. The substance was a commercial glucose. (Sample No. 14.)

"*Experiment 7.*—Fifteen litres of hopped wort, with 7.5 litres of a 25 per cent solution of commercial glucose (Sample No. 1), were fermented. Four litres of the fermented liquid were evaporated down to 400 c.c., and of the residue 150 c.c. were taken. No effect was felt.

"*Experiment 8.*—Fifteen litres of hopped wort and 7.5 litres of a 25 per cent solution of grape-sugar (Sample No. 13) were fermented. Five litres of the fermented liquid were evaporated to 500 c.c. and 200 c.c. taken. No effect was felt. The extract represented 160 grms. of grape-sugar.

"The experiments described above occupied about two

months, during which time Dr. Duggan repeatedly took large quantities of the extracts. At the end of the experiments, and during the entire period, his health continued excellent.

"There was nothing whatever to indicate that the extracts contained anything injurious to health, and the conclusion seems to be fully justified that the samples examined by us, and which we have every reason to believe were fair average samples of the substances found in the market, contained nothing objectionable from a sanitary standpoint. In the experiments the experimenter took into his system everything that could possibly be objectionable contained in from 120 grms. to 160 grms. of the glucose, or grape sugar, *i.e.*, from a quarter to a third of a pound. It must be borne in mind, further, that the extract which was taken into the stomach must have contained any objectionable mineral as well as organic substances present in the glucose employed. Hence, the results seem to be final as regards the injurious nature of glucose or grape-sugar made from maize.

"These experiments extended over a period of only about two months. On the question, therefore, whether any injurious effect would follow the continuous use of this material, the committee has no information.

"Our experiments have, of course, no direct connection with those of Schmitz, Nessler, and Von Mering, already referred to. These gentlemen experimented upon potato-sugar as furnished by manufacturers in Germany. Our conclusions are valid only for maize-sugar as furnished by manufacturers in this country.

"It should be further remarked that, although our experiments show conclusively that the products of fermentation of glucose are not dangerous to health, it does not necessarily follow that beer made by the fermentation of glucose is as good as that made in the usual way. That is a matter which does not fall within the scope of our investigation."

The report was prepared by a committee of the National Academy of Sciences, which consisted of Professors George F. Barker, of the University of Pennsylvania, W. H. Brewer, of Yale Cottage; Wolcott Gibbs, of Harvard College; Charles F. Chandler, of Columbia College; and Ira Remsen, of Johns Hopkins University.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING SEPTEMBER 30TH, 1884.

By WILLIAM CROOKES, F.R.S.

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford.

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To COLONEL SIR FRANCIS BOLTON, *Water Examiner*,
Metropolis Water Act, 1871.

London, October 6th, 1884.

SIR,—We submit herewith the results of our analyses of the 182 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily from September 1st to September 30th inclusive. The purity of the water, in respect of organic matter, has been determined by the Oxygen and the Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter, and the quantities of free oxygen present in the whole of the samples submitted to analysis.

Of the 182 samples submitted to examination, two were found to be "very slightly turbid," and one "slightly turbid." The remaining 179 samples were perfectly clear, bright, and well-filtered.

The results as to the state of aëration of the whole of the samples, and as to the degree of freedom from colour of all but the one sample recorded as "slightly turbid," have not differed appreciably from the results met with in the previous summer months' supplies. The proportion of organic matter has continued low, though not so exceptionally low as was noticeable in the supply for August.

We are, Sir,

Your obedient Servants,
WILLIAM CROOKES,
WILLIAM ODLING,
C. MEYMOOT TIDY.

NOTICES OF BOOKS.

A Treatise on the Purification of Coal-Gas and the Advantages of Cooper's Coal-Liming Process. By R. P. SPICE, M. Inst. C.E. London: E. and F. N. Spon.

In the very first sentence of this book the author strikes a significant key-note. Says he: "Several years have elapsed since modern chemical knowledge was brought to bear, inconveniently to say the least of it, upon the Gas Manufacturers of London; and many hard battles have been fought in Parliamentary Committee Rooms concerning the vexed question of what are called sulphur compounds. Formerly these obnoxious and troublesome bodies were not thought of, and probably not known except to the learned who inhabit the higher regions of scientific life; who can tell common people more than they would like or care to know concerning the air we breathe, and the water or milk which we drink or ought not to drink."

Frankly speaking, we do not at all like the spirit of these remarks. No doubt it would be exceedingly convenient for the manufacturers of various products if "common people" would only buy them without enquiries as to their purity. But even the said common people have been able to observe the injury done to books, pictures, dyed and printed tissues, metal articles, &c., in rooms where an impure gas is used for lighting. Hence we are hard-hearted enough to prefer the convenience of the many to that of the few. We think ourselves not only entitled, but in duty bound, to warn the "common people" against hydrogen sulphide and carbon disulphide in the gas they consume. As a matter of course, if any methods can be found of obtaining gas in a state of greater purity an advantage will accrue to both sides. Mr. Spice's object in the work before us is to demonstrate the advantages of the "Cooper process," i.e., the admixture of the coal before distillation with a certain quantity of lime. But these advantages might have been equally well shown without the initial sneers at "modern chemical knowledge" and the "learned who inhabit the higher regions of scientific life."

The advantages which the Cooper process is said to possess are, as claimed in the patent, "an increased yield of ammonia and ammoniacal products," "a diminution of the impurities in crude gas"—that is, evidently in the gas before it has been subjected to purification—and, lastly, that "the resulting coke is for certain purposes improved."

The first of these claims is, on theoretical principles, indisputable. Every chemist knows that a nitrogenous organic body ignited with lime must give off more of its

nitrogen in the form of ammonia than if ignited alone. It is here laid down that the increase in the yield of ammonia by the Cooper process is very considerable. According to Mr. Wanklyn the yield is at least doubled. As to the tar produced,—a very interesting subject to chemical manufacturers—we find no precise statements either concerning quantity or quality.

The point on which the greatest accent is here laid is evidently the suppression of sulphur compounds. It is admitted that the addition of lime to coal for this purpose has been claimed before, in patents which have now expired. But the validity of Mr. Cooper's patent is maintained, it appears, on no less an authority than Mr. R. E. Webster, Q.C., on the grounds, apparently, that a different proportion of lime is used than had been proposed by former inventors. Haddock (1819) used 12½ per cent of lime, and did not mix it with the coal; Leslie (1859) took 10 per cent of slaked lime, and mixed it with the coal. Mr. Cooper, as here quoted, takes about ½ cwt. of quicklime per ton of coal and slakes it with its own weight of water, thus bringing the total of slaked lime to 5 per cent. Into the questions of patent-right which here suggest themselves we cannot enter.

We should, however, like to know Mr. Spice's warrant for asserting that the Leslie process is "absolutely impracticable and valueless," especially if it, as he says, never has been worked?

We are told that the Cooper process supersedes the lime purifiers—wet or dry—thereby doing away with that very objectionable article "blue billy," and that though it does not render the oxide of iron purifiers unnecessary it increases their vitality from a week to a year.

As regards the gas made, Mr. Spice makes no "claim" for any gain in either quantity or illuminating power.

The effects of the liming process upon the coke are evidently a bone of contention. Some persons who have given it a trial report an increase and others a decrease in quantity. Some practical authorities assert that there is a deterioration in quality, whilst others contend that the combustibility of the product is increased. These are points upon which practical metallurgists will easily reach a final decision.

We think that Mr. Spice would have served his cause quite as well had he adopted a more courteous tone towards dissidents.

The Electricians' Pocket-Book: The English Edition of Hospitalier's "Formulaire Pratique de l'Electricien." Translated with additions by GORDON WIGAN, M.A. Cassell and Co., Limited: London, Paris, and New York.

We have here a work which must prove exceedingly useful to all persons—and they are rapidly increasing in numbers—who are engaged either in the theoretical study of electricity or in its practical applications. The author begins with definitions, first principles, and general laws. He goes on to units of measurement, measuring instruments, and the methods of using them for measuring currents, resistances, potential and electromotive force, electrical quantity, capacity and energy, and for testing cables. In the next part we find a variety of practical information and experimental results.

We regret here to find that both author and translator have retained the very objectionable hydrometer scale of Beaumé instead of direct specific gravity, or Twaddell's scale, which two admit of mutual conversion by the simplest calculation. If England is called upon to abandon her traditional standards of weight and measure France may, in turn, be not unreasonably expedited to give up Beaumé.

The subject of conductors brings us to the "Birmingham wire gauges," of which, for the promotion of confusion, there exist no fewer than fourteen!

In the chapter on the production and application of electricity there is a short description of all the principal

batteries in use; of accumulators; of thermo-electric batteries, and of the mechanical generators of electricity.

Some of the more important applications of electricity are next passed in review, such as the transmission of power, with special notice of the experiments of Marcel Deprez; electric lighting, telegraphy, and telephony.

Lastly, we have a chapter of recipes and processes. Here we notice that Mr. Wigan has in one case translated the French term *eau forte* (nitric acid) too literally. The corresponding English term, still used by artisans in various branches of trade is *aqua fortis*.

There is, in conclusion, a bibliography of the authorities consulted, and an index to the tables contained in the work.

Manual of Chemical Manipulations, followed by a Manual of Operatory Chemistry. (Manuel de Manipulations Chimiques suivi d'un Manuel de Chimie Operatoire.) By FR. DE WALQUE. Louvain: D. Aug. Peeters-Ruelens.

In that part of the work before us which is devoted to chemical manipulations the author takes into consideration, first, working with glass, the mechanical division of solids, the weighing of solids, and the weighing and measuring of liquids and gases. He then turns successively to operations in the dry and in the wet way.

Upon glass-working M. de Walque lays a great, but not an exaggerated, weight. At the same time it is evident that no man can by reading become an expert glass-worker, without seeing how the various operations are actually performed.

The instructions for pulverising and otherwise comminuting bodies convey not a few hints which will be very useful to the student.

The directions for weighing, for the management of the balance, and the verification of weights are also satisfactory. The author declares, not without truth, that in laboratories where numerous students work the exactitude of the balances cannot be depended on, and he recommends in such cases Borda's methods of double weighing or of substitution.

In speaking of burettes, the "English burette" (Binks's) is said to be exceedingly convenient for use, an opinion which we do not share, seeing that after a quantity of the liquid has been dropped out at the orifice some time has to elapse before the quantity remaining reaches its final level, not to speak of the effect due to the heat of the hand. Mohr's burette is also mentioned, but without the name of its author.

We next come to the directions for the production and application of heat. It may perhaps surprise us that spirit-lamps should be mentioned before coming to gas as used in the Bunsen burner. But on the Continent alcohol is decidedly cheaper than in England, and is not, like the ordinary methylated spirit sold here, rendered practically useless by the addition of shellac.

In places where gas was not procurable we have seen the outside of platinum capsules densely coated with soot, owing to this unfortunate ingredient. Mention is here also made of those spirit-lamps on the principle of the aeolypile. These instruments sometimes ignite a crucible beautifully, but just at the last moment they throw a somersault, overturning the crucible and spilling its contents. The gas-furnaces of Perrot, Schlösing, &c., are mentioned, but we find no notice of the "solid flame" burner of Fletcher, which is very useful in the laboratory. We cannot, however, follow the author in his very complete instructions for all the various processes occurring in chemical practice.

So far the work before us may be regarded as a treatise on chemical manipulations. The remaining part is a manual of experimental and analytical chemistry, beginning with the development of hydrogen gas. Here we find little deserving special notice, whether commendatory or otherwise. The properties and reactions of the various

compounds and the methods for their preparation are, as far as we perceive, laid down in accordance with the present state of knowledge. It might have been well, however, in speaking of arsenic hydride, to have cautioned the student concerning the danger of inhaling this gas.

An appendix gives a set of tables for qualitative analysis.

The next section of the book is devoted to a brief view of organic chemistry, somewhat curiously arranged, and in which we find no mention of some of the most important bodies.

The illustrations given at the end are numerous, but by no means so well executed as we often find in French works.

CORRESPONDENCE.

THE LATE DR. ANGUS SMITH'S ALKALI REPORT.

To the Editor of the Chemical News.

SIR,—As the one who had charge of Dr. Angus Smith's proof-sheets I think it a duty to call attention to the unintelligibility of the last two lines in his Presentation of the Alkali Report, as it may reflect on the writer's clearness in dictation, on the Secretary's carelessness, or on my neglect in allowing such to pass uncorrected.

This non-meaning is not found in Dr. Angus Smith's manuscript, nor in the first copy of Report sent for revise, nor in the revised copy sent to the Secretary of the Board.

Had this mistake occurred in Dr. Angus Smith's lifetime it would have been a matter of little or of no importance, as any reader would at once see that he could not have written such meaningless sentences.—I am, &c.,

JESSIE KNOX-SMITH.

Gowrie House, York Place, Manchester,

DR. EDMUND W. DAVY'S MOLYBDIC ACID TEST FOR ALCOHOL.

To the Editor of the Chemical News.

SIR,—Amongst the "Chemical Notices from Foreign Sources" in the CHEMICAL NEWS, vol. I., p. 175, there is a paragraph under the heading "A Reaction for Alcohol," from which it would appear that the reaction, which I had proposed several years ago as a test for alcohol, had recently been brought forward by some Continental chemist who was evidently unaware that it had been previously published.

The reaction referred to is that which takes place on bringing (under particular circumstances) a solution of molybdic acid in strong sulphuric acid in contact with alcohol, when a deep azure blue colouration is produced. This test, which is one of exceeding delicacy, I brought before the Royal Irish Academy in the year 1876, when it was first published in its *Proceedings*; and it subsequently appeared in the CHEMICAL NEWS, vol. xxxiv., p. 137, where I pointed out some of its useful applications. In the following year I also published in the *London Pharmaceutical Journal* (vol. viii., 3rd series) a further application of this test, viz., its employment in the detection of alcohol when used as an adulterant of the essential oils, for which purpose it is especially serviceable.

As to the exception which Messrs. Gladstone and Tribe have taken to this test (alluded to in the paragraph referred to), on the ground that this reaction is inconclusive, since a series of other reducing agents produce the same

effect as alcohol, this circumstance I myself pointed out when proposing the test; but I may observe that the same objection applies to all the other tests that have hitherto been proposed for that substance; and, notwithstanding this defect, I still maintain that from the facility of its application and its extreme sensitiveness it may be very usefully employed as a test for alcohol, not only in the cases I have pointed out in my published papers, but in many others.—I am, &c.,

EDMUND W. DAVY, M.D.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 13, September 29, 1884.

The Vegetation of the Amai anthaceæ: Distribution of the Fundamental Principles.—MM. Berthelot and André.—The increase of lignine and of analogous principles extends to all parts of the plant, both absolutely and relatively. It forms ultimately three-fourths of the weight of the stem and the root in vigorous amarantus, but remains less in the leaves. In species where vegetation is feeble and fructification incomplete the proportion of lignine scarcely exceeds half the total weight. The proportion of soluble and transportable hydrocarbons increases during vegetation; its maximum coincides with the epoch of inflorescence, especially in the stem. The albumenoid principles are at first concentrated in the leaves but afterwards in the leaves and the flowers. The potassium salts, the presence and proportion of which are correlative with phenomena of oxidation, are at first concentrated in the stem and leaves. Subsequently they are more uniformly distributed. The roots contain the lowest relative proportion. Insoluble mineral matters tend to accumulate in the leaves except in plants which vegetate feebly, where they seem to remain in the roots.

Separation of Cerium and Thorium.—M. Lecoq de Boisbaudran.—The author proceeds as follows; the mixed solution, almost neutral (sulphates or chlorides) are treated with a few drops of hydrochloric acid and boiled for a few minutes along with turnings of pure copper. The per-salts of cerium are thus entirely reduced to the minimum stage. There is then added to the liquid, without removing the copper turnings, a decided excess of cuprous oxide, and the whole is kept at a gentle boil for at least three quarters of an hour. The precipitate, collected on a filter, is washed with distilled water previously boiled with a little cuprous oxide. This precipitate, which contains the thoria as well as a small quantity of cerium oxide (due especially to deficient washing), is re-dissolved in hydrochloric acid, mixed, if needful, with a little nitric acid. The copper is removed either by means of sulphuretted hydrogen in a very acid solution, or by an excess of ammonia. The ceriferous thorina is submitted a second, or at most a third, time to the same treatment, and is then free from cerium and no longer takes an orange-yellow colour on contact with oxygenated water. The various ceriferous solutions are collected and freed from copper by means of sulphuretted hydrogen or ammonia. Considering the facility of repeating the treatment with copper or cuprous oxide there is no inconvenience in leaving rather large traces of cerium in the first precipitate of thoria obtained, but it is essential this latter oxide should be completely precipitated. It is safer, therefore, to prolong the

boiling of the liquid with cuprous oxide for an entire hour. If there is any suspicion that traces of thoria have been left in the mass of ceria it may be re-dissolved in hydrochloric acid, and the solution submitted to a new and more prolonged ebullition in presence of copper and cuprous oxide.

Solubility of Gallium Ferrocyanide: Correction of a Former Statement.—Lecoq de Boisbaudran.—The author, when treating of the separation of gallium from manganese, observed that at ebullition gallium prussiate is more easily soluble in its mother-liquor if there is added to it a certain quantity of manganese chloride. Other experiments, however, seem to show that the effect obtained depends not on the presence of the manganese, but on a decided acidity of the solution of manganese chloride employed. In fact, if we add a sufficient quantity of hydrochloric acid to the mother-liquor of pure gallium ferrocyanide, this also dissolves on boiling.

The Products obtained on Treating Tellurium with Nitric Acid.—D. Klein and J. Morel.—It is generally admitted that in the reaction of tellurium and nitric acid the only product is tellurous anhydride. M. Klein in a former communication described a basic telluric nitrate obtained on attacking tellurium with a large excess of hot dilute nitric acid. The authors having re-examined the matter find that on treating tellurium with nitric acid there is formed—(1) a solution of tellurous hydrate soluble in nitric acid (at about 0°); (2) a tellurous nitrate, which is decomposed at 70° to 80°, forming tellurous anhydride and a basic nitrate. This tellurous nitrate is formed at about 20°, and is decomposed spontaneously on standing, even in the cold, into basic nitrate and anhydride. The basic telluric nitrate is also decomposed by water. The properties of tellurous anhydride have been very incorrectly described. It is spoken of in the text-books as slightly soluble in water. But it is almost as insoluble as barium sulphate, 1 part requiring for solution 150,000 parts of water.

Journal de Pharmacie et de Chimie.
Series 5, Vol. ix., June, 1884.

Assay of the Quinine Sulphate of Commerce.—J. C. DeVry.—The author states that all the quinine sulphates of commerce which he has analysed contain cinchonidine sulphate in proportions ranging from 5 to 18 per cent. This is not an adulteration, but a natural consequence of the presence of conchoidine in the barks employed. The manufacturer, though he can prepare the acid quinine sulphate chemically pure, is unable to produce the ordinary (basic) quinine sulphate pure on an industrial scale. If he could effect this it would not be accepted in the market, as a light sulphate is demanded. But the basic quinine sulphate, when chemically pure, is not light, but relatively heavy. When 5 grms. of commercial quinine sulphate are dissolved in 200 grms. of boiling water, and adding 5 grms. of Seignette's salt, likewise dissolved in a very small quantity of boiling water, the liquid remains limpid for an instant, and then forms on cooling regular crystals. After twenty-four hours these crystals are carefully collected on a filter, washed with the smallest possible quantity of water, and dried in the air. On treating in this manner the various quinine sulphates of commerce it will be found that the weights of tartrate obtained are not always identical, because the quantity of these tartrates depends on the water of crystallisation and on the presence of cinchonidine, the tartrate of which does not crystallise out under these conditions, but remains in solution. Consequently the weight of the tartrates obtained is one mark of the commercial value of quinine sulphate. On treating various samples of quinine sulphate in this manner the author has obtained quantities of tartrates varying from 88.84 to 93.14 of the sulphate employed.

Now ready, Sixth Edition, much enlarged, with Engravings,

ON THE CHEMISTRY OF POTABLE WATER.*

By Professor ODLING, M.B., F.R.S., F.R.C.P.,
President of the Institute of Chemistry.

I. Sources of Water Supply.

THE water of most towns is derived, as is well known, from one or other of three typical sources, constituted respectively by springs, or streams, or lakes; this last-named source being taken to include not only natural lakes, but also those huge artificially formed reservoirs, in which the surface water collected from more or less extensive gathering grounds is retained by means of embankments, and stored up for distribution to consumers. Although some streams, indeed, are fed largely by springs, and some lakes are little else than local expansions of streams or rivers, still a general distinction in character between supplies derived from the three just spoken of typical sources, is, on the whole, broadly recognisable; and this, notwithstanding the fact of the considerable differences in composition manifested by individual spring waters, derived from different springs or wells, by individual stream waters, derived from different streams or rivers, and by individual lake waters, derived from different lakes or reservoirs. Despite the marked preference of a few authorities for some one variety of source to the exclusion of the others, the majority of engineers have come to recognise each variety as having its own characteristic excellences and concomitant defects, and are accordingly ready to avail themselves, in different cases, of whatever kind of source is rendered by local circumstances most available and suitable for the particular town to be supplied. From all three varieties of source alike, numerous large populations have been furnished for generations past, with an abundant, and, as the result has shown, with a satisfactory and wholesome supply of water; although, indeed, in a few special instances, supplies from all three varieties of sources alike have, in different ways and under exceptional circumstances, proved detrimental to the health, and even, in certain cases, fatal to the lives of some among the population supplied. All three varieties of source have, under the best advice of the time, been continually resorted to from the earliest period of water supply undertakings, nearly three centuries ago, down to the present day. Thus, while the youngest of the companies supplying London has obtained its supply, since 1862, wholly from deep wells sunk in the chalk, the new works for the supply of Liverpool and Manchester respectively, which may both take rank among the greatest hydraulic undertakings of the century, are intended to introduce and distribute river water in the one town and lake water in the other. All experience, indeed, goes to show that the supply of excellent water is not confined to its supply from any single variety of source; and that for the purpose of water supply, there are alike good wells and bad wells, good lakes and bad lakes, good rivers and bad rivers. Just, moreover, as the best of river waters or lake waters will fall short in regard to an excellency characteristic of well water, so will the best of well waters fall short in regard to an excellency characteristic of lake water or river water. The comparison of one sort with the other sorts of water must be made as a whole. To select arbitrarily the special good point of one sort of water as a standard, to the neglect of the countervailing good points of other sorts, and to measure the quality of

the other sorts solely in reference to this selected standard, is clearly the conduct rather of an advocate than of a judge.

II. Purity of Water.

Water, as conceived of by the chemist, is a definite compound of 100 parts by weight of oxygen, united with 12.5 parts by weight of hydrogen. So exceedingly difficult is it of production, even if it ever has been produced in an absolutely pure state, that it may be regarded rather as an ideal than a real chemical substance. All natural water, besides the matter, never entirely absent, which it holds in suspension, is a solution of various mineral matters, of various organic matters, and of various gases in the ideal water, or protoxide of hydrogen, of the chemist. Of the different kinds of foreign substance habitually or exceptionally present in natural water, some kinds are beyond question prejudicial, and in particular cases highly prejudicial; most kinds are simply innocuous; while not a few kinds, as saline matter in moderate proportion, and more particularly dissolved aerial matter, are positively beneficial. Looked at, however, from a strictly chemical point of view, any matter whatever foreign to the ideal chemical compound water, constitutes an impurity of the natural water in which it occurs, whether this foreign matter be a prejudicial or a beneficial constituent, whether it consists of sewage matter, by which the water is fouled, or of healthful oxygen, by which it is aerated. The chemist uses the word pure, not in the sense of opposite to nasty, but much in the way it is often used in ordinary language, to express the exclusion from one thing of anything else, whether better or worse. Thus, we talk no less familiarly of pure rubbish or pure dross than of pure gold. We speak of pure nonsense as readily as we speak of pure truth, irrespective of the circumstance that the nonsense would be benefited, though to the prejudice of its purity, by its contamination with a few grains of sense. So chemists speak of pure water, irrespective of the circumstance that, for all the needs of life, the water is benefited, though to the prejudice of its chemical purity, by the presence both of its dissolved gases and of a proportion of dissolved saline matter. Chemists, then, are in the habit of using the word "purity" to signify oneness of chemical nature. Accordingly, in the eyes of a chemist, the matter, for example, of an old copper penny would have its degree of purity equally lowered by the same addition made to it of any kind of other matter, whether of base metal, like tin, or of noble metal, like silver, or even gold. Similarly, in the case of natural water, the small proportions of other substance existing together with the main substance, protoxide of hydrogen, interfere with the oneness of its chemical nature; or, in other words, constitute the natural water a mixture of substances, instead of being a single substance, which is alone looked upon by the chemist as a pure substance. It follows, that the water of the chemist is one thing, the water of nature another. The ideal water of the chemist is a single substance; the water of nature, like the air of nature, is a mixture of substances. Just as this last is a variable mixture of the pure chemical substances—nitrogen, oxygen, water vapour, carbonic acid, and ammonia, with traces of various other kinds of matter, so is the water of nature a variable mixture of the pure chemical substances—protoxide of hydrogen, common salt, saltpetre, gypsum, limestone, carbonic acid, nitrogen, and oxygen, &c., together with various kinds of organic matter. Air, from which the minor constituents of atmospheric air have been carefully abstracted, is sometimes spoken of as purified air; but air, deprived in this way of its so-called impurities, is absolutely incapable, in relation alike to animal and vegetable life, of fulfilling the functions of an atmosphere. The substitution of such purified air for actual atmospheric air would mean the cessation on the earth's surface of all life as it now exists. Similarly, with regard to natural water, some of its minor constituents we know to be essential, others of them we have reason to think advantageous to the fulfilment of its functions in nature. Bearing in mind, indeed, the interaction every-

* A Paper read at the Conference of the Society of Arts on Water supply. Held at the International Health Exhibition, July 14th and 15th.

where of life and the conditions of living, we can scarcely doubt that the actual mixed substance, water, is better suited to supply the wants of our daily life than the ideal unmixed substance would be; and, further, we have no reason whatever to look upon this ideal substance as furnishing a standard of excellence, to which it is desirable that our daily supply should, as far as practicable, and in all respects, approximate. What we really desiderate is not chemical purity, but hygienic freedom from anything hurtful. In some water, as in some air, an objectionable constituent may be met with; but in the case neither of water nor air is there any presumption on the score of wholesomeness, in favour of a single substance as such, rather than of a mixed substance as such. The presumption is indeed the other way. No one desires unmixed oxygen, or even oxygen and nitrogen free from commixture with the minor constituents of our native air; so neither is there any reason to desire unmixed protoxide of hydrogen, freed from the minor constituents of wholesome natural water. It is clearly open to a chemist, addressing himself to chemists, to speak of the constituents of ordinary water, other than protoxide of hydrogen, as impurities in the water; provided of course that he is consistent, and includes the desirable dissolved gases of the water among its impurities and as contributories of the sum total of its impurity. It is also open to a chemist, addressing himself to chemists, to make a comparison of different natural waters in respect to the relative proportions of their total impurity, or of their saline impurity, or of their calcareous impurity, or of their organic impurity, or of their aerial impurity, &c. But it is not, I take it, open to a chemist, addressing the general public, to speak as a chemist of some particular selected constituent, characteristic of the class of natural waters derived from one kind of source, as an impurity, and to leave it to be inferred by the general public that because this constituent is, in a strict chemical sense, an impurity, it is therefore a something nasty and unwholesome, and that the class of waters in which it is more especially met with are, in proportion to the extent of its presence, nasty and unwholesome. The general public do not know that the chemical impurity of a water may be good or bad, noxious or innocuous, desirable or undesirable, wholesome or unwholesome. They are unaware that no scale of wholesomeness or desirableness can be inferred from a scale of chemical purity, with respect to some particular constituent stigmatised as an impurity, until it has been established by evidence that this particular chemical impurity is of an unwholesome or prejudicial character. It is a mere dialectic artifice, and not a very worthy artifice, to use the word impurity in a strictly scientific sense, with intention to have it accepted in a popular sense as bearing a meaning which, scientifically, by no means belongs to it.

III. Organic Matter of Water.

The saline matter of water is a useful expression to denote the sum of the dissolved mineral constituents, and the organic matter of water a useful expression to denote the sum of the dissolved organic constituents of natural water. The saline matter of one water is not necessarily, or yet commonly, identical with the saline matter of another water; nor is the saline matter of the selfsame body of water necessarily identical throughout its entire extent, or from one period of time to another. The same holds good with regard to the organic matter of water. It is a different thing in one water from what it is in another; and may be different in the same water from place to place and from time to time. But just as there is a character or nature more or less common to the usual varieties of dissolved saline matter, so also is there a character or nature common, within certain limits, to the usual varieties of organic matter met with in potable water. So far, a certain parallelism holds good between the saline matter of water on the one hand, and its dissolved organic matter on the other. But in many important particulars the parallelism fails. Thus the saline matter occurs, for the

most part, in appreciable proportion, say from $\frac{1}{10}$ to $\frac{1}{5}$ of a per cent. It is constituted of definite chemical substances, possessed of well-determined properties; and its amount is capable of estimation with all desirable accuracy—with considerable accuracy by direct weighing, and with yet greater accuracy indirectly, by the separate estimation of its several constituents. The dissolved organic matter of potable water, on the other hand, never amounts to more than an exceedingly minute proportion, say from $\frac{1}{5000}$ to $\frac{1}{1000}$ of a per cent; what are its separate constituents, and what their chemical nature, is almost if not wholly unknown; its amount is, moreover, incapable of direct determination, and the different means for its indirect determination are far from satisfactory. Chemists are capable, however, thanks to Dr. Frankland, of determining with a considerable degree of accuracy the quantity of carbon that exists in any water, in the form of organic matter. Evidently, if all organic matter contained the same proportion of carbon, a determination of the organic carbon present in any water would be tantamount to a determination of its organic matter. But in reality, the proportion of carbon existing in different individual varieties of organic matter has, on the contrary, a very wide range of variation. Still, it would appear, from such imperfect investigations as have been made, that the proportion of carbon existing in the organic matter of water—that is to say, the mean proportion of carbon present in the whole of the several individual constituents of the organic matter taken together—is not subject to any such considerable range of variation, and that it may, without risk of serious error, be valued at about 40 per cent. Disregarding then for the moment the consideration of the nature of the dissolved organic matter present in natural water, and confining attention only to its quantity, it may be taken as admitted that the determination of the organic carbon in water is an absolute, and more than fairly accurate, determination; that the organic matter of water is in a general way proportionate to the amount of its organic carbon; that the amount of organic matter may accordingly be represented by some multiple of the organic carbon; and that for purposes of comparison, at any rate, this multiple may be taken provisionally as 2.5, corresponding, of course, to the occurrence of 40 per cent of carbon in the organic matter.

The inquiry next presents itself as to what, on the basis of these propositions, is the quantity of organic carbon, and consequently of organic matter, present in the three classes of water derived respectively from each of our typical varieties of source. Speaking generally, it may be said that the proportion of organic matter is decidedly least in spring or well water—that is to say, if we limit our attention to such waters only as would be taken for town supply, for there are, of course, foul well waters, in which the amount of organic matter is in excess of anything ordinarily met with in the water of lakes and natural rivers. As between lake sources in general, and river sources in general, it is not easy to assign the order of seriation. The proportion of organic matter found in different lake waters is, on the whole, more uniform than the proportion found in the waters of different rivers. Accordingly, while in some river waters the proportion of organic matter is somewhat higher, there are other river waters in which it is very considerably lower than the proportion commonly present in lake water. On the whole, it would seem that river water in general must take precedence of lake water in respect to the smallness of its proportion of dissolved organic matter, subject, however, to the observation that the proportion of this constituent is more variable in river water; or that it is liable to a greater range of variation, both as between the water of one river, and the water of another, and as between the water of the same river at different seasons. In order to give some idea of the quantities of organic carbon, and consequently of organic matter, present in the water, furnished from different varieties of source for town supply, I have made an abstract of the results set forth in the Registrar-General's monthly

MEAN OF EIGHTEEN MONTHLY ANALYSES.

Source.	Proprietary.	Organic Carbon.		Organic Matter.
		Parts per 100,000.	Grains per gallon.	Grains per gallon. (estimated.)

reports for the last year and a-half, beginning, that is to say, with the report for January, 1883, and ending with the report last made, for June, 1884, in respect to the supplies of London, Birmingham, and Glasgow. I have resorted to the reports of the Registrar-General, in part, because they alone furnish the results of a regular series of analyses of the water supplied to other towns than London; and, in part, because, with regard to London, I have, for the purpose of this address, preferred to bring before you the results of analyses for which I am not in any way responsible. There is not, however, any appreciable difference between the mean results for the period obtained by Dr. Frankland, on the one hand, and by my colleagues and myself on the other, in respect to the composition of the London waters examined by both of us.

The five Thames waterworks companies, as is well known, take their supply from the river at Hampton, Ditton, and Molesey. They furnish just under 50 per cent of the total supply of the metropolis. The East London Waterworks Company take their supply from the River Lea, some distance below Ware. Their subsiding reservoir at Walthamstow has the enormous area of 222 acres, equal to that of a good-sized lake. The company have power to take in addition ten million gallons of water daily from the Thames at Sudbury. It is but seldom, however, that they resort to the Thames at all; and very rarely indeed to the extent of more than one-quarter of the daily amount they are privileged to obtain. Substantially, the water of the East London Company is water from the Lea. The New River Company takes somewhere about four-fifths of their supply from the Lea, above Ware, and the remaining one-fifth from Chadwell springs and a series of deep wells sunk in the chalk. The East London and New River Companies jointly, furnish about 44 per cent of the total supply of the metropolis. The Kent Waterworks Company take their water entirely from deep wells in the chalk, and furnish from this source rather more than 6 per cent of the total supply of the metropolis. The water supplied to the town of Birmingham by the Corporation is taken from various sources, lake or reservoir, stream, and well, but in what relative proportions I am unable to say. The water supplied to the town of Glasgow by the Corporation is taken, as is well known, from Loch Katrine. The subjoined table shows the actual quantities of organic carbon, expressed both in parts per 100,000 and in grains per gallon, and the estimated quantities of organic matter in grains per gallon, present in these six several supplies of water, as determined by monthly analyses of the waters conducted during the last year and a-half.

It will be seen that the organic matter of the Kent Company's water, which is a spring-water, is under one-tenth of a grain per gallon; that the organic matter of the New River Company's water, which is mainly a river-water, is considerably under two-tenths of a grain per gallon; that the organic matter of the East London Company's water, which is a river-water, that of the Birmingham Corporation's water, which is a mixed water, and that of the Glasgow Corporation's water, which is a lake-water, are alike about two and a-half tenths, *i.e.*, a quarter, of a grain per gallon; while the organic matter of the Thames Companies' supply of river-water is under three-tenths of a grain per gallon. It is to be noted however, that,

although the average proportion of organic matter in the Thames-derived water supplied to London, is a little in excess of that in the Birmingham and Glasgow Corporations' supplies, the excess is entirely due to the effect of the winter floods. Comparing the results in the summer nine months, March to September, 1883, and March to June, 1884, the proportion of organic matter in the Glasgow Corporation's supply is somewhat in excess of the proportion found in the Thames supply, the number of grains of organic matter being for the Thames-derived water 0'22, and for the Glasgow water 0'25 grain per gallon. Similarly, the organic matter of the East London Company's water, during the summer months, falls appreciably below that of the Glasgow Corporation's supply at the same season of the year—the season, that is to say, during which a high character of water is considered to be more especially demanded. The above statements, as to the particular fractions of a grain of organic matter ordinarily present in a gallon of different kinds of water, serve to convey some idea of the always exceeding smallness of the quantity. A better notion, however, of the minuteness of even the highest proportions of organic matter found, say, in any London water, is afforded by stating the results in another way. Thus, if we suppose for an instant that the Thames companies' water, instead of containing under three-tenths of a grain, contained seven-tenths of a grain of organic matter per gallon—a maximum which has been occasionally approached in the supply of one or other of the Thames companies at a period of flood—even this exceptional proportion would but correspond to the presence in the water of exactly the thousandth part of 1 per cent of organic matter. Whether or not, variations within the limit of such a small proportion of dissolved organic matter present in potable water, ranging from about the one-thousandth part of 1 per cent exceptionally met with in a Thames-derived water, down to the eight-thousandth part of 1 per cent habitually met with in a chalk spring-water, are matters of any real significance, must obviously depend on the character of the dissolved organic matter present in the different waters. It will suffice for the present to observe that, so far as mere quantity of organic matter is concerned, the water supplied to London from the Thames and Lea takes, on the whole, precedence of the highly reputed, and deservedly reputed, water furnished to Glasgow; as, doubtless, it will take precedence of the water about to be furnished to Manchester.

As regards range of variation, it is noticeable that, while the mean proportion of organic matter present in the summer supply of the Thames Companies, as calculated from the average of forty-five analyses reported to the Registrar-General, is 0'22 grain per gallon; and the mean proportion present in the yearly supply, as calculated from the average of ninety analyses, is 0'28 grain per gallon; the proportion in one particular sample of water out of the ninety samples analysed fell to 0'17 grain, in two samples it rose to 0'50 grain, in one sample to 0'53 grain, and in yet another sample to 0'60 grain; but that in no one sample out of the ninety did it reach the maximum of 0'70 grain per gallon, so as to constitute the thousandth part of 1 per cent of the water. It happens similarly in nearly all natural waters, that while the absolute variation in the proportion of organic matter present at different

times is almost infinitesimally small, the relative variation is, on the other hand, strikingly large. Thus the proportion of organic matter present in the Glasgow Corporation's lake-water at different times varies as 1 to 2; that in the Kent Company's spring-water, in the East London Company's water, and in the Thames Companies' water, varies as 1 to 3 or $3\frac{1}{2}$; that in the New River Company's water varies as 1 to 4; and that in the Birmingham Corporation's water varies as 1 to 7; but the larger range of variation in the water of these last two supplies is dependent, doubtless, on the circumstance of their being mixed supplies, constituted of unequal proportions of their several contributories at different times. In the official phraseology with which we are so familiar—phraseology of but little meaning, though the words are strong—it would be said that while the degree of "pollution by organic impurity" of the Glasgow water is twice as great at one time as at another, the degree of "pollution by organic impurity" of the Birmingham water is seven times as great at one time as at another. The large extent of relative variation thus noticeable in respect to the organic matter of water is common, as might be expected, to those other of its constituents, which also exist absolutely in very small quantity, and is, indeed, almost a consequence of the smallness of their absolute quantity. A somewhat parallel comparison may be adduced in the case of personal wealth. We know that while the wealth of a capitalist will, for the most part, vary only by a small percentage from month to month, the whole fortune of a beggar, his utmost riches being a matter of no consideration, may vary many-fold in the course of a day, although by the absolute amount of only a few halfpence put into or taken out of his ragged pocket.

IV. General Considerations.

So far, attention has been directed to the organic matter of potable water solely from the point of view of its quantity. A much more important inquiry, however, has reference to its nature or quality. But this is too large and important a matter to be taken up at the far end of an address, limited strictly to the duration of a short half-hour. That the organic matter of potable water is constituted in the main of dissolved, unorganised, and non-living matter, does not admit of question. Anything like an adequate discussion, however, of the origin, nature, and possible hygienic influence of this main portion of the organic matter could not but involve a very long story. It may suffice here to say that, having regard to its origin and nature, and to the minuteness of its proportion, the presumption against any unwholesomeness attaching to its presence is very strong. To what extent living and organised matter may be also present in potable water; how far such living organic matter may include a something capable of developing zymotic disease; and, admitting all this, how far the liability of different waters to contain more or less of noxious living organic matter is related to the varying amounts which they contain of innocuous non-living organic matter, are questions far more difficult of solution. They are questions on which, in the present imperfect state of our knowledge on the subject, it behoves every one to speak with caution; but in my own view, having regard to what is observed and recorded respecting the health of differently supplied populations, and to what little is known of the natural history of disease-producing organisms, the preponderance of evidence does not, I think, favour an alarmful answer. Other persons, however, are of a different opinion. But the address which I have been asked to read at this Conference is on the chemistry of potable water; and my concern to-day is solely with the chemical aspect of the subject. It is not from biologic or pathogenetic inquiries, but from the results of the chemical analysis of the water supply to London—from the mere determinations of the quantity of its organic matter—that its wholesomeness is month after month, by suggestion, im-

pugned. On this point I join issue altogether. Further, it seems to me an abuse of chemistry, that a chemist, who on other than chemical grounds may, rightly or wrongly, have satisfied himself of the unwholesome of a particular water supply, should state and summarise the results of his analyses in such a fashion as to make it appear that the unwholesomeness, which he really infers on other grounds, is deducible from the results of his periodical chemical examinations. It is well understood that a statement, of which the verbal accuracy cannot be challenged, may, nevertheless, be far from a warrantable statement. It may convey a *suggestio falsi*, and include a *suppressio veri*. Such I take to be the case with the statement, paraded month after month, in what is an official, and should be a scrupulously impartial, report, as to the relative "amounts of organic impurity" contained in individual samples of metropolitan water, compared with a particular decennial average amount present in the Kent Company's water,—a standard, by the bye, of which the value is known and used only by the reporter, whose comparison, accordingly, it is impossible to check. This monthly statement suggests, I take it, the notion that spring-water is the proper type of what river-water, or at any rate of what metropolitan water, should be—a notion entirely without foundation, and discordant with the reporter's own strong recommendation of lake-water for the supply of London. It further suggests the notion that the desirableness and general wholesomeness of different waters are inversely proportional to their relative "amounts of organic impurity," irrespective of the origin and nature of this so-called impurity,—a notion equally devoid of foundation. On the other hand, the statement in question suppresses the fact that spring-water, lake-water, and river-water, have each their special characteristics, excellences, and defects. It suppresses the fact that the so-called "previous sewage contamination" of the standard spring-water is as relatively high as its "amount of organic impurity" is relatively low. It suppresses the fact that the "amount of organic impurity" in the metropolitan river supply, though three-fold or fourfold that present in the spring water supply, is nevertheless almost infinitesimal in absolute quantity. It suppresses the fact that the "amount of organic impurity" in the highly reputed Loch Katrine supply is, during the summer months, in excess of, and is on the average of the year substantially identical with, the summer and yearly amounts respectively present in the metropolitan river supply. It further suppresses the fact that the head waters of the Thames, by the time they reach Lechlade, about 22 miles only from their source, and about 120 miles above the Companies' intake, have exchanged their character of spring water for that of river water, and irrespective of urban contamination, contain an "amount of organic impurity" identical in quantity with, and chemically undistinguishable in kind from, that met with in the river water at Hampton. I dispute altogether the notion suggested by the mode of statement adopted in the monthly reports made to the Registrar-General, that the relative unwholesomeness of the Kent Company's water, the New River Company's water, and the Birmingham Corporation's water, was, during the last eighteen months, approximately as the numbers 1, 2, and 3; or, in other words, that it was in the proportion of the 8-hundredths, the 15-hundredths, and the 23-hundredths, of a grain of dissolved organic matter per gallon, present in the three supplies respectively. I contend, further, that the New River Company's water would have been no more wholesome or unwholesome respectively, if, instead of actually containing 15-hundredths of a grain of organic matter per gallon—this organic matter being chiefly of vegetable origin, and a product of ordinary fluvial life—it had contained, like the Kent Company's water, as little as 8-hundredths of a grain, or, like the Birmingham Corporation's water, as much as 23-hundredths of a grain of organic matter, the absolute variations of a tenth of a grain or so of such

dissolved organic matter per gallon, being too small to have any real hygienic importance whatever.

If it were indeed the fact that the dissolved organic matter of potable water, taken as a whole, is of such a nature that, in the proportions in which it is met with, it is capable, on occasions, of developing and spreading epidemic disease, it is manifest that no plea, based on the actual smallness of its proportion, would be of any avail to save it from hopeless condemnation. It is manifest also, on this assumption, that the determination of the variations in the proportions of organic matter present in a water, notwithstanding the minuteness of even the maximum proportion, would be a determination of the highest significance; and further, that any information furnished in intelligible language to the general public, as to the results of a comparison of different waters with one another in regard to their respective proportions of organic matter, would have an extreme degree of interest and value. But all this is based on the hypothesis that the dissolved organic matter of water, or at any rate the dissolved organic matter of some water, taken in its entirety, is a noxious constituent of the water, capable, in proportion to its quantity, of setting up epidemic disease; a view, it need scarcely be said, which is sustained by no sort of evidence, and supported by no weight of authority. If, indeed, the organic matter of water were really of this noxious character, the conclusions above set forth, with regard to the propriety and value of a comparison of waters with one another in respect to so noxious a constituent, would be undeniable. But if, on the other hand, the minute proportion of dissolved organic matter met with in potable water is constituted mainly of innocuous vegetable extractive, with a trace or more of innocuous animal extractive; and if, at the same time, this organic matter does not affect in any appreciable degree the taste, or colour, or appearance of the water, clearly all variations in the amounts present in potable water, that fall within the limits of an exceedingly minute proportion, are matters of no consideration whatever; and this whether they be variations in the proportions existing in different waters, or variations met with in the same water at different times. And the same conclusion would hold good, even if the organic matter of water, while constituted in the main and at most times wholly, of innocuous extractive, was, nevertheless, liable to include at other times a sub-proportion of an effectively noxious agent; unless, indeed, it could be shown that the liability of different waters to contain this noxious agent was in proportion to their relative amounts of dissolved organic matter—a proposition so preposterous as never to have been seriously put forward. Whether or not there exist any good grounds for calling in question the excellence and wholesomeness of the water, supplied to probably the healthiest great city in the world, is another matter. Speaking as a chemist, I represent that there are no chemical grounds for such a contention. In support of this position, I would call to mind that the last Royal Commission on Water Supply, after hearing very varied evidence, much of it of the usual alarmist character, reported to the effect that the presence of a small quantity of organic matter in drinking water was not necessarily prejudicial; and that there was not any evidence to satisfy them that the particular organic matter present in filtered Thames water was prejudicial. Their conclusion on the general question is expressed in the following words:—"Having carefully considered all the information we have been able to collect, we see no evidence to lead us to believe that the water now supplied by the companies is not generally good and wholesome."

Action of Water and Nitric Acid upon Basic Telluric Nitrate.—MM. Klein and J. Morel.—The basic telluric nitrate behaves nearly like the nitrates already known as decomposable by water, *e. g.* that of bismuth. There is not, however, formed a basic sub-salt or a hydroxide, but tellurous anhydride.—*Comptes Rendus*, No. 14.

NOTES OF WORK BY STUDENTS OF PRACTICAL CHEMISTRY IN THE LABORATORY OF THE UNIVERSITY OF VIRGINIA.

No. XIII.

Communicated by F. P. DUNNINGTON,
Acting Professor of General and Analytical Chemistry.

I MUST acknowledge my obligations to Mr. W. G. Brown for the efficient aid given me in directing much of the following work.—F. P. D.

(104). Examination of Blue Quartz from Nelson Co., Va. By ROBT. ROBERTSON, of Danville, Va.

Nelson county lies in the belt of country which extends along the eastern slope of the Blue Ridge, is known as the Piedmont region, and is composed of archæan rocks. Near the middle of this belt, and also of Nelson county, passes a strip of light-coloured land locally known as the "Kaolin belt." This is from $\frac{1}{2}$ to 3 miles wide and of undetermined length, and is largely the product of decomposition of a granulitic rock (felspar and quartz). The aggregation of these minerals varies much, the quartz being in some places in small grains and in others forming rather large masses. In some localities the quartz formed a considerable component of the rock, in others but little or none is mixed with the felspar. In all its occurrence, however, the quartz presents a characteristic waxy lustre, and a colour varying from pale to deep blue. It, therefore, appears of interest to ascertain to what this colour is due.

The thin brown films which penetrate this quartz are so numerous that no homogeneous pieces with any dimension exceeding a few centimetres can be obtained, yet the whole forms a firmly coherent mass.

A fragment was fused before the hot-blast blowpipe flame and retained its blue colour. The pulverised mineral was digested in hydrochloric acid to remove all ferric oxide which might exist in these films, and then treated with hydrochloric acid to remove all silica. The analysis presented the following composition:—

Ferric oxide	0.539
Titanic oxide	0.069
Silica (by diff.)	99.392

100.000

A thin section of the rock was examined under the microscope and found to show throughout the mass a network of extremely thin acicular brown crystals, thus presenting when magnified about 400 diameters an appearance very similar to that of sagenite to the naked eye. Some of the crystals were twinned, forming the geniculations common with rutile. The angles of these geniculations when lying approximately in the plane of vision measured 70° , 71° , 76° , and 52° , 57° ; hence probably identical with the arrangement of the needles in sagenite observed by Dr. A. von Lasaulx in Bonn, being twinned at the angles $65^\circ 35'$ and $54^\circ 44'$. This thin section is decidedly yellow by transmitted light, also shows the threads of iron above referred to, and by reflected light is blue.

In view of the blue colour of some varieties of titanic oxide, when seen by reflected light, it appears possible that the partial reflection of light by the surfaces of these microscopic crystals occasions the colour in questions, or the latter may be in a measure due to the interference of light occasioned by these crystals.

It is to be noted that this belt of granulitic rocks and the accompanying gneiss frequently show crystalline masses of rutile on the surface, which have weathered out on decomposition. Moreover the magnetic iron ores contained in these rocks show a large amount of titanic oxide.

(105.) *On Argentic Hydrate.* By J. D. BRUCE, of Coles Ferry, Va.

In view of the ready decomposition of cupric hydrate by heat, it appeared probable that if a solution of a silver salt was treated with a solution of a soluble hydrate at a low temperature, argentic hydrate might be precipitated and not argentic oxide as at ordinary temperatures.

A dilute solution of silver nitrate in 90 per cent alcohol was prepared, also a similar solution of potassium hydrate. The exact strength of each of these solutions was then ascertained. Portions of each of these solutions containing equivalent amounts of silver nitrate and potassium hydrate were mixed and found to give the usual brown pulverulent precipitate of argentic oxide. Then similar portions of these solutions were put into test-tubes and these cooled to -10° F. by means of hydrochloric acid and snow, one solution poured upon the other and gently shaken; the resulting precipitate was flocculent and light brown. The latter experiment repeated several times, at lowering temperatures, afforded a precipitate with less and less colour.

The most satisfactory experiment was made on a morning when the temperature of the atmosphere was 2° F. Hydrochloric acid was cooled to -28° F. and mixed with an equal weight of freshly-fallen snow in a beaker wrapped with cotton and card board; in this portions of the solutions taken as above were cooled. A thermometer graduated to -40° F. had the alcohol carried considerably below the graduation, showing a temperature of about -50° F. The perfectly clear silver nitrate and potassium hydrate solutions were mixed as before, and the resulting precipitate was flocculent and almost pure white, with perhaps a very slight tinge of brownish red. The precipitate thus obtained assumed colour, as the temperature was increased, so that at -40° F. it was a pale brown, and no attempt to separate the precipitate without alteration succeeded.

Although repeated attempts were afterwards made to repeat these results, the thermometer not falling below 20° F. again during the winter, the exceptionally cold mixture, such as was obtained on the one morning, could not be procured again. In each case, however, the colour of the precipitate more nearly approached pure white, as the temperature approached that which existed in the experiment above described.

So far as is ascertained, argentic hydrate is but slightly soluble in water. The analogies to be drawn from the properties of compounds of mercury, copper, lead, &c., render it exceedingly probable that the white flocculent precipitate above in question was argentic hydrate.

(106.) *Analysis of Amazon Stone from Amelia Co., Va.* By C. C. PAGE, University of Va.

In the mica mine of Amelia Co. referred to above, the giant granite contains several varieties of felspar; of two forms of this felspar analyses have been made in this laboratory.* In addition to these, an amazon stone is found, which, in the larger crystals, usually shades off to white, but in some crystals of moderate size is of uniform colour. It is light green or bluish green in colour, the lustre of cleavage faces is vitreous to pearly, sp. gr. = 2.564 .

Analysis afforded the following:—

Silica	64.12
Alumina	16.84
Ferric oxide	2.28
Lime	0.32
Magnesia	0.26
Potash	13.34
Soda	1.88

99.04

A thin section viewed under the microscope in polarised light gave the characteristic grated structure of microcline, and showed also a slight admixture of a plagioclase.

* CHEMICAL NEWS, Nos. 1197 and 1143.

(107.) *Analysis of Apatite from Amelia Co., Va.* By G. H. ROWAN, of Jacksonville, Ala.

In a vein of coarse granite about a mile from Amelia, C. H. Va., from which large sheets of mica are obtained for commercial purposes, and in which the rare mineral microlite has been found* along with brilliantly phosphorescent fluor spar, columbite, helvite, beryl, and monazite†; there also occurs sparingly, imbedded in felspar, apatite of the following character.

It is in translucent white crystals, with a shade of violet, being cracked in various directions, laminated parallel to z , of vitreous lustre, and quite fragile. On heating, it phosphoresces with a yellow light. The following crystalline faces were identified.—

O, I, i 2, r, 2, 2 - 2 (Dana.)

Sp. gr. = 3.161 . Analysis gave:—

Line	53.94
Alumina	0.19
Ferride oxide	0.81
Phosphoric oxide	41.06
Fluorine	3.30
Chlorine	trace
Loss by ignition	0.81
Insoluble residue	0.63

100.72

Deduct O, replaced by fluorine.. 1.39

Total 99.33

Corresponding to the formula— $\text{Ca}_3\text{P}_2\text{O}_8 + \frac{1}{2}\text{CaF}_2$.

The insoluble residue was probably due to adhering mica.

(108.) *Analysis of Albite from Amelia Co., Va.* By ROBERTSON.

This is another of the varieties of felspar referred to in the preceding article. It is found in occasional small crystalline masses, within masses of albite, having a bluish grey colour with slight opalescence and the colours of labradorite. Cleavage on O pearly and regularly striated, and on i i pearly. Sp. gr. = 2.618 .

Analysis gave the following:—

		Oxygen ratio.
Silica	67.06	768
Alumina	21.72	216
Lime	1.59	10
Magnesia	0.03	
Soda	10.01	57
Potash	0.39	

100.83

Which approximates to the composition of six molecules of albite mixed with one molecule of anorthite.

(109.) *On the Action of Sulphuretted Hydrogen upon Metallic Silver.* By J. M. CABELL, of Richmond, Va.

I. A piece of pure silver, cleaned by aid of borax, potassium cyanide, and water, was heated within a glass-tube, hammered between polished steel to a rectangular form, put into a thin glass bulb, heated gently, and dry air passed over it; the silver was then sealed within the bulb.

Sulphuretted hydrogen generated from golden sulphide of antimony and hydrochloric acid was passed successively through water, 24 inches of dried calcium chloride, 4 inches of phosphoric anhydride, then through a 2 foot tube containing in its middle the above thin bulb with the silver,

* For a more complete description of this locality see *Amer. Jour. of Science*, vol. xxv., May, 1883.

† *Amer. Chem. Journ.*, May, 1881, p. 130.

and at each end 3 inches of phosphoric anhydride, confined by plugs of cotton-wool; from this the gas passed through 4 inches of phosphoric anhydride, 16 inches of dried calcium chloride, and into a jar of lime.

A slow current of sulphuretted hydrogen was passed as above for three hours, then by jarring the tube the thin bulb containing the silver was broken, the current continued for forty-five minutes, and then the 2-foot tube sealed so as to leave the silver still confined between the layers of phosphoric anhydride. In twelve hours the silver was slightly tarnished (the phosphoric anhydride, however, showed evidences of some moisture). After three weeks it was considerably tarnished.

II. A second experiment was conducted as before, except that the silver was not hammered but quite rough, and glass-wool was used in place of cotton, to confine the phosphoric anhydride. In twelve hours the silver had turned quite dark, and the phosphoric anhydride showed evidence of more moisture than it did in the previous experiment.

III. In a third experiment, the silver was hammered as in I., and then polished bright. It was then (not sealed in a bulb) put in a 2-foot tube between the layers of phosphoric anhydride, confined by glass-wool. Then hydrogen was passed successively through an acid solution of potassium permanganate, potassium hydrate, sulphuric acid, 2 feet of dried calcium chloride, 4 inches of phosphoric anhydride, and then through the tube with the piece of silver arranged as above; this continued for an hour, while the latter tube was gently heated. Sulphuretted hydrogen was then passed through the apparatus for three hours, and the 2-foot tube sealed. After twenty-four hours the flat polished surface of the silver remained bright, but the edges were slightly tarnished. The silver was then heated to about 150° C., and it was darkened.

IV. In a fourth experiment, the silver was prepared and arranged as in III., the posterior portion of the apparatus was connected with a Sprengel air-pump in place of the jar of lime, and the anterior end closed. The whole, including both the calcium chloride tubes, was exhausted, and then pure dry hydrogen let slowly in; the whole again exhausted, and the silver gently heated for fifteen minutes. While thus heating the silver, which was within a soft glass tube, the former was blistered (at a temperature considerably below a red-heat) and the polish of the surface, to some extent, destroyed. After removing the heat, hydrogen was again let in and passed through the apparatus for seventy-five minutes; in the course of this the silver was heated for ten minutes. Sulphuretted hydrogen was then passed through and the tube sealed as before. After four months at summer temperature the edges of the silver which were not so well polished were slightly aged upon, while the main portion of the surface presented no change in appearance.

From the above we may infer that, in absence of water, silver does not decompose sulphuretted hydrogen at the common temperatures.

(110.) *Analysis of Cassiterite from King Co., N.C.* By J. D. BRUCE.

Through the kindness of Dr. C. W. Dabney, of Raleigh, N.C., I obtained this specimen from the deposit of tin ore recently discovered. While numerous assays of this ore have been made, I am not aware of any full analysis. The portion examined is of resinous lustre, transparent, and of light brown colour. Sp. gr. = 6.956.

According to a method recently suggested,* the powdered mineral was gently heated within a glass tube, and dry hydrogen passed over it, the residue, consisting mainly of metallic tin, was digested in hydrochloric acid, the insoluble residue filtered off, the tin precipitated as stannous sulphide, and the filtrate treated in the usual manner. The analysis gave the following composition:—

Stannic oxide	95.176
Ferric oxide	1.455
Lime	0.277
Magnesia	0.020
Water (loss by ignition) .. .	0.218
Insoluble residue	2.841

99.987

The insoluble residue was probably in the main silica. Another analysis afforded almost identical results.

(111.) *Analysis of Pinite from Madison Co., N.C.* By CHAS. L. REESE, of Baltimore, Md.

This mineral is found in the Smoky Mountain near the Warm Springs, N.C., and is sold at the latter place in the form of cuff buttons and similar articles. It is amorphous, white with tinge of green, translucent, has waxy lustre, rough fracture, with greasy feel, and is found in irregular masses. Hardness = nearly 3; sp. gr. = 2.822.

The average of two concurring analyses by Mr. Reese gave results, A. I append also an analysis of this mineral from the same locality by Mr. C. H. Slaytor, F.C.S., made in Prof. Bunsen's laboratory in Heidelberg (see B).

	A. (C.L.R.)	B. (C.H.S.)
Silica	47.28	47.31
Alumina	36.47	38.11
Lime	0.28	—
Magnesia	trace	—
Potash	11.40	13.37
Soda	0.74	—
Water	4.39	1.05
	100.56	99.84

The oxygen ratio for bases, silica, and water = 3:4:1, varying somewhat from the typical oxygen ratio 3:4:1, as do so many specimens of this species.

(112.) *On Crystallised Phosphorus Anhydride.* By J. M. CABELL.

Phosphorus was burned with a limited supply of air, the white flakes allowed to settle, and quickly transferred to a glass bottle. Hydrogen was passed successively through an acid solution of potassic permanganate, potassium hydrate, sulphuric acid, 2 feet of dried calcium chloride, and then into a 2-foot tube, of which the first and last 6 inches were filled with the above mixture of oxides of phosphorus, confined by glass-wool; the intervening space was left empty. The current of hydrogen was passed for some minutes, and then the anterior portion of the oxides of phosphorus gently heated. When the temperature rose to about 350° F. crystals began to deposit on the sides of the empty portion of the tube, while the residue became semi-fused. No measurements of these crystals could be made, but they were apparently mono-clinic, showing the forces of the base and prism and the pinacoids. The tube was then broken, and the crystals were quickly transferred to litmus-paper, which they did not redden for some seconds, the aqueous solution gave no reaction for phosphoric acid with ammonium molybdate, and none with magnesia mixture. After warming it with nitric acid it gave both the above reactions for phosphoric acid. It is therefore inferred that these crystals consisted of phosphorous anhydride.

(113.) *Analysis of Chrysocola (?) from Gila Co., Arizona.* By ROBT. ROBERTSON.

This specimen was received at the Baltimore Copper Works in a lot of ore from the Old Dominion Copper Mine, near Globe, Arizona.

It consists mainly of coal-black particles united by a much smaller amount of bright bluish green chrysocola, which appears to have filled up the interstices of a loose

* *Zeit. für Kryst. Bech.*, vol. 11., p. 318.

pile of fragments of the former. The dark portion is amorphous, of a purple-black colour, opaque, with lustre from sub-metallic to dull; fracture rough, with tendency to conchoidal; streak grey; hardness = 3. Sp. gr. = 2.04.

Analysis afforded the following:—

Silica	31.58
Cupric oxide.. ..	30.28
Alumina	6.27
Ferric oxide	0.84
Water	28.71
Manganese oxide (Mn ₂ O ₃).. ..	2.22

99.90

Neglecting the Mn₂O₃ and Fe₂O₃ as most probably uncombined, we have the oxygen ratio—

Hence we have the formula for asperolite, $\text{CuSiO}_3 + 3\text{H}_2\text{O}$, with one-third of the copper replaced by an equivalent amount of alumina. It is to be noted that there is undoubtedly no free cupric oxide, and yet the small amount of oxides of manganese and iron suffice to impart a black colour.

(To be continued.)

VISCOSITY OF OILS.

By W. P. MASON.

As is well known, lubricating oils are rated by their viscosity, the degree of viscosity being fixed by determining the rapidity of flow through a small orifice, and then comparing the same with the rate of flow of rape-seed oil.

The problem is a simple one, yet very widespread dissatisfaction exists regarding results. Oil has been repeatedly shipped as "full test," returned on account of too low viscosity, and, upon being re-tested at the shipping point, found to vary widely from the original figures.

The difficulty lies in the fact that the conditions under which tests are made are seldom twice alike. It is greatly to be doubted if the following questions are often asked:—"What were the dimensions of the containing vessel, the nozzle (if one were used), and the orifice? and of what material were the first two made? At what temperature was the oil during the experiment? what was its specific gravity? what head was used? and was any change of head allowed for on account of variation in specific gravity?"

Overlooking such vital points cannot fail to produce total confusion.

With a view towards obtaining results referred to some definite standard, and therefore comparable, the following viscosimeter is suggested:—

A glass cylinder, twenty-two inches long and one and a-quarter inches in diameter, is fitted to a brass bottom one-eighth of an inch in thickness. Through the centre of the brass plate a hole is bored, one thirty-second of an inch in diameter, and from the lower and outside surface the metal is bevelled away from the hole a half-inch or more. We have thus practically an orifice in a thin plate. Eighteen inches above the plane of the orifice the cylinder is marked with a heavy line (the standard head), and between the sixteen and twenty-one inch points graduation marks are etched an eighth of an inch apart.

In using this instrument all readings are compared with distilled water at 15.5° C. (60° F.), as being something far more definite than rape-seed oil. The water head is taken at eighteen inches, and the quantity of flow limited to 100 c.c. The desired head is maintained by supplying the liquid from a separatory funnel or other vessel provided with a stopcock.

To take the viscosity of an oil:—See that the temperature be normal; take the specific gravity, and therefrom calculate what the head should be to equal eighteen inches of water (it will, of course, be inversely as the specific gravity). Fill to and maintain the calculated head. Determine the time required to fill the 100 c.c. vessel, and divide this time by that required to fill the same vessel with water under standard conditions.

An instrument such as the above has been constructed and used in this laboratory with excellent results.

Troy, N.Y., Oct. 14, 1884.

A METHOD OF TESTING FOR IODINE IN THE PRESENCE OF LARGE QUANTITIES OF BROMINE.

By PHILIP S. BRITO, M.B., late Demonstrator of Anatomy, Aberdeen University, and Science Student, University of Edinburgh.

WHEN engaged in analytical work in the Chemical Laboratory of the University of Edinburgh I discovered the method of testing for traces of I. In the ordinary process of analysis, from a solution supposed to contain Br or I, we liberate the halogen by the aid of small quantities of chlorine, and carry it down with chloroform. The violet colour of I, or the dark sherry-brown of Br, picks out the element. But in a mixture containing both the colour of the less abundant halogen is masked. When I preponderates it is got rid of by the addition of CuSO_4 and H_2SO_4 . When, however, the Br is in very great quantity, I find that the addition of a crystal or two of FeSO_4 completely decolourises the brown colour, and renders visible the minutest traces of I dissolved by the chloroform. The value of this test may be gathered from the fact that in the KBr supplied as a reagent in the laboratory, and which is supposed to be pure, the application of the FeSO_4 crystals demonstrates the existence of a trace of I as an impurity. Further, when the colour alone is not decisive, and any doubt exists, its application will settle the point. The behaviour of the Br is probably due to the oxidising power it possesses in common with its sister Cl. How far the decolourisation can be taken advantage of to determine volumetrically the amount of Br in a given exercise can be settled by actual experimentation. However, the ferrous sulphate method when used as a qualitative test works well, and my fellow students and I have never found it to fail, so that although it transpires that the method is not new, yet if this contribution succeed in directing attention to it I shall have done some slight service towards the furtherance of chemical knowledge.

ON THE DETERMINATION OF IRON AND CHROMIUM IN ALLOYS.

By H. PETERSON.

THE author's method depends upon the fact that chromium sulphate in a sulphuric solution is oxidised to chromic acid on boiling with potassium permanganate. Half a gramme of the finely comminuted alloy is boiled in a covered beaker with 35 c.c. of dilute sulphuric acid, and dissolved. The solution, if it contains soluble hydrocarbons, is then mixed with a saturated solution of permanganate. When this has been done the ferric salt formed is reduced with zinc, diluted to 1 litre, and the iron is titrated with permanganate. When the titration is completed the liquid is heated to a boil and permanganate (1 c.c. = 0.01 gm. Fe) is dropped in from a burette until there appears a plentiful deposit of MnO_2 , which indicates the end of the reaction. MnO_2 is formed by the action of permanganate upon manganous sulphate after all the chromic oxide has been

oxidised. The mixture is then poured upon a large filter, the precipitate is well washed with hot water and allowed to cool. The chromic acid in solution is then titrated by adding ammonium ferrous sulphate in excess and titrating back. If merely the determination of the chrome is required the case is much simplified. It is neither necessary to destroy the hydrocarbons nor to dilute so largely. —*Chemiker Zeitung, Gathen.*

TO REMOVE NOXIOUS VAPOURS IN THE EVAPORATION OF CORROSIVE LIQUIDS.

By Ls R. C. COOLEY.

In the chemical laboratory of Vassar College, a Richards aspirator with the necessary water supply and waste pipes is furnished to every student. It is used not only for rapid filtration, but in other processes wherever a current of air is needed. I have also applied it to the process of evaporation, first, for the purpose of carrying away the noxious vapours arising from corrosive liquids, and second, for evaporation in partial vacuo.

To fit the aspirator for general use it is mounted upon one corner of the student's work-table in the manner

annoyance from their fumes, by means of this simple artifice.

The Flask.—Let the cork of a flask be pierced with two holes, one for a bent tube to enter the aspirator tube, *v*, the other for a straight tube which may be adjusted so that its lower end will be little above the liquid within. A current of air will then pass through this straight tube, over the surface of the corrosive liquid in the flask and sweep its fumes away into the waste.

To evaporate in partial vacuo, provide the flask with a cork carrying the bent tube only. No air can enter, and the aspirator will then create a vacuum, to a degree depending on the head of water at command.—*American Chemical Journal.*

ON ELECTROLYTIC DETERMINATIONS.

By J. WIELAND.

THE author has tested the value of the numerous electrolytic determinations which have been proposed, and gives a brief summary of his results:—

Iron, as stated by Classen, can be very satisfactorily determined in an oxalic solution; it is precipitated in a very compact state and of a steel-grey colour.

shown in Figure 1. A small glass-tube, *t*, joined to the exhaust pipe by rubber tubing, passes through the air-tight cork of an eight-ounce wide-mouth bottle. A larger tube reaches nearly to the bottom of this bottle. The tube *sv* is a little smaller and enters the end of this larger tube, while a piece of rubber tubing stretched over the junction makes a tight but flexible joint. The outer end at *v* has a rubber tube stretched over it, by means of which connection is made with whatever apparatus is to be exhausted. Disconnection is made at this point, while the aspirator is still running, to prevent the water from the bottle *r* backing over into the vacuum which has been produced in the filter bottle or other vessel employed.

The Ventilating Funnel.—The stem, 6 or 8 inches long, of a glass funnel, is bent at a right angle near the body. The end of the stem is thrust through the rubber tubing, and into the somewhat larger tube, *v*. The evaporating dish is then brought up under the mouth of the funnel until the funnel rests upon it (Fig. 2). The aspirator is then started and the heat applied. The current of air flowing over the edge of the evaporating dish into the funnel carries the fumes with it to be condensed in the reservoir bottle, *r*, or off with the stream of water into the sink. The edge of the funnel may rest inside the evaporating dish with the same result; the same funnel is thus used with dishes of varying diameter. Two sizes are at present in use; one of 3 inches diameter for evaporating dishes, another of 1½ inches for crucibles. The evaporation of acids to dryness is conducted on the open tables without

The determination of manganese in the same manner is less to be recommended. There appears at the negative electrode also a black deposit, which dissolves partially in dilute sulphuric acid with strong effervescence, and is therefore not pure peroxide. The peroxide precipitated even after careful washing still retains potassa. According to Riche, however, the determination of manganese in a sulphuric solution gives good results. The peroxide precipitated according to this method is foliaceous, and is therefore easily washed. A nitric solution cannot be recommended, as in this case a little manganese is always dissolved on filtration.

Classen finds a separation of iron and manganese on the circumstance that in presence of a large excess of ammonium or potassium oxalate the manganese is not deposited until the greater part of the iron has been precipitated, and more than half the ammonium oxalate is decomposed. The author, however, though he carefully followed Classen's instructions, could never succeed in effecting a satisfactory separation, even in presence of a very little manganese. The manganese peroxide which began to be deposited in a very short time contained considerable quantities of iron. As Classen lays down no exact rule as to the strength of the current to be applied, the author carried out a series of experiments with different strengths of currents, from 3 to 8 Bunsen elements (970 to 3170 c.c. of detonating gas hourly). The addition of ammonium and potassium oxalate and the quantities of manganese were modified in various manners

Classen separates iron and aluminium by means of the same reaction. Here the opposite case occurs; we obtain always a few m.grms. iron in excess, as some aluminium is deposited along with the iron at the negative pole.

The separation of lead as such, from an alkaline solution, as recommended by Parodi and Mascagni, cannot be recommended, as the metallic lead very readily becomes oxidised, and its desiccation is therefore attended with much difficulty.

Small quantities of lead, however, can be very satisfactorily separated from a nitric solution, as proposed by Riche. If the quantity is greater (0.6 gm. lead) losses readily occur, as lead peroxide does not adhere firmly to the electrode. The current must not be too powerful.

Cadmium, if acted on by a thermo-battery (yielding hourly 250 c.c. detonating gas = 0.4 ampère) is deposited from an oxalic solution in a very spongy state, and is readily oxidised on drying. If the current is reduced to 0.05 ampère by the introduction of resistances, cadmium in small quantities (up to 0.3 gm.) is deposited in a sufficiently compact state. There was employed as a negative experiment in these experiments a platinum capsule containing about 150 c.c. Cadmium is deposited very well even with stronger currents from a potassium cyanide solution (Beilsten and Jassein), and from a weak sulphuric solution (Luckow, Smith).

The electrolytic determination of bismuth offers great difficulties on account of its tendency to form basic salts and to deposit in a spongy state. With very feeble currents (0.01 to 0.05 ampère) it is practicable to obtain bismuth in a compact state from oxalic and nitric solutions. The precipitation is very tedious.

The author is continuing his researches.—*Berichte der Deutsch. Chem. Gesellschaft.*

THE PRECIPITATION OF GOLD.

If we compare the various processes for the precipitation of gold it appears that the method with ferrous sulphate in an acid solution is simple in execution and complete, provided only the solution is free from chlorine, bromine, nitric acid, and from calcium, magnesium, and sodium hypochlorites. This is not the case with the mother-liquors of chlorination processes which may contain all the above-mentioned bodies. Ferrous chloride has the same effect, but is dear, easily decomposed, and can be conveyed only in vessels of glass or porcelain. The precipitation with hydrogen is more complicated, as a special apparatus and a temperature of 50° to 60° are requisite. It is, however, applicable in all cases, if no copper is present in the solution. The precipitate settles quickly after the reduction of all the oxidised compounds.—*Chemiker Zeitung, Gathen.*

NOTICES OF BOOKS.

A Guide to the Mineral Gallery of the British Museum (Natural History). With an Introduction to the Study of Minerals. Printed by order of the Trustees. 1884.

GUIDE books to the treasures in our great National Museum can be neither too numerous nor too copious. To be of real service they should be compiled in such a manner that the student may easily find what he desires and the casual visitor gain some scraps of knowledge concerning the objects he is looking at. It would be inexpedient to attempt to suit the requirements of all visitors to this collection by issuing in a single pamphlet information of a technical and popular character combined. A double set of guides or catalogues is essential, and the one before us, drawn up by Mr. Fletcher, is intended for the ordinary

visitor to the mineral department, although there is much valuable information that the student will appreciate.

The Introduction to the Study of Minerals, which occupies almost one half of this pamphlet, is a highly interesting chapter, and serves its purpose in an admirable fashion. In it the origin and the growth of the ideas that have made mineralogy, or rather crystallography, a science are well told. Ignoring the indefinite notions about crystals of Gessner, Cæsalpinus and other early writers, a succinct account is given of the great steps that the science made from the measurements by Steno down through those of Romé de l'Isle and Häuy to Mitscherlich. The ideas concerning primitive and secondary forms of de l'Isle, the integrant molecules of his contemporary and rival Häuy, and the axial method of representing crystals by the latter's pupil, Weiss, are explained at some length in the simplest language. The relations between optical phenomena and crystalline symmetry, although perhaps of rather a too recondite character for the general reader, have a few paragraphs devoted to them and a short outline in which the classifications that were proposed by Mohr and by Berzelius are explained. We think, however, with all this matter it would have been well to have described more explicitly with the aid of a few diagrams the six (or seven) systems of crystallisation of the textbooks, parameters, and the notations of Naumann and of Miller, in a popular way; a few concluding paragraphs on these points might have given this chapter a more definite form.

In a Guide-book intended for the general public we should have liked a little more information relating to the different species,—where and how they are usually found and their associations. The names also of many of the minerals might have received a little explanation; names which to the casual visitor accompanied with this Guide must appear strange, or even with a little knowledge of Latin and Greek, meaningless. Most students will recall some mineralogical fact, however trivial, connected with such names as scolecite, axinite, phenakite, miargyrite, euxenite, automolite or xanthokon, whilst to the popular mind meerschaum and epsomite have meanings of a sort.

Now that the Natural History branches of science have acquired a palace with ample space for themselves there can be little excuse for crowding or throwing these interesting objects together in a higgledy-piggledy manner more apt to weary than instruct the visitor. This little pamphlet shows evidence of reform taking place in several ways, especially in the collections of models of crystals, groups of characteristic minerals to illustrate thermal, optical, and electrical phenomena, colour, taste, hardness, and specific gravity; aiming at making our museum what it ought to be, an educational institution. In the mineral cases themselves we hope soon to see a uniform and complete system of chemical notation used for the students' sake, with the banishment of the Berzelian hieroglyphics that occasionally used to meet the eye.

In Mr. Fletcher's introductory chapter to this guide the young student will find an excellent summary of the history of mineralogy that might be stitched into his Nicol or Dana with advantage.

Report, Port of London Sanitary Committee. With the Half-yearly Report of the Medical Officer of Health for the Port of London. For the Half-year ending 30th June, 1884.

When we consider that annually there are something like twenty-six thousand ships inspected by the sanitary officers of the Port of London, ships from every quarter of the world, of every nationality, bringing all manner of cargoes, from the excrement of birds to the produce of the orchards of Italy, or the spices of the East, we might expect to learn of the importation of many strange diseases. This report, however, contradicts our conjecture, for of the 13,000 vessels inspected during the first six months of the year, only in some six per cent were sanitary defects

noted and remedied, and nine of the vessels only required fumigation.

As regards the cholera epidemic the worst the sanitary officers had to deal with was the burning of the effects, in three instances, of persons who had died of the disease outside the port. The dread of cholera has proved a blessing to the sailor, as he has had, thereby, the cleanliness of his quarters more strictly looked after. Among foul cargoes apparently the worst was amongst ourselves, being a quantity of waste lime from one of our gas-works; the fumes being so bad that "the master and crew had quite lost their eyesight (temporarily), and a woman and two children had been taken ill."

Within the last few years the importation of frozen meat into London has risen and gives prospects of soon assuming vast proportions. "The trade in frozen meat," this report tells us, "is so rapidly growing that its proper treatment has become a very serious question." When we hear of fish by the tons and carcasses by the thousands being annually or even monthly destroyed as unfit for human food, surely it is to the discredit of our chemists that nothing can be done to save this valuable commodity.

As for the state of the river in which the vessels float, its lamentable condition is too well known to need description. We read that "it is announced that the Metropolitan Board of Works are intending to attempt to deodorise the river by means of chloride of lime," but that "this will prove a very expensive and unsatisfactory procedure." Now that this extraordinary experiment has been tried, we trust the next report will give full details of the cost and result.

CORRESPONDENCE.

BUTTER ANALYSIS.

To the Editor of the Chemical News.

SIR.—Surely Dr. Leffmann, who writes in the *CHEMICAL NEWS*, vol. I., p. 192, on the "Results of Some Examinations of Butter," cannot have read Mr. Wanklyn's paper on "the Analysis of Butter" (*Society of Public Analysts' Proceedings*, March 19), or he would not have credited Mr. Wanklyn with the discovery "that when butter is heated with alcoholic soda butyric ether is given off." This fact has been well known for the last ten years, and has been used ever since as a qualitative test for butter-fat. Mr. Wanklyn merely endeavoured—unsuccessfully in my opinion—to render that simple test a quantitative one.

I would have not thought it worth while to write to you on so small a matter, had not on the subject of the paternity of the various processes of butter analysis now in use most persistent misstatements been made. The odour referred to by Dr. Leffmann was first observed by myself and Mr. Angell, and duly registered in our little treatise on "Butter." So was also the fact that the percentage of insoluble fatty acids in butter-fat is much lower than in other fats. The method which we based upon this difference is in most works, including "Watts's Dictionary," attributed to Dr. Mutter. The soluble fatty acids were first accurately determined by Dr. Dupré, but the method described by him is generally credited to Heintz, who, in point of time, took up the subject much later.—I am, &c.,

OTTO HEHNER,
Hon. Secretary Society of Public Analysts.

Trichloric Camphor.—M. P. Cazeneuve.—This compound, $C_{10}H_7Cl_3O$ appears in small white crystalline masses, insoluble in water, very soluble in cold alcohol, ether, chloroform, carbon disulphide and all the solvents of camphor; it melts and solidifies at $+54^\circ$. It belongs apparently to the β series of the chlorinised camphors.—*Comptes Rendus*, No. 15.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 14, October 6, 1884.

Experiments made at Turin and Lanzo on the Distribution of the Electric Light at Great Distances.—M. Tresca.—The total circuit between the Exhibition at Turin, the station at Lanzo, and the intermediate stations measures 80 kilometres. The wire is of chrome bronze, 3.7 millimetres in diameter, and not coated. The installation is perfectly successful.

Nitrates in Plants at Different Periods of Vegetation.—MM. Berthelot and André.—The absolute weight of the nitrates increases up to inflorescence, passes through a minimum, and then increases again, but without reaching the earlier centesimal proportion. At first two-thirds of the potassium exist as nitrate, and finally only one-twelfth.

No. 15, October 13, 1884.

Decomposition of Cupric Oxide by Heat.—MM. Debray and Joannis.—It is generally admitted that the product of this decomposition is an intermediate oxide, a compound of the cupric and the cuprous oxides. The experiments undertaken by the authors show that cupric oxide is split up into cuprous oxide and oxygen, the cuprous oxide remaining simply mixed with undecomposed black oxide, without forming intermediate compounds therewith.

Nitrates in Different Parts of Plants.—MM. Berthelot and André.—Experiments on borage prove that the nitrates are chiefly concentrated in the stem, the principal seat of their formation, which contains both the relative and absolute maximum. The root contains less, which shows that they do not come from the soil, at least in their totality. In the leaf the nitrates tend to disappear, being converted into albumenoid principles in consequence of the reductive actions which are there carried on.

Galvanometer with Astatic Needles.—M. E. Ducretet.—This apparatus cannot be intelligibly described without the accompanying illustration.

No. 16, October 20, 1884.

Alkaline Hydrates. Third Memoir. Hydrates of Potassa and Soda.—E. J. Maumené.—The normal hydrate of potassa was prepared in 1796 by Lowitz, but he did not determine its composition, indicating merely the loss of 43 per cent water of crystallisation. At this time calcined potassa was supposed to be anhydrous. The author exhibited to the Academy crystals containing, when well dried, 50 per cent potassa and 50 of water. He assigns them the formula $(KO)_2(HO)_{47}$. Lowitz indicates another hydrate which contains less water and develops heat when moistened. To 1 KO they contain 3.15 of water. This is a hydrate of the second order. In a third hydrate, described by Walter, the water is reduced to 25 per cent. From the study of the hydrates of baryta, strontia, potassa, and soda, it is permissible to conclude: that the general theory is the only basis for the explanation of chemical action. It destroys the hypothesis of the hydrates MO, HO , upon which rests one of the corner stones of the so-called atomic theory. It frees chemistry from all the hypotheses, all useless for explanation, and all of a nature calculated to injure the intellectual education of the student.

Use of Potassic Manures in Bretagne.—G. Lechartier.—The author shows the importance of potassic manures on soils whose reserve of potash has been exhausted by crops obtained under a prolonged system of phosphatic manuring.

NOTES AND QUERIES.

*. Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Blowpipe Test for the Calcium Group.—Even the most volatile salts, as the sulphate of Ba, Sr, and Ca, may be detected separately or mixed together by merely heating on very thin platinum wire, say 3 inches to the grain, in a Bunsen flame. In a mixture of the sulphates the calcium flame shows first, then strontium; the barium green is finally seen, and lasts some time. A pocket spectro-scope of course aids their detection rendering it more to be relied on.—C. T. BLANSHARD, M.A., F.C.S.

MEETINGS FOR THE WEEK

MONDAY, Nov. 3rd.—Royal Institution, 5. General Monthly Meeting. Society of Chemical Industry, 8. "Some Points in the Examination of Tallow and some Commercial Oils, especially for Acidity," by W. H. Deering. "On the Processes concerned in the Conversion of Starch into Alcohol, and their Relation to Brewing and Distilling," by W. S. Squire.

THURSDAY, 6th.—Chemical, 8. "On the Vanadates of the Amines," by G. H. Bailey. "On the Action of Aldehyds and Ammonia on Benzil (continued)," by F. R. Japp, Ph.D., and S. C. Hooker. THE LITERATURE OF OZONE AND PEROXIDE OF HYDROGEN.

SECOND MEMOIR.

By ALBERT R. LEEDS.

Preface.

At the meeting of the Chemical Section of the New York Academy of Sciences, held June 12th, 1880, I had the pleasure of presenting to the Academy a first Memoir upon "The Literature of Ozone and Peroxide of Hydrogen." This memoir consisted of four parts. First. A historical and critical essay upon the "Lines of Discovery in the History of Ozone," from the first observation of Schönbein in the year 1840, to the facts made known in the earlier portion of the year 1879. This prefatory essay discussed under separate sections, the original discovery of ozone, its sources and its properties; also the nature of the constituent matter of ozone; finally, the exact nature of the relations existing between ozone and ordinary oxygen.

The second part of the memoir was an "Index to the Literature of Ozone (1785-1879)." This memoir was drawn up on the plan suggested by my friend and predecessor as Corresponding Secretary of the Academy, Dr. H. Carrington Bolton. Dr. Bolton has been led, during the course of his classic investigations upon the Fluorides of Uranium (*Berl. Akad. Ber.*, 1866, 209), to prepare for his own more exact knowledge a partial index to the literature of uranium. In the hope of saving future investigators from the great labour of repeating his work, Dr. Bolton completed this Index, and published it in the *Annals of the New York Academy of Sciences*, or as the society was then called, the New York Lyceum of Natural History, vol. ix, Feb., 1870. This first publication was followed by a second (*idem*, xi., Nov., 1875), in which Dr. Bolton has given in the compass of 44 finely printed octavo pages, an "Index to the Literature of Manganese," beginning as far back as the year 1596, and brought down through nearly three centuries, to the year 1874.

His labours prompted Prof. E. J. Hallock to continue the work by preparing an "Index to the Literature of Titanium," (1783-1876), published in *Ann. N. Y. Acad. Sci.*, vol. i., p. 53, Dec., 1876, and Prof. G. J. Rockwell a similar "Index to the Literature of Vanadium" (1801-1876), *idem*, vol. i., p. 133. Since the publication of the two indices by the author, the Academy has also published an "Index to the Literature of Electrolysis," *idem*, vol. ii., p. 313, by Mr. W. W. Webb.

The third portion of the author's preceding memoir was an essay upon "The History of Antozone and Peroxide of Hydrogen." It pointed out the fallacy of the arguments and proofs offered by Schönbein and Meissner, for the existence of the so-called antozone, and described the experiments of von Babo, Nasse, Engler, and others, by which the certainty of the non-existence of antozone has been demonstrated. The essay furthermore gave some account of the artificial sources of peroxide of hydrogen, and of the experiments devoted to a demonstration of its probable occurrence in nature. This was followed by a fourth part, devoted to an "Index to the Literature of Peroxide of Hydrogen" (1818-1878), similar in plan to that upon ozone.

In returning to this subject, it is with the hope of assisting fellow-students in two ways. First, by bringing these indices down to date, which will make the preceding work of much greater utility. Secondly, by pointing out the

uselessness of repeating, as is being constantly done, the investigation of matters previously studied with thoroughness, and of overlooking other topics which are at present incompletely understood.

I. Sources and Preparation of Ozone.

The formation of ozone is to be looked for in all cases where the molecule of oxygen undergoes decomposition under conditions which render it possible for the constituent atoms to exist in a free or uncombined condition for an interval of time. This setting free of the constituent atoms of the molecule is what was known in the older chemistry as the nascent state of the element in question. And whilst the increased energy of chemical properties possessed by the element, at the instant of being liberated from a previous chemical combination, or in *statu nascenti*, was a fact of universally recognised importance, yet a satisfactory explanation of this increase of energy was not possible until the distinction between the chemical atom and the chemical molecule was established as a fundamental fact of the newer chemistry. Ordinarily, the nascent atom immediately enters into combination again, either with an atom of the same kind, as, for instance, an atom of hydrogen with an atom of hydrogen to form a molecule of hydrogen in all respects similar in its properties to ordinary hydrogen gas, or with an atom of a different kind to form a different substance. In the case of oxygen, however, these free atoms may not only reunite by twos to form the ordinary dual molecule, known as oxygen gas, but by threes to form the triple molecule, which is ozone.

According to the older chemistry, it would have been difficult to assign a reason why free hydrogen atoms might not reunite to form a triple molecule of hydrogen, just as well as free oxygen atoms. And as a matter of history, Osann endeavoured to prove that the hydrogen given off in electrolysis differs from ordinary hydrogen, just as the oxygen given off differs from ordinary oxygen. He ascribed to such electrolytic hydrogen a weak acid smell, and the power of readily reducing silver and other metallic salts, and distinguished it by the name of ozone-hydrogen. But these properties were in reality due to other bodies in the electrolytic hydrogen, to say nothing of the fact that absolutely pure hydrogen gas has the power of slowly reducing silver from its salts.

It is not in accordance with our present knowledge concerning hydrogen, to regard the existence of such a body as Osann's supposed ozone-hydrogen as possible. For in all its known chemical combinations, hydrogen possesses but one bond of chemical attraction, and a molecule of hydrogen possessing three or more hydrogen atoms would lack the bonds to hold it together. Chlorine, on the other hand, has one, three, five, or seven bonds, according to the nature of the element with which it is brought into combination, and whilst it is certain that we do not understand the true meaning of this varying number of bonds, yet there is no reason why a number of allotropic modifications of chlorine might not exist, with different densities, colour, chemical properties, &c. So is it likewise with phosphorus, arsenic, nitrogen, and other polyvalent elements. The allotropic form of phosphorus, for example, may be due to one of three causes: a difference in the amounts of internal energy, a difference in the relative positions of the constituent atoms, or a difference in the number of these atoms. The first supposition we need not entertain, because it would carry with it the admission that the differences between the substance-matter of all the elements themselves consists in differences in the quantity and kind of their internal energy. This admission chemists are not prepared to make. The last supposition includes the second, and explains the most important difference in the properties of the allotropic modifications of an element, their specific gravities. Moreover it is in harmony with the only case of allotropism, in which we are enabled to compare the allotropes in the gaseous condition, and it is in the gaseous condition that the relative number of atoms

in a molecule may be best compared. The specific gravity of ozone is to that of oxygen as 3 to 2, which is in harmony with the supposition, the most probable one on many other grounds as well, that the molecule of ozone consists of three, the molecule of oxygen of two atoms of oxygen.

The difference between the ordinary translucent modification of phosphorus and the red, may be explained by supposing the molecule of the former to contain 7 atoms, that of the latter 8. In this case the weights of the molecules would be as 217 to 248, or as 1·83 to 2·1, which latter numbers represent the actual specific gravities. Similarly, if we suppose the molecule of crystallised metallic phosphorus, the third allotropic modification, to consist of 9 atoms, its molecular weight in the solid condition would be to the molecular weight of ordinary phosphorus as 279:217=2·35:1·83, which latter numbers represent the actual specific gravities as determined by experiment.

Nitrogen was announced by Mr. Stillingfleet Johnson, in two papers read before the English Chemical Society in 1880, to be capable of existing in two allotropic modifications, his announcement being based on an experiment in which a certain kind of nitrogen, that obtained by the decomposition of ammonium nitrite, had been made to enter into direct union with hydrogen to form ammonia, while another kind of nitrogen, that existing in atmospheric air, would not so combine. But Mr. H. B. Baker has shown (CHEMICAL NEWS, xlviii, pp. 187, 279), that Mr. Johnson's results were erroneous, the mixed gases containing oxides of nitrogen, which gave rise to ammonia under the conditions of the experiment; and the existence of a new allotrope of nitrogen is still under discussion.

To return from this consideration of allotropism in general, and examine the thesis at the beginning of the section:—The formation of ozone is to be looked for in all cases where the molecule of oxygen undergoes decomposition under conditions which render it possible for the constituent atoms to exist in a free or uncombined condition for an interval of time.

This setting free of the component atoms of the molecule (*status nascens*), always precedes the formation of ozone, inasmuch as before a combination of atoms by threes can occur, a decomposition of the preceding combinations by twos must take place. This, it will be urged, is a self-evident proposition, and I am very glad to admit that it is. But I am not the less impressed with the importance of distinctly formulating it in this place, because in much of the writing upon this topic it is ignored, and also because in many places this oxygen of the nascent state (free atoms), is called active oxygen and is frequently confused with ozone itself. This confusion is so probable (since ozone is most certainly the active allotrope of oxygen), that it appears to me inexpedient to speak of nascent oxygen as active oxygen, and of the process of making it as the activation of oxygen. To guard against this danger, I shall term the process the *atomation* of oxygen, and the freed atoms themselves, not active, but *atomic* oxygen. But, it may be asked, what experimental proof is there that atomic oxygen precedes in every instance the formation of ozone? The answer is to be found in the fact that ozone is incapable of producing certain chemical changes, readily producible by atomic oxygen; whilst, on the other hand, atomic oxygen, under the conditions referred to, can produce not only these chemical changes, but at the same time, and by a similar action, ozone itself.

The proof of this statement is set forth in a paper which the author published in the *Journal of the American Chemical Society* for 1879, p. 232, and subsequently in the *Proceedings of the German Chemical Society*.

It was there shown that carbon monoxide would undergo conversion into carbon dioxide, under the same circumstances as would bring about the conversion of ordinary oxygen into ozone; that is to say, when a mixture of carbon monoxide and air was subjected to the action of

moist phosphorus. Later in the same year, I was induced by the theoretic importance of the subject, to study it anew, and to endeavour to learn whether the production of the carbon dioxide in this experiment was due to the action of ozone, or whether it was due to the production in the first place of atomic oxygen, and the subsequent combination of this atomic oxygen on the one hand with carbon monoxide to form carbon dioxide, and on the other hand with oxygen to form ozone.

Whether, in chemical language, the action was—

or, as a first step,

and then, as second steps occurring simultaneously,

In this second series of experiments (*Ibid.*, p. 450) I employed oxygen ozonised by the ozonising battery to the extent of 72 m.grms. of ozone per litre, while in the earlier experiments the percentage did not exceed 5 m.grms. per litre. But no production of carbon dioxide took place, however long the carbon monoxide and ozone remained in contact. Furthermore, when carbon monoxide and oxygen were separately submitted to the electric effluve, and then brought together, no carbon dioxide was formed. But when the two gases were first brought together in suitable proportion, and then the mixture submitted to the electric effluve, carbon dioxide was produced in quantities readily admitting of quantitative measurement.

I regarded this experiment as demonstrating the existence of atomic oxygen as prior to, and necessary to, the production of both carbon dioxide and ozone. In other words, that equations (2) and (3) represented the true sequence and co-ordination of the phenomena, and not equation (1).

Three years subsequently Baumann repeated this experiment (*Ber. der Deutsch. Chem. Gesell.*, xiv., 2706), and obtained the same result. These results having been questioned by Remsen and Keiser (*Amer. Chem. Journ.*, iv., 454) on the ground of their having obtained a negative result, I repeated my original experiment with air and carbon monoxide over moist phosphorus, every source of error being rigorously guarded against, and obtained even larger amounts of carbon dioxide than in my earlier investigation,—in one case 15·5 m.grms. Since that time Baumann has likewise repeated the experiment, and obtained in one trial, 23·3 m.grms. carbon dioxide, in another case 64·6 m.grms.

The atomation of oxygen, and the setting free of atomic oxygen, as a step necessarily antecedent to the formation of ozone, has therefore, I conclude, been established by rigorous experimental proof. In the case of the electric effluve, the intervening oxygen dielectric undergoes polarisation, and a certain number of its molecules are decomposed into atoms. Certain of these atoms re-combine among themselves, or combine with the oxygen molecules, to form ozone, the amount of the ozone produced depending upon the strength of the electric effluve, upon the duration of electrification, the temperature, presence of foreign gases or vapours admixed with the gaseous electrolyte, and the other conditions of the experiments.

If the atomation of the oxygen be brought about by the reduction of the oxygen molecule by means of phosphorus, partly covered by water, there will be formed by the atomic oxygen thus produced, ozone, hydrogen peroxide, and ammonium nitrate. If ammonium nitrite is produced, as an intermediary step, it is not found in the final products. These three substances, as I have always insisted since the publication of the investigation upon which the statement is based (*Journ. Amer. Chem. Soc.*, 1879, vol. i., 150), are three necessarily associated bodies, all secondary in their genesis, and dependent upon the previous formation of atomic oxygen. The reaction takes place, primarily, according to the equations—

and secondarily, according to the equation—

The ozone passes off in the atmosphere. The hydrogen peroxide and the ammonium nitrate mostly remain behind in the jar-water, though certain amounts can be detected in the wash-waters, if any such be employed to wash the escaping ozone. The white cloud above the wet phosphorus is mainly hydrogen peroxide associated in a state of vesicular suspension with aqueous vapour, and constitutes the antozone cloud of Schönbein (the atmizone of Meissner).

In all these cases, besides the production of atomic oxygen as a necessary antecedent, its formation at temperatures consistent with the possible formation of ozone, hydrogen peroxide, &c., must be predicated. And inasmuch as ozone is slowly converted even at the boiling point of water into oxygen (at once at a temperature of 237° C.), the importance of maintaining a low temperature is manifest. When the atomation of oxygen is brought about by moist phosphorus, no action occurs below 6° C. At 24° the formation of ozone is at a maximum, the production falling off very rapidly, as the temperature rises above this point. When atomic oxygen is set free in the electrolysis of acidulated water, the gas evolved at the positive electrode contains, according to Soret, 1 p. c. of ozone, when the temperature of the electrolyte is maintained at 6° C., and 2 p. c. when at 0°.

But whilst the lower temperatures spoken of are those most favourable to the permanence of the products of the action of atomic oxygen, yet the evidence is very strong that even under circumstances apparently unfavourable and at high temperatures, the atomic oxygen may bring about the formation of ozone, hydrogen peroxide, and ammonium nitrite. It was stated by Loew (CHEMICAL NEWS, xxi., p. 107), that ozone is formed when air is blown through a gas-flame under proper conditions. This was denied by Böttger (*Chem. Centr.*, 1870, 161), who stated that ammonium carbonate and hydrogen peroxide are formed under these conditions. During the same year (1870), Than brought forward certain experiments to show that ozone was formed during the rapid combustion of all hydrogenous bodies. (*J. pr. Chem.* [2], i., 415.) The year following Pincus confirmed Than's statement (*Pogg. Ann.*, cxliv., 480), and Struve published his research to show that ozone, hydrogen peroxide, and ammonium nitrite, all three were formed in the combustion of hydrogen (*Bull. de l'Acad. Imp. des Sci. de St. Petersburg*, xv., No. 3). By experiments conducted with extreme care, Zoeller and Grete (*Berl. Berichte*, x., 2144), showed that in the burning of pure hydrogen in pure air, ammonium nitrite is formed in very notable quantities. Much later Böttger (*Chem. Centr.*, 1878, p. 574) found that hydrogen peroxide is formed on the explosion of a mixture of pure oxygen and hydrogen. Inasmuch, however, as certain very careful observers, like Zoeller and Grete, have demonstrated the formation of one only of the three products, it is necessary that a more complete demonstration of the production of all three bodies in rapid combustion be brought forward, before it can be regarded as finally established.

The subject of the atomation of oxygen was studied at great length by Schönbein, and a large number of important facts noted by him. But at that time the true nature of ozone was not known. According to Schönbein, ozone itself was one kind of atomic oxygen, namely, the free atom in an electro-positive condition, and antozone another kind of atomic oxygen, the free atom in an electro-negative condition. He supposed that it was the latter kind which, in contact with water, generated hydrogen peroxide. Although ozone is certainly not what Schönbein

supposed it to be, yet the existence of atomic oxygen, as something necessarily preceding the formation of ozone, may now be regarded as a demonstrated fact. And whilst it has not been shown that the free oxygen atoms may exist in two electro-negative conditions, yet such an hypothesis is theoretically not untenable, nor has it been demonstrated to be false.

Latterly, the number of cases in which the formation of active oxygen has been noted has been largely increased. Thus Hoppe-Seyler has pointed out that is formed when palladium-hydrogen is shaken up in contact with water and air (*Berl. Berichte*, xii., 1551). Under these circumstances he noted the formation of the third by-product, ammonium nitrite, as well. The author, prompted by theoretical considerations, sought for the presence of ozone and hydrogen peroxide, since according to the hypothesis above enunciated, both should be present. Ozone he failed to detect, hydrogen peroxide was found in quantity large enough to admit of its quantitative estimation (*Berl. Berichte*, xiv., 976). So also palladium, platinum, and other so-called "carriers of oxygen," owe the energetic oxidising actions which occur in their presence, and which were formerly spoken of as "catalytic," to their power of affecting a separation of the oxygen molecule into its constituent atoms. This is shown by the experiments of Traube and Baumann, who found that palladium will cause the oxidation of carbon monoxide to dioxide in presence of hydrogen peroxide, whilst without palladium no such oxidation occurs. It has been likewise noted by the author that platinum black, when shaken up in a bottle partly filled with air, along with a solution of indigo, turns the latter yellow by causing its oxidation and the formation of isatin. Since this very powerful oxidising action is not produced by oxygen in its ordinary condition, it may be ascribed to the atomation of the oxygen under the influence of the platinum black.

The number of observed cases of the formation of atomic oxygen has been largely increased by the recent researches of Radziszewski on the phosphorescence of Organic Bodies. He divides such phosphorescent organic bodies into two groups: 1st. Those which phosphoresce when the atomic oxygen which they already contain, and which has been previously formed under the influence of some activating agent like sunlight, operates upon the organic body, on the addition of an alkali. 2nd. Those bodies which, on the addition of an alkali, themselves form atomic oxygen, and by combining with this atomic oxygen, become phosphorescent. To the first group belong various hydrocarbons, especially the aromatic, the terpenes, &c. To the second, belong more especially the aldehyds, or such bodies as when treated with an alkali form aldehyds. To the latter sub-division belong the fats of the series $C_nH_{2n-2}O_2$. Radziszewski explains in like manner the phosphorescence of organisms, since he finds in them a fat, together with an alkaline body. And in one of these, the *Pelagia noctiluca*, he thinks he has demonstrated the presence of atomic oxygen, by showing that the *Pelagia* develops a blue colour when placed on porous plates moistened with potassium iodide, starch paste, and tincture of guaiacum.

II. Nature and Properties of Ozone and Hydrogen Peroxide.

The recent remarkable discoveries concerning the properties of ozone have strengthened the grounds on which the hypothesis of the nature of ozone stands. Recently, a lengthy series of memoirs has been written by Traube, in which he controverts both the present theory, as to the constitution of hydrogen peroxide, and the views now entertained of its action as an oxidising agent. Hitherto, chemists have looked upon hydrogen peroxide as oxidised water, from the fact that it yields up one of its atoms of oxygen with great readiness, and therefore acts as an energetic oxidising agent. In order that water may take up another atom of oxygen, a molecule of oxygen or an

* In an article upon the "Preparation of Phosphoric Acid by the oxidation of Phosphorus with Air in Presence of Moisture" (*Pharm. J. Trans.* [3], xiv., 24-26, and *Journ. Chem. Soc.*, December, 1883, p. 1050), W. T. Wenzell has obtained the same results, and has adopted in their explanation the hypothesis here stated.

oxide must be decomposed, or an atom of atomic oxygen must enter into direct combination. Thus—

Traube, on the other hand, has brought forward a number of experiments to show that peroxide of hydrogen is reduced oxygen; that is to say, the oxygen in the peroxide enters as a whole molecule, and as a molecule exists in combination with two atoms of hydrogen. But whilst Traube states the above as his hypothesis, and that both the atoms of oxygen are combined in the same manner, and with the same degree of chemical attraction, yet the structural formula which he gives is the same as the one ordinarily adopted; nor is the fact that one only of the oxygen atoms is readily parted with, explained by his theory any more satisfactorily than by the ordinary one. Moreover, the experiments, as detailed by Traube, are in opposition to the results many times obtained by the author in their repetition.

Without detailing these results in this place, it will suffice to state that when zinc in fine division is shaken up with water and air, the oxygen of the air causes an energetic oxidation of the zinc. As a result of this oxidation, the oxygen molecule is divided, one atom going to the zinc and the other being for an instant set free. This atomic oxygen brings forth very energetic oxidations, oxidising indigo to isatin, forming hydrogen peroxide, decomposing potassium iodide, and developing nitrous acid. The latter speedily disappears, being oxidised by the peroxide of hydrogen to nitric acid, while the excess of peroxide of hydrogen, which appears to be the most abundant product of the reaction, is decomposed by the zinc.

It might be supposed that these phenomena are due to the oxidation of nascent hydrogen set free by the decomposition of the water itself. But this is not the case. Pure zinc does not decompose water, and ordinary zinc decomposes it in too small an amount to explain the observed phenomena. This being the case, zinc acts in a manner analogous to phosphorus, viz.:

An experiment recently performed by Kappel can be best explained in like manner. On agitating Cu with an alkaline solution and air, he obtained the reaction both for ozone and hydrogen peroxide, but not the nitrous reaction. His test-papers suspended above the liquid became blue, but were immediately decolourised, a result attributed to the decomposition of the ozone first formed, by the peroxide of hydrogen. For on passing a current of air so as to remove the ozone, the hydrogen peroxide reaction was readily obtained. (*Berl. Berichte*, xv., 2359.)

III. Liquefaction and Colour of Ozone.

The most important discoveries during the past three years concerning the properties of ozone, are those made by Hautefeuille and Chappuis. They found that ozone is a blue gas, the colour appearing sky-blue even when only so much ozone is present as is obtained in the ozonation of the oxygen contained in a tube a metre in length by the silent discharge. Furthermore, they found that under very great pressures the condensed gas becomes indigo blue. If the pressure is increased to 75 atmospheres and then suddenly relieved, a dense white cloud is formed, showing the beginning of liquefaction, whilst the same phenomenon does not take place with pure oxygen until a pressure of 300 atmospheres is attained. The ozone must be compressed slowly and with constant cooling, otherwise it will explode with evolution of heat and light. By mixing the ozone with carbon dioxide, and then submitting the mixture to great cold and pressure, Hautefeuille and Chappuis succeeded in obtaining a deep blue liquid, the blue colour being due to the liquefied ozone.

The same observers have studied the absorption-spectrum of ozone, and accurate measurements of the same have been made by W. N. Hartley. The latter has extended the research to the absorption of certain parts

of the sun's rays by atmospheric ozone. By this new optical method he has arrived at the conclusions—1st. That ozone is a constant constituent of the upper atmosphere. 2nd. That it is present in larger amounts in the upper than in the lower part of the earth's atmosphere. 3rd. That it is the cause of the blue colour of the sky.

IV. Atmospheric Ozone.

In a former paper published in the *Annals* of the Academy, "Upon Ozone and the Atmosphere," I have detailed at length the experiments by which I sought to show that the so-called ozonoscopes, such as Schönbein's potassium iodide starch-papers, and Houzeau's potassium iodide and litmus papers, were of no value as tests for ozone *per se*, since they were equally affected by hydrogen peroxide, which is also present in the air. Schöne has arrived at the same results. But he has also shown that whilst even thallium papers are of no value as ozonoscopes, they are of value in the determination of atmospheric hydrogen peroxide by exact chemical methods. Thus at the very time when the estimation of atmospheric ozone by any known chemical method had been found impossible, the researches of Hautefeuille, Chappuis, and Hartley pointed out an entirely unlooked-for means of overcoming the difficulty. But as yet the practical utilisation of their discovery, and the influence of moisture, hydrogen peroxide, and other constituents of the atmosphere, in confusing or rendering difficult the observation of the ozone absorption-spectrum, have not yet been made known.

NOTES OF WORK BY STUDENTS OF PRACTICAL CHEMISTRY IN THE LABORATORY OF THE UNIVERSITY OF VIRGINIA.

Communicated by F. P. DUNNINGTON.
Acting Professor of General and Analytical Chemistry.
(Concluded from p. 210).

(114). Estimation of Sulphur Dioxide. By C. L. REESE.

The process proposed is as follows:—

A standard solution of potassium permanganate is employed to ascertain the strength of a solution of hydrogen dioxide according to the reaction.

Now put the portion of the sulphur dioxide solution to be determined into a glass stoppered bottle; to this add a few drops of a solution of titanium sulphate, and then titrate with the solution of hydrogen peroxide until the yellow colour produced by the action of the latter on titanous oxide is permanent on shaking. The colour may appear before all the sulphur dioxide is oxidised, but it will then disappear on shaking. The odour of the sulphur dioxide well enables one to judge of the amount of hydrogen peroxide needed in the titration, since a very small amount of it can be thus detected after shaking.

The following experiments were made:—

A portion of a solution of sulphurous acid, obtained by bubbling the gas through water, was treated with excess of hydrogen peroxide, boiled, acidified, and then treated with excess of barium chloride; the amount of barium sulphate obtained corresponded to sulphur dioxide originally present, 1.096 grm. A similar portion estimated by the above method gave sulphur dioxide, 1.104 grm., being 100.7 per cent of the former. A sealed glass tube containing pure liquefied, sulphur dioxide was weighed, and the whole of the contents dissolved in a three litre flask of water; the tube finally weighed gave the total

weight of sulphur dioxide employed; we will call this 100. A measured portion of this was oxidised by excess of hydrogen peroxide and the sulphur trioxide weighed as barium sulphate. Two other portions were titrated by hydrogen peroxide according to the above method, giving the following estimates of the sulphur dioxide:—

By weight of liquefied gas ..	100
" " barium sulphate ..	99.7
" 1st titration ..	96.6
" 2nd " ..	97

The errors in the process are undoubtedly mainly due to the loss of sulphur dioxide which occurs on exposure of the solution to the air.

In view of the very unsatisfactory character of the estimation of sulphur dioxide by direct oxidation by potassium permanganate, the above method of making this estimation, suggested by Mr. W. G. Brown, although not very accurate, will prove of some value as a volumetric method.

(115). *Comparative Oxidation of Solutions of Sulphurous Acid and of Sodium Sulphite.* By C. L. REESE.

While it is well known that solutions of the sulphites are oxidised on exposure to the air, I believe it is generally thought that these solutions are more permanent than are those of sulphurous acid solutions under similar conditions. On more than one occasion I have been annoyed to find that a reagent bottle in which there had been put a solution of sodium sulphite contained only the sulphate. I therefore proposed to Mr. Reese to examine the relative rates of oxidation of these solutions. Owing to a misunderstanding, the strength of the several solutions were not such as I preferred, but this was noted when it was too late to correct it.

The sodium sulphite employed was that of E. Merck; it contained about one-fifth of sulphate, and I therefore state the strength of the solution in terms of the sulphur dioxide present. Three solutions of the sulphite, 1, 3, and 5, and two solutions of sulphurous acid, 2 and 4, were put into half-gallon green glass acid bottles, nearly filling them. The neck of each of these was closed up by a cork, through which passed a short open tube 2 m.m. in diameter bent outside the bottle to keep out dust. These stood side by side in daylight in the balance room, and each week portions were removed for analysis. No record was kept of the temperature, which varied often between 50° and 90°, the experiment extending from March 19th to June 12th. The method of estimation of the sulphur dioxide employed was that described in the previous article. The gradual diminution of the SO₂ and its oxidation is expressed in the following:—

TABLE I.—Parts of SO₂ in 1000 Parts of Water.

	1.	2.	3.	4.	5.
Beginning ..	21.10	6.00	3.77	1.063	0.765
After 1 week ..	20.60	5.94	2.45	0.971	0.183
" 2 weeks ..	18.30	5.29	1.28	0.737	0.028
" 3 " ..	17.16	4.97	0.64	0.664	0.006
" 4 " ..	16.42	4.62	0.29	0.577	—
" 5 " ..	15.53	4.61	0.18	0.461	—
" 6 " ..	14.21	4.29	0.11	0.362	—
" 7 " ..	13.03	3.73	0.00	0.240	—
" 8 " ..	11.93	3.52	—	0.162	—
" 9 " ..	11.05	3.16	—	0.100	—
" 10 " ..	9.21	2.95	—	0.072	—
" 11 " ..	8.70	2.77	—	0.055	—
" 12 " ..	7.34	2.55	—	0.031	—
After 12 wks. total amount oxidised	13.76	1.85	3.77	1.055	0.765

We may throw the result in another form, in each case designating the amount of sulphur dioxide originally present as 100. We have the following:—

* The irregularities of the apparent alteration of the sulphur dioxide solution may in part be due to the irregularities of the temperature.

TABLE II.

	1.	2.	3.	4.	5.
Beginning ..	100	100	100	100	100
After 1 week ..	98.1	99.1	65.1	91.3	23.8
" 2 weeks ..	86.7	88.2	35.4	69.3	2.3
" 3 " ..	81.4	82.9	17.0	62.3	0.7
" 4 " ..	77.8	76.9	7.8	54.3	0.0
" 5 " ..	72.6	76.8	4.8	43.4	0.0
" 6 " ..	67.3	71.6	2.7	34.0	0.0
" 7 " ..	61.7	62.1	0.0	22.6	0.0
" 8 " ..	56.5	58.6	0.0	15.1	0.0
" 9 " ..	52.4	52.7	0.0	9.4	0.0
" 10 " ..	43.6	49.2	0.0	6.5	0.0
" 11 " ..	41.2	46.1	0.0	5.1	0.0
" 12 " ..	34.1	42.5	0.0	2.9	0.0
After 12 wks. oxidised	65.9	30.8	100.0	98.3	100.0

From the above we may draw the following conclusions:—

First. That with each of these substances the weaker solutions oxidise more rapidly.

Second. That with weak solutions the sulphite is more rapidly oxidised than sulphurous acid.

Third. That although solution 2 was not so much oxidised as solution 1, yet it lost its strength almost as rapidly by reason of the escape of sulphur dioxide, and we might expect a stronger solution to part with any additional strength yet more rapidly.

Fourth. That the sulphite solution, so long as any sulphite remained, took up oxygen at about a constant rate independently of the strength of the solution, this rate being probably determined by the extent of the exposure to air.

(116). *Analysis of Infusorial Earth, Richmond, Va.* By J. M. CABELL.

Since the analyses heretofore made of this well-known infusorial earth appear to have been of rather impure specimens, Mr. Cabell procured from the middle of the exposed bed of this earth just below the coloured normal school on President's Hill, in Richmond, Va., a specimen which, without any previous treatment, proved to be almost exclusively composed of distinguishable infusoria.

It is white with tinge of yellow, feels a little harsh; sp. gr. of mass coated with varnish = 0.922, the sp. gr. of powder = 2.321.

Analysis afforded the following:—

Silica dissolved in 1st hour	29.60	75.68
" " 2nd "	4.79	
" " undissolved	41.29	
Alumina ..		9.88
Ferric oxide ..		2.92
Lime ..		0.29
Magnesia ..		0.69
Potash ..		0.02
Soda ..		0.08
Nitrogenous matter (nitrogen × 6) ..		0.84
Water by H ₂ SO ₄ 3.37		8.37
" by 100° C. 1.17		
(less N) by ignition 3.83		
		98.77

To ascertain the solubility of the silica as above, the powder was boiled in a 20 per cent solution of sodium hydrate.

(117). *Analysis of a Variety of Chloropal from Albemarle Co., Va.* By L. N. CHAPPELL, of Forestville, N. C.

This mineral is found in leaf-like pieces, in sizes from fine grains up to 8 c.m. in diameter and 1 c.m. thick, in a mass of disintegrating rock which could not be recognised, the remainder of which formed a ferruginous clay. This

decomposing rock appears to follow a vein of limonite and quartz; the larger pieces of the green mineral lying nearest to the limonite. The country rock is largely composed of quartz, felspar, and epidote, with occasionally almandine. The mineral in question is massive, quite soft when first dug up, but on drying becomes harder and brittle with earthy fracture, cuts under the knife, giving a faintly greasy lustrous surface, is greasy to touch, not adhering to the tongue, of light yellowish green colour. Hardness about 1 sp. gr. = 2.06. Fuses to a black glass at about 3. Is decomposed with separation of silica by hydrochloric or sulphuric acid.

Analysis afforded the following:—

		Oxygen ratio.
Silica	38.64	128
Alumina	20.05	60

Ferrous oxide	0.04	
Lime	1.09	
Magnesia	0.44	
Water	15.71	120
	98.15	

giving the formula—

which nearly corresponds to that of pinguite, a variety of chloropal, $2\text{Al}_2\text{O}_3, 3\text{SiO}_2 + 4\frac{1}{4}\text{H}_2\text{O}$.

(118.) *Analysis of Kaslinite from Calhoun Co., Ala.* By G. H. ROWAN.

An unusually pure specimen of clay from a deposit about 12 miles S. W. from Jacksonville presents the following properties.

White, with a tinge of cream colour, earthy, with clayey odour, adheres to tongue, feels slightly greasy; sp. gr. of powder = 2.509, sp. gr. of specimen coated with varnish = 1.688.

Analysis afforded the following:—

		Oxygen ratio.
SiO ₂	45.77	197
Al ₂ O ₃	89.45	150
CaO	0.79	
H ₂ O	13.96	100
MgO, Fe ₂ O ₃	trace	
	99.97	

Showing a very close agreement with the theoretical composition of kaolinite, $2\text{SiO}_2, \text{Al}_2\text{O}_3, 2\text{H}_2\text{O}$.

After this analysis was completed it was found that an examination of this clay was made in 1855 by Dr. J. W. Mallet.

[See Second Biennial Report of the Geological Survey of Alabama, by M. Tuomey, 1858.]

(119.) *Analysis of Marmalite from Himmelfahrt Mine, Freiberg.* By JAMES DOUGLAS BRUCE.

This specimen was received of Dr. O. Krantz among some minerals for analysis, and presented the usual appearance of marmalite. An analysis afforded the following composition:—

Zinc	50.82
Iron	14.52
Copper	2.35
Antimony	1.14
Manganese	trace
Sulphur	31.67
Insol. residue	0.14
	100.64

Agreeing with the formula 3ZnS.FeS .

The unusually large amount of antimony and of copper present occasions this note of it.

(120.) *Analysis of Garnet (var. Spessartite), from Amelia Co., Va.* By C. M. BRADBURY, of Petersburg, Va.

This mineral is from the mica mine above referred to.

It is of a pale pink to flesh-red colour, resembling rhodonite more than the usual form of garnet. Hardness = 6.5; sp. gr. = 4.20.

Analysis afforded the following:—

Silica	36.34
Alumina	12.63
Ferrous oxide	4.57
Manganous oxide	44.20
Lime	1.49
Magnesia	0.47
Water	trace
	99.7

It will be noted that the manganese is unusually high, and the iron and alumina unusually low.

University of Virginia,

ON THE ACTION OF PHOSPHORUS TRICHLORIDE ON ANILINE.

By C. LORING JACKSON and A. E. MENKE.

THE only paper on this subject which we have been able to find was published by Tait in 1865.* In it he describes the product of the action of phosphorus trichloride on aniline as a white salve-like mass easily soluble in water, alcohol, and ether, which, when freed from an excess of aniline, had the composition $(\text{C}_6\text{H}_5\text{NH})_3\text{P}_3\text{HCl}$, gave a chlorplatinate and several double salts, but yielded no satisfactory result when he attempted to set free the base.

We were induced to take up the study of this reaction by the hope that a further investigation of Tait's substance might lead to interesting results; but in this we were disappointed, as we have not succeeded in obtaining it, and, as far as our experiments go, are inclined to think it must have been a mixture instead of a definite compound. At the same time we cannot state with absolute certainty that it is not present in the product formed when a decided excess of aniline is used, since the impossibility of continuing our work after the beginning of the summer vacation prevented us from making the investigation of this product as thorough as we wished. For the same reason other parts of this research can be published only in a very fragmentary and imperfect condition.

The isolation of the compounds containing phosphorus formed by the action of phosphorus trichloride on aniline, in the proportion of one molecule to three, is surrounded by difficulties which we have found insurmountable; but, in spite of this, our experiments have determined with a fair degree of certainty the nature of these compounds, as will appear from the following general statement of our results, and the argument which can be based upon them.

When aniline is added to phosphorus trichloride in the proportion of three molecules of the former to one of the latter, the product, a variable mixture of aniline chloride and a substance containing phosphorus, gives a clear solution with water or alcohol. If, however, this product is heated, a waxy mass is obtained, which is soluble in alcohol; but water throws down from this solution a white precipitate having the formula $(\text{C}_6\text{H}_5\text{NH})_2\text{PHO}$. Of the three most probable products of the reaction of phosphorus trichloride and aniline,—

- (1) $\text{C}_6\text{H}_5\text{NHPCl}_2$,
- (2) $(\text{C}_6\text{H}_5\text{NH})_2\text{PCl}$,
- (3) $(\text{C}_6\text{H}_5\text{NH})_3\text{P}$,

* Jahresbericht der Chem., 1865, 411. *Instil.*, 1865, 254.

only (2) could yield $(C_6H_5NH)_2PHO$ by the action of water or alcohol, and we therefore infer that—

exists in the product after it has been heated. On the other hand, this substance cannot exist in the original product, as this dissolves in water without residue, whereas $(C_6H_5NH)_2PCl$ is converted by water into the insoluble $(C_6H_5NH)_2PHO$; but it must be formed from one of the constituents of the crude substance during the heating. Of the two probable products of the reaction, (1) and (3), mentioned above, it is hard to see how—

by heating with aniline chloride, could be converted into $(C_6H_5NH)_2PCl$, while—

could easily undergo this change under these conditions; from which we conclude that $C_6H_5NHPCl_2$ and aniline chloride are the products of the action of aniline on phosphorus trichloride under the conditions mentioned. This conclusion is supported by the fact that alcohol or water acts violently on the original product forming aniline phosphite, and it is highly improbable that $(C_6H_5NH)_3P$ would give such a violent reaction.

The remainder of this paper contains a detailed account of the experiments on which the above conclusions are based, a description of the properties and behaviour of the new substance $(C_6H_5NH)_2PHO$, and a somewhat fragmentary account of two crystalline substances formed by boiling the crude product with an excess of aniline, one of which may be a derivative of $(C_6H_5NH)_3P$, although this point needs confirmation by further experiments.

Action of Phosphorus Trichloride on Aniline.

When aniline is added to phosphorus trichloride the reaction is attended with so much heat that each drop of the aniline hisses like red-hot iron in water when it touches the trichloride; and, if the substances are mixed in about the proportion of three molecules of aniline to one of the trichloride, the product is a hard white solid, with no trace of the salve-like consistency described by Tait. It was proved to be a mixture by the following analyses of three different preparations, which were freed from an excess of either reagent by washing with ether before analysis.

	I.	II.	III.
Carbon	50.82	54.41	43.59
Hydrogen	6.28	7.07	7.10
Chlorine	19.38	23.15	—
Phosphorus ..	5.48	2.92	—

In the hope of isolating the phosphorus compound, the action of various solvents on the mass was studied,—of all the common solvents, water, alcohol, methyl alcohol, and acetone were the only ones in which it was not essentially insoluble; but, as we found that acetone dissolves aniline chloride, there was no prospect of achieving the purification of the phosphorus compound by its means, and either water or alcohol decomposed it, giving a clear solution,* which, on evaporation, left a viscous residue, apparently composed of chloride and phosphite of aniline, as it deposited crystals of the former after standing for some time, and upon solution in water and addition of plumbic acetate gave a heavy white precipitate, which, freed from plumbic chloride by washing with hot water, was found to be plumbic phosphite, by the following analysis:—

0.6986 grm. of the salt gave 0.7380 grm. of plumbic sulphate.

	Calculated for $PbHPO_3$.	Found.
Lead	72.13	72.16

From this result it is probable that no anilido-phosphorus acid was formed.

* When water was used there was sometimes a slight residue of $(C_6H_5NH)_2PHO$.

From what has been said it appears that the product described above differs from Tait's in consistency, in its solubility in ether, and in composition; but if, instead of fulfilling the conditions given above, the trichloride is added to a large excess of aniline, a substance is obtained which resembles Tait's in its salve-like consistency and the fact that it gives a considerable extract with ether; at the same time we cannot think that it has the composition ascribed to it by him, because our analyses given above show that the substance must contain aniline chloride, and this would not have been removed by mere solution in water, the only purification to which it was submitted by Tait. We may add that the solid matter apparently extracted by ether was really dissolved in the excess of aniline, as it proved insoluble in ether after the aniline was removed, and, as aniline dissolves aniline chloride, we saw no prospect of purifying the phosphorus compound in this way. If, on the other hand, an excess of phosphorus trichloride was used, the product was a white compact mass, from which a considerable amount of solid matter was extracted with ether; but this was due evidently to its solubility in phosphorus trichloride rather than in ether, and, as it contained only 2 per cent of phosphorus, it was not thought worth while to pursue this part of the subject further.

Action of Heat on the Original Product.

If the mixture, analyses of which were given above, is heated, it turns orange-red, and gives off aniline chloride, the purity of which was determined by analysis, and a small quantity of a phosphorescent gas, probably phosphoretted hydrogen. This change takes place slowly and partially even at 100°, much more rapidly and completely at 150°, or at even higher temperatures. We usually heated the mass in a porcelain dish over a free flame, regulating the temperature so that aniline chloride sublimed off freely, but no spontaneously inflammable phosphoretted hydrogen was given off. The product when heated with alcohol gave a colourless solution, and a residue of an orange or red colour, according to the length of time it had been heated. As this residue was insoluble in all solvents, and could not be purified completely by washing, we are in doubt as to its precise nature; but, as one preparation contained as much as 81.73 per cent of phosphorus, it cannot be an organic compound, but is either amorphous phosphorus, or the red oxide or solid hydride of that element. The alcoholic solution when treated with water gave a white precipitate of—

while anilide chloride and phosphite were left in solution, with, so far as we could find, no other substances. The formation of the red body is not essential to the production of the mother-substance of $(C_6H_5NH)_2PHO$, as we obtained, by short heating in a dry test-tube, a yellowish waxy mass, which dissolved completely in alcohol, and yielded a large amount of $(C_6H_5NH)_2PHO$ on addition of water; upon longer heating, however, the yellowish substance turned orange-red.

Before going to the description of the phosphorus anilid $(C_6H_5NH)_2PHO$, we may add, that we tried to obtain the chlorine compound from which it is formed by treating the freshly heated orange mass with benzol or with absolute ether, as these solvents seemed to offer the best chance of success. The amount extracted in either case was extremely small, and possessed the most unpromising properties, the ether extract containing lumps of ordinary phosphorus imbedded in a viscous mass, while the benzol extract resembled semi-liquid paint, and gave no evidence that it was a homogeneous compound; it was analysed, however, and contained 5.12 per cent of chlorine and 21.27 per cent of phosphorus, whereas $(C_6H_5NH)_2PCl$ requires 14.17 per cent of chloride and 12.37 of phosphorus.

Phosphorus Anilid, $(C_6H_5NH)_2PHO$.

The preparation of this substance has been just described. In order to purify it, as it did not crystallise, the crude

precipitate was re-dissolved in a little alcohol, and precipitated with water; the viscous mass thus obtained was kneaded thoroughly with water, dissolved again in alcohol, and once more precipitated and washed with water; it was then dried at about 50°, and its composition determined by the following analyses of a number of different preparations.

I. 0.3488 grm. of substance gave 0.7992 grm. of carbonic dioxide and 0.1918 grm. of water.

II. 0.2856 grm. gave 0.6502 grm. of carbonic dioxide and 0.1610 grm. of water.

III. 0.2190 grm. gave 0.5012 grm. of carbonic dioxide and 0.1180 grm. of water.*

IV. 0.3402 grm. gave after treatment, according to Carius, 0.1590 grm. of magnesian pyrophosphate.

V. 0.2016 grm. gave 0.0976 grm. of magnesian pyrophosphate.

VI. 0.4623 grm. gave 49.9 c.c. of nitrogen at a temperature of 25° and pressure 766 m.m.

that the substance behaves like an anilid of phosphorus acid.

Action of an Excess of Aniline on the Original Product.

If the immediate product of the action of phosphorus trichloride and aniline, or this product after it has been heated, is boiled for some time with an excess of aniline, there results a mixture of various substances from which we have succeeded in isolating the orange-red substance and phosphorus anilid already described, chloride and phosphite of aniline, and a crystalline substance melting at 208°. There seems to be also a substance with a higher melting-point, and on one occasion a body melting at 150° was obtained; unfortunately we were obliged to break off work on this part of the subject before we had done more than analyse the two substances melting at 208° and 150° respectively, so that we have as yet no satisfactory data for determining their constitution, and also have been able to make no exhaustive search for other products.

	Calculated for (C ₆ H ₅ NH) ₃ PHO.	I.	II.	Found.	III.	IV.	V.	VI.
Carbon	62.07	62.47	62.04	62.41	—	—	—	—
Hydrogen	5.60	6.10	6.26	5.99	—	—	—	—
Phosphorus	13.36	—	—	—	13.05	13.52	—	—
Nitrogen	12.07	—	—	—	—	—	—	12.13

Properties.—It forms a white amorphous mass which melts at 87°; all our attempts to obtain it in crystals have been unsuccessful; it is freely soluble in cold alcohol and in ether, insoluble in cold water, but melts under boiling water, and perhaps dissolves to a very slight extent. It is a perfectly neutral body, neither acids nor alkalis affecting it in the cold; even alcoholic sodic hydrate or sodic ethylate acts on it with difficulty; on the other hand, fuming hydrochloric acid, when boiled with it for twelve hours, decomposes it completely into aniline chloride, phosphoric acid, and a small quantity of carbonaceous substance. The formation of the aniline chloride was proved by an analysis of the sublimate, 0.2776 grm. giving 0.3114 grm. of argentic chloride,

	Calculated for C ₆ H ₅ NH ₂ Cl.	Found.
Chlorine	27.41	27.74

the formation of phosphoric acid by qualitative tests with argentic nitrate and ammoniac molybdate.

Action of Nitric Acid.—When the substance is gently heated with fuming nitric acid it forms a red solution, from which water precipitates a red resinous body which contains phosphorus, but was not studied further, as the quantity was not large, and its properties were uninviting. By far the principal products of the reaction were contained in the aqueous solution, which left on evaporation yellow crystals having acid properties, and easily characterised by their appearance and melting-point, 120°, as picric acid. Another preparation yielded instead of picric acid the unsymmetrical meta-dinitro-phenol, melting at 113°—115°. These results can be explained by supposing that the nitric acid saponifies the anilid, forming aniline nitrate and phosphoric acid, and the former is afterwards converted into the nitro-phenols by the combined action of nitrous and nitric acids.

Action of Acetic Anhydride.—If phosphorus anilid is heated with acetic anhydride and fused sodic acetate on the water-bath, and the product extracted with ether, a viscous mass is obtained, which gradually becomes partially converted into crystals free from phosphorus, melting at 112° after re-crystallisation from water, and therefore acetanilid.

From all the observations described above it appears

* We found it best to carry on the combustions in a closed tube, the substance being mixed with oxide of copper, as, if burnt in a boat in oxygen, the carbon was apt to come low, since the fused phosphoric acid prevented the complete combustion of the substance.

Substance melting at 208°.—This compound is obtained from the mixed products of the reaction by washing out the soluble salts with water, extracting the residue with hot alcohol, and purifying the extract by crystallisation from alcohol, till it shows a constant melting-point. It was dried at 100° and analysed.

I. 0.3352 grm. gave 0.8032 grm. of carbonic dioxide and 0.1770 grm. of water.

II. 0.2946 grm. gave 0.7047 grm. of carbonic dioxide and 0.1520 grm. of water.

III. 0.2528 grm. gave 0.1200 grm. of magnesian pyrophosphate.

IV. 0.2492 grm. gave 0.1200 grm. of magnesian pyrophosphate.

V. 0.3424 grm. gave 40.44 c.c. of nitrogen at a temperature of 20.5° and a pressure of 757.3 m.m.

	I.	II.	III.	IV.	V.	Mean.
Carbon ..	65.34	65.24	—	—	—	65.29
Hydrogen ..	5.86	5.73	—	—	—	5.79
Phosphorus ..	—	—	13.25	13.47	—	13.36
Nitrogen ..	—	—	—	—	13.38	13.38

These results agree most nearly with the formula (C₆H₅NH)₃P₂O₄H₂, but are not far removed from (C₆H₅NH)₇P₃O₂H₂, as is shown by the following comparison:—

	Calculated for (C ₆ H ₅ NH) ₃ P ₂ O ₄ H ₂ .	Mean of Analytical results.	Calculated for (C ₆ H ₅ NH) ₇ P ₃ O ₂ H ₂ .
Carbon ..	65.61	65.29	65.37
Hydrogen ..	5.71	5.79	5.70
Phos... ..	14.12	13.36	12.06
Nitrogen ..	12.75	13.38	12.71

According to the first of these formulæ the substance would be a derivative of the red oxide or hydrate of phosphorus, while the second can be developed into—

it is possible, therefore, that a study of the decomposition products of the substance might throw light on its composition. With this view we heated some of it to 140° in a sealed tube with hydrochloric acid and obtained phosphorus and phosphoric acids, aniline chloride, some carbon, and an odour of phenol, but no red product; we have also found that boiling aniline with the red substance, so often mentioned, does not give this compound melting at 208°, so that our results are in favour of the second for-

mula so far as they go, but need revision before much weight can be given to them.

Properties.—The substance crystallises in small white prisms apparently of the monoclinic system, or in long radiating needles, with, as far as we could determine, the same melting-point and composition as the prisms; it melts at 208°, and is insoluble in water, freely soluble in hot alcohol, less so in cold, essentially insoluble in ether. Potassic hydrate in aqueous solution does not act on it at first, but gradually decomposes it if the two are boiled together; sulphuric acid acts in the same way; the decomposition with hydrochloric acid has been described already.

Substance melting at 150°.—This compound was obtained at the very end of the term in an attempt to prepare more of the substance melting at 208°: on this account we cannot give the conditions which determine its formation, or anything more concerning it than the following analyses:—

0.3492 grm. of substance gave 0.7122 grm. of carbonic dioxide and 0.2004 grm. of water.

0.2562 grm. gave, according to Carius, 0.1330 grm. of argentic chloride and 0.0890 grm. of magnesian pyrophosphate.

	Found.
Carbon	55.62
Hydrogen	6.37
Chlorine	12.83
Phosphorus	9.70

It would not be worth while to attempt to determine the formula of this substance until these results have been tested by further analysis. It crystallises in rather thick white radiating needles, melts at 150°, and resembles the preceding substance in a general way in its solubility.

At no distant date we hope to be able to return to the study of this subject in order to determine the nature of the two substances just described, to investigate more thoroughly the products of the reaction, which are soluble in water, and to take up the compounds formed by aniline and phosphorus trichloride in presence of diluents, which, according to a preliminary experiment, promise to be of great interest.—*American Chemical Journal*.

PROCEEDINGS OF SOCIETIES

ROYAL INSTITUTION OF GREAT BRITAIN.

General Monthly Meeting, Monday, November 3, 1884.

The Hon. Sir WM. R. GROVE, M.A., D.C.L., F.R.S.,
Manager and Vice-President, in the Chair.

Messrs. Charles Hartree and Robert Wilson, C.E., were elected Members of the Royal Institution.

William Miller Ord, M.D., was elected a Manager in the room of the late Right Hon. the Lord Claud Hamilton.

The presents received since the last meeting were laid on the table.

NOTICES OF BOOKS.

The Life and Works of Thomas Graham, D.C.L., F.R.S. Illustrated by 64 Unpublished Letters. Prepared for the Graham Lecture Committee of the Glasgow Philosophical Society. By Dr. R. ANGUS SMITH, F.R.S. Edited by J. J. COLEMAN, F.C.S. Glasgow: J. Smith and Sons.

THE substance of this work was to have been delivered at the second "Graham Lecture" before the Glasgow Philosophical Society. The severe illness of Dr. Angus Smith,

however, compelled him to hand the manuscript over to Professor Ferguson, by whom it was read on the day appointed. Since the lamented death of the author it has been revised by Mr. Coleman, who has added a few explanatory remarks.

The work before us consists of two parts. The former of these is a life of Graham,—fragmentary, but exceedingly interesting, based to a great extent upon correspondence then in the possession of Dr. Angus Smith.

It appears that Graham showed a taste for experimental science, and that, like Darwin, he narrowly escaped the Church, which in the earlier part of the century was often the destiny of intellectual youths. He graduated at the University of Glasgow, and afterwards went to Edinburgh to continue his studies under Hope and Leslie. He writes:—"The Professors here are all at loggerheads with each other. Leslie calls Hope in his class-room 'the showman in the other corner,' while Hamilton has just received £500 damages from Hope for defamation." Concerning Hope we find the remark "I have heard him lecture once or twice, and set him down for a complete puppy." Of Leslie he writes:—"Although an excellent mathematician and natural philosopher (or as we should now say physicist), he is no great chemist."

About the year 1828 Graham, though doing valuable work, and fast rising in reputation, was much hampered by poverty. His sister, Mrs. Reid, communicates the following curious anecdote:—"I dare say you know of his taking a very poor little room at Portobello, and laying wires in the sea, mostly after dark, for his experiments. His landlady found some of his things below the bed in his room, and told him she did not like to see such things: she doubted he was after no good, and he had better take his leave. She put his wires, &c., out at the door, and bid him walk; she would rather want a week's rent than let him in again. So poor Tom had to hide his things and walk back to Edinburgh that night. The rent of the room was 3s. per week without fire, which was a great deal more than he could spare at that time."

After this little taste of the "Martyrdom of Science" we find Graham again at Glasgow, where he taught mathematics until, in 1830, he was elected Professor of Chemistry at the Andersonian University.

In 1836 he paid a visit to Muhlhouse, and made the acquaintance of Kœchlin, Schlumberger, and others of the Alsacian colonists. We catch here some amusing cross-lights as regards official science:—"I was amused at the feeling which seems to prevail here in regard to the French Institute (Academy of Sciences). They have never published Schlumberger's valuable papers on Madder, because they impugn the results of a brother academician, M. Robiquet, although Kœchlin spoke on the subject to Gay-Lussac, Chevreul, and others. The fact, I believe, is that this exclusive dealing results from no bad feeling; but the Institute is a coterie,—all the members are familiar with each other, and unwilling to give each other cause of offence. Gay-Lussac, likewise, who is chemical editor of the *Annales de Chimie*, is an exceedingly mild man, and is certainly carried too far by the fear of offending his brother academicians. There is one of my papers (on Phosphoretted Hydrogen) which he has promised to publish, but which I should not be surprised to find him restrained from doing when he finds that I give more credit to H. Rose than will be agreeable to M. Dumas."

After leaving France he went to Giessen, and spent two days with Liebig. Thence he went to Jena, to attend the German "Congress of Naturalists and Physicians."

Concerning Mitscherlich he writes:—"He has a most insinuating address, but there is a cold propriety in everything he says and does. I was sorry also to notice (and I made the same observation concerning Dumas) that when I stated any little discovery of my own he was fretted, and could not conceal a little disappointment, because it had escaped him." This was not like the hearty good feeling of Liebig or H. Rose.

In 1837 Graham was appointed Professor of Chemistry

at University College—an appointment which he held for eighteen years. In the autumn of the same year he speaks of a reconciliation between Liebig and Dumas, and refers to the project of publishing a chemical journal in three languages, under the joint editorship of Liebig, Dumas, and himself.

In connection with Liebig's visit to England in 1844, we find mention of the then proposed College of Chemistry, which Liebig believed to be "a job of certain parties."

In 1855 Graham succeeded Sir John Herschel as Master of the Mint.

The remainder of the work consists chiefly of abstracts and titles of the numerous memoirs by Graham, as published in the *Philosophical Transactions*, the *Journal of the Chemical Society*, the *Philosophical Magazine*, &c. A question which has forced itself upon our mind whilst studying this work is, whether in the first half of this century Britain did not take a relatively higher standing in chemical science than she does at present? Some such idea seems to have occurred to Mr. Coleman, since we find him writing—"This completes the letters of Graham, who belonged to a group of chemists of the first rank, whose education and experience were acquired entirely on British soil, and, moreover, of a group of chemists whose powerful generalisations materially advanced the science throughout Europe."

The Alkali-Maker's Pocket-Book. Tables and Analytical Methods for Manufacturers of Sulphuric Acid, Nitric Acid, Soda, Potash, and Ammonia. By G. LUNGE, Ph.D., Professor of Technical Chemistry, Zurich, and F. HURTER, Ph.D. London: G. Bell and Sons.

THE work before us is one of the most useful additions to our chemical literature which have appeared for a long time. In all countries where chemical manufactures are carried on there have been continual complaints of a want of uniformity in analytical methods and in tables employed in valuing chemicals. So long as different methods were in use among experts discrepancies in the results were always to be expected. Hence Herr Strof, manager of the Griesheim Alkali Works, proposed to the German Society of Alkali Makers that they should have published a standard manual of methods which all parties in the trade should adopt. Accordingly a committee of the most influential owners and managers of alkali works was appointed, and Prof. Lunge was requested to collect and elaborate the matter for the standard handbook. This choice of an editor was eminently judicious, and the general instructions given him are framed in the spirit of common sense. One method only was to be chosen for each analytical operation, as well as for preparing each standard solution and for sampling materials. So long as the chemist has his choice between two or more methods an element of discrepancy is never wanting.

The one method to be selected must above all things permit of a necessary degree of accuracy. If two or more methods were found equally accurate the preference was given to the one which occupied least time and required least apparatus. This selection of processes required involved not merely prolonged discussion but extensive trains of experimental research.

The standard tables of specific gravities of various saline solutions involved also much labour. For this purpose existing tables have been carefully verified and where necessary new ones calculated.

The German edition of this book has been very generally accepted by German alkali manufacturers, consumers, brokers, &c., as well as by commercial analysts.

The English edition contains chapters on Deacon's process and on chimney testing from the pen of Dr. Hurter, who has also re-calculated the tables in accordance with the English system of weights and measures. After a very careful examination we feel bound to express the hope that the tables, methods, &c., may meet with the

same general acceptance which they have done in Germany.

A Course of Qualitative Chemical Analysis. By the late W. G. VALENTIN, F.C.S. Revised and corrected by W. R. HODGKINSON, Ph.D., and H. M. CHAPMAN. Sixth Edition. London: J. and A. Churchill.

THIS work has proved such a general favourite that there is very little room for discussion as to its value. Nor has the present edition undergone any essential change of plan. It may, indeed be asked whether a degree of prominence is not given to notation and to the doctrine of atomicity, scarcely called for in a manual of chemical analysis. The reactions of the rarer metals are given with exceptional care and accuracy.

Journal and Proceedings of the Royal Society of New South Wales for 1883. Edited by A. LIVERSIDGE, F.R.S. Sydney: Thomas Richards. London: Trübner and Co.

THE Royal Society of New South Wales combines with its more legitimate functions those of a Society of Arts. Thus in the issue before us we find no fewer than three papers, occupying more than one-fifth of the entire transactions, devoted to irrigation. It must, of course, be remembered that in the climate of Australia irrigation is not, as in England, a mistaken whim, but the one thing needed to transform a desert into a garden.

In a paper on the "Roots of the Sugar Cane," by Mr. H. Ling Roth, it is shown that in light alluvial soils they may penetrate to a depth of 12 to 15 feet. This fact is of the greater practical importance, as in Porter's "Sugar Cane" (1843), they are said to be never more than a foot in length!

Dr. E. H. Rennie finds that the discolouration of white bricks made from certain clays in the neighbourhood of Sydney is due to the presence of vanadium. Whether this metal occurs in such proportions as to be industrially important the author has not yet ascertained.

A paper on the "Chemistry of Australian Products" consists of abstracts from the *CHEMICAL NEWS*, the *Journal of the Chemical Society*, the *Pharmaceutical Journal*, the *Comptes Rendus*, and other European sources.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. xcix., No. 16, October 30, 1884.

Elementary Force of Solar Induction, the Periodic Duration of which is a Mean Day.—M. Quet.—The author puts forward the following general proposition:—The force of induction produced by any system whatever of electric currents upon a particle m of positive electric fluid is perpendicular to the relative velocity ov of this particle, and to the direction od of the line of force which passes through the point o of the magnetic field. It is directed towards the left of the personified velocity and towards od . Lastly, it is measured by the area of the parallelogram constructed upon ov and od : if f designates this force we have $f = m d v \sin e$, e being the angle $v o d$.

Disruptive Discharges of the Holtz Machine.—M. l'Abbé Maze.—On employing a Holtz machine the exciter of which is constructed so that a spark may be drawn at will to the right or the left of the axis of the apparatus,

it is found that the position to be given to the movable part of the exciter is by no means indifferent.

On Phosphorus Trifluoride.—H. Moissan.—Phosphorus trifluoride is a gaseous body obtained by causing very dry copper phosphide to react upon lead fluoride free from silica. At the temperature of -10° , and a pressure of 40 atmospheres, it is a colourless liquid which does not attack glass. The density of the gaseous trifluoride is 3.022. It is incombustible in presence of air, but if mixed with half its volume of oxygen it detonates on contact with the electric spark. It is slowly decomposed at common temperatures in presence of water.

Manufacture of Superphosphates and of Precipitated Phosphate from a Theoretical, Analytical, and Practical Point of View.—M. Kienlen.—An extensive treatise incapable of useful abstraction.

Reversion of Phosphoric Acid.—T. S. Gladding.—Translated from the *American Chemical Journal* for March last.

Industrial Society of Mulhouse. Session of the Chemical Committee, July 10th, 1884.—Dr. Goppelsröder announces that he has succeeded in discharging indigo-blues and turkey-reds by the electric current, using as an electrolyte solutions of chlorides mixed with caustic soda. The tissue saturated with these solutions is placed between two metal plates which serve as electrodes. The same chemist prints indigo as follows:—The calico is steeped in a mixture of finely ground indigo and a solution of caustic alkali. It is then placed on a metal plate forming one of the poles of the galvanic battery or of the dynamo-machine. Upon the cloth is then laid a second metallic plate forming the other electrode. At the negative pole the indigotine is converted into white indigo, with which the fibres become saturated. On taking away the upper plate, exposing the cloth to the air, and washing strongly, it is found to be dyed an indigo-blue as fast as that obtained by the ordinary process. The hydrogenation of indigo by the galvanic method only takes place imperfectly in the cold. Heat is needed to effect a rapid reduction. A prolonged action of the current destroys the indigo.

MM. Yung and Rudolf sent in a note on a process for determining indigo by measuring the quantity of air absorbed by a reduced solution. The details are not published.

M. H. Kœchlin communicated a new method of fixing chromium oxide, founded on the property of alkaline solutions of chrome of giving up their oxide to organic fibres on being left in contact for some hours, without occasion for drying. Thus, if cotton is steeped in a mixture of 2 parts acetate of chrome at 16° (probably Beaumé), 2 parts caustic soda at 38° , and 1 part of water, and washed after twelve hours, the mordanting is complete.

M. Schmid criticised the views of Müller-Jacobs on the "sulpholeates," and showed that the presence of a triglyceride in turkey-red oils is not necessary.

Notes on the Mouras Closets.—In these closets the faecal matters are conducted into air-tight tanks, previously filled with water. No chemicals are employed, but the water is said to liquefy and digest paper, textile matters, and fatty bodies. The effluent water has the same specific gravity as pure water, and has an odour *sui generis* but decidedly supportable. It may either be passed into the streams or used for irrigating meadows.

Foreign Patents having Reference to the Chemical Arts.—Specifications of patents for the continuous electrolytic production of magnesium; for improvements in the electrolysis of the haloid salts of the light metals, and for the preparation of tetra-hydro-paraquin-anisol.

Decree on the Question of Salicylised Wines.—The result of an action against a merchant of Bordeaux for having imported 967 hectolitres of wine containing salicylic acid.

Foreign Patents for the Preparation of Colouring Matters.—Specifications for the use of chlorinised formic ether in place of carbon oxychloride; for the preparations of double compounds of iodine chloride, with the bases of the quinoleic series; improvements in the preparation of violet colouring matters by the action of carbon oxychloride upon tertiary aromatic monamines, and preparation of azo-colours by means of alpha-naphthol-disulphonic acids.

Revue of Organic Chemistry.—Abstracts from the *Berichte der Deutschen Chem. Gesellschaft*.

Justus Liebig's Annalen der Chemie,
Vol. 225, Part 1.

Sulphur Compounds of Molybdenum.—Gerhard Krüss.—The author here describes sodium monosulphomolybdate, ammonium disulphomolybdate; the corresponding potassium salt; primary ammonium pyrodisulphomolybdate, and the analogous potassium and sodium salts; potassium sulphonmolybdate; normal ammonium sulphonmolybdate; basic potassium sulphonmolybdate. He gives some remarks on the spectral analysis of the oxysulpho- and sulphonmolybdates, and describes primary potassium persulphonmolybdate and persulphonmolybdic acid, which is the first free inorganic sulpho-acid the existence of which has been positively proved.

On Hydro-para-cumaric Acid.—C. Stöhr.—This acid, which occurs in rhubarb, has also been prepared synthetically. With nitrous acid it gives the phenol reaction. If the pulverised acid is covered with strong sulphuric acid it gradually dissolves with a transient red colouration. On adding a trace of sodium nitrite it becomes a deep brownish red, which on dilution with water turns to a deep gold-yellow, and on heating becomes a pure green.

On Quinine and Homoquinine.—O. Hesse.—The author refers to his discovery that quinine does not occur exclusively in the Cinchonaceæ, but is met with in a bark formerly called *China cuprea*, but now identified as *Remijia pedunculata*. In this plant it is not accompanied by cinchonidine, but often by homoquinine. The author concludes that homoquinine is a modification of quinine, present in many specimens of *China cuprea*. There are several modifications of quinine which on suitable treatment pass into ordinary quinine.

Researches on the Specific Volumes of Liquid Compounds.—W. Lossen and A. Zander.—Not capable of useful abstraction.

BICHROMATE OF SODA.

Potter and Higgin's Patent

100 parts equal to 101—104 parts
Pure Potassium Bichromate.

PERFECTLY SOLUBLE IN ITS OWN
WEIGHT OF WATER.

Is used in place of the Potash
Salt in all its applications, and
gives perfect satisfaction.

*Is sold in large or small lots to suit consumers,
packed in strong 5-cwt. barrels.*

IS LOWER IN PRICE THAN THE POTASH SALT.

SOLE MAKERS—

VOL. L. No. 1303.

COMPOSITION OF THE ASH OF STRAWBERRIES.

By JOHN M. H. MUNRO, D.Sc., F.C.S.

DURING last summer I took an opportunity of determining the composition of the ash of a sample of ripe strawberries, grown in the field by a Kentish fruit-grower. 256 grms. of the ripe fruit, deprived of the stalks, yielded on prolonged drying at 100° 27.38 grms. dry matter, which, after careful incineration, left 1.10 grms. ash. The strawberries therefore contained :—

Water	89.30
Organic matter	10.27
Ash	0.43

100.00

The composition of the ash was as follows :—

Sand and insoluble matter ..	6.61
Phosphate of lime	23.91 containing 11.70 P_2O_5 .
" " magnesia	trace
Carbonate of potash	60.77 containing 41.40 K_2O .
Magnesia	2.93
Soda	1.29
Sulphuric acid (SO_3)	3.88
Undetermined	0.61

100.00

It seems evident from the above figures that in the strawberry the whole of the potash exists in combination with organic acid, and the whole of the phosphoric acid as phosphate of lime. The quantity of potash present is very considerable, even when compared with that contained in the grape. I am informed by strawberry growers that when the plants forced in pots are grown with the aid of guano or very rich soil, it is generally found that although many blossoms are produced they do not all set, or if they do the fruit is inferior in size and quality to the smaller quantity produced by less vigorous plants grown in poorer soil. The stronger and more highly forced plants are also found to be more liable to mildew.

Considering the benefit often derived by the vine from applications of potash manures, it seems at least possible that a special manure containing a fair proportion of potash would produce good results with strawberries grown in pots and with other fruits forced under similar circumstances. The experiment may have been tried here and there, but not, so far as I can learn, by growers of fruit for the market.

College of Agriculture, Downham, Salisbury.

ON THE DETECTION OF CYANIDES IN THE PRESENCE OF COMPOUND CYANIDES.

By W. J. TAYLOR.

CYANIDES, when in the presence of compound cyanides, cannot well be detected by any of the ordinary methods. Thus, for example, a mixture of potassic cyanide with ferrocyanide will, when distilled with a very dilute acid,—sulphuric, hydrochloric, or even acetic,—behave in the same way as a solution of the pure ferrocyanide alone;

I find that both solutions yield hydric cyanide, which, when received in ammoniac sulphide, readily forms sulphocyanide, giving the well-known reaction with ferric chloride.

It is accordingly necessary to find a substance which, while freely decomposing the cyanide, will, at the same time, leave the ferrocyanide untouched. This condition is fulfilled by hydro-sodic carbonate.

Substituting this carbonate for either of the acids used in the above experiments, a 10 per cent solution of potassic ferrocyanide was left undecomposed, no trace of the red colouration being given with ferric chloride, while, at the same time, a 1.10 per cent solution of potassic cyanide gave the reaction perfectly, 0.002 grm. being thus very easily detected.

Mercuric cyanide is somewhat refractory, not giving the colouration if treated with the carbonate alone; but if, in addition, some clean metallic zinc be taken, the colouration is at once seen.

For this purpose 20 c.c. of a 1.10 per cent solution of mercuric cyanide was distilled with 2 grms. of carbonate and 5 grms. of zinc. The first c.c. was distilled over, treated as before, and the blood-red colouration was readily observed.

Potassic sulphate, potassic ferricyanide, potassic sulphocyanide, and ammoniac salts do not interfere with the reaction.

In the detection, then, of cyanides in presence of compound cyanides, all that is required in qualitative analysis is to distil with an adequate volume of water, and an excess of hydro-sodic carbonate: if the preliminary examination shows that mercury exists in the mixture, a few grammes of zinc must be added.

This method of detection will probably be found of value in medico-legal investigations. Moreover, as it ends with the formation of a coloured liquid, it can obviously be made quantitative—or at least approximately so—by comparative experiments with the colorimeter.

Glasgow, November 5, 1884.

ANHYDROUS ANALYSIS.

By Lieut.-Col. W. A. ROSS, R.A., F.G.S.

ANHYDROUS analysis may be described as the chemical separation of inorganic substances, combined as in a mineral, by means of apparatus and reagents absolutely free from water. This expression of objects desired necessarily implies (a) that the processes may be made quantitative; and (b) that results are obtained by the direct application of fire to the assay, without any metallic or other interposition, as the "wall" of a crucible.

The most convenient, and indeed as far as yet known the only, way of thus applying fire in a sufficiently pure and concentrated form, is by means of the little chemical instrument invented by the Swedish mine-master, Von Svarb, in 1731; described in a series of lectures on Assaying, delivered in Leyden by a Scotchman (Cramer) in 1737, published in a Latin book at the same place in 1741, and figured for the first time in Von Svarb's own treatise on results obtained by him, misappropriated by Cronstedt, translated into English by Von Engeström, and published under the name of the latter in London, in 1770. The simplicity of the instrument by which such varied and important effects can be produced may be inferred from the name given it by civilised scientific nationalities,—the French calling it simply a reed or pipe (*chalumeau*); the Germans, a soldering-pipe (*löthrohr*); and the English, a blowing or blowpipe.

It is, in fact, nothing more than a wind-pipe attached to human lungs or artificial bellows, having an elastic air-reservoir, such as human cheeks, to prevent re-absorption of delivered air by the bellows whilst distending, and a "jet" or issue-passage of comparatively minute bore. The effect

of applying the minute but energetic current of air or blast, thus afforded, to an ordinary hydrocarbon flame, as that of a candle, is exceedingly curious and unexpected: the luminous, upright, elliptical flame disappears as by magic, and is instantaneously replaced by a non-luminous horizontal cone of dark blue light. The cause of this strange metamorphosis has been explained as follows:—The blast, which cannot penetrate the candle-flame, blowing it down therefore on its side, creates a vortex in the surrounding air; this vortex sucks in the prostrate flame, converting it necessarily to its own shape, of a cone with a vertex as fine as the point of a sewing-needle; and all this is effected so rapidly that the eye cannot follow the details of change.

If this explanation be correct (and no other has ever been offered of the above-mentioned well-known phenomena) it would appear that the laws governing the application of vorticeous air to flame might be used with advantage and economy of fuel, in operations on the large scale, as in Metallurgy.

The process of testing minerals, &c., with Von Svarb's blowpipe, assisted by solid, fusible, and portable salts,—as borax, microcosmic salt, sodium carbonate, &c.,—was exceedingly improved in every detail by Assessor Gahn, and finally carried to great perfection by Professor C. F. Plattner, of Freiberg, and it maintains a position in the *curricula* of most mining colleges of Europe (except English), and of America to this day; but it is a great and obvious error to call such work "blowpipe analysis," inasmuch as there is not even a pretence of separation in the matter.

If, however, we treat mineral powders with the point of the blue cone of fire or pyrocone above described, not in borax, but in its acid constituent "boron trioxide," or, as it was formerly called, "boracic acid," a *bond fide* separation into pyroborates of different form, colour, and weight takes place in most cases after a few minutes treatment.

Alkali or alumina contained in the mineral exercises a dissolving effect upon assays, by boric acid before the blowpipe, and therefore has the result of mixing such separated borates together again, by dissolving them therein; but by previously fusing the mineral containing these ingredients by means of its own alkali, or with the addition of a little soda, on aluminium plate before the blowpipe, then boiling for a few seconds the fused crushed mass in distilled water (by which the alkali is removed), and, lastly, treating the dried residual powder in boric acid again,—or, in the case of alumina, in phospho-boric acid,*—separated borates or phospho-borates are once more obtained. Thus fusible or zeolitic silicates, which generally afford a jelly to hydrochloric acid, afford also a jelly to boric acid before the blowpipe, only of course much more quickly, and, having been thus rapidly identified as to their general nature, can be afterwards analysed as above described.

The only drawback to the efficiency and general practical utility of this new system of analysis is the small scale upon which these chemical separations are at present necessarily effected by means of "beads" before the mouth blowpipe, or hand or foot blower. But it will be evident to the philosophical or physical chemist (and what real chemist is not philosophical?) that the laws of Nature being unalterable on any or every scale, by the employment of a much higher temperature, with properly supported masses of anhydrous reagent (instead of beads on platinum wires), analytical results of almost any size desired—or, at all events, large enough to be weighed in the biggest assay-balances—would be obtained.

It is known, for instance, if a mass of pure fused boric acid, the size of a hen's egg, were placed upon a solid block or cube of aluminium, and treated with mineral powder before an oxy-hydrogen blowpipe, that definite spherical borates or pyroborates of the following metals, large enough to be weighed in any balance, could be, in

an extraordinarily short space of time, obtained by simply boiling the mass in distilled water:—Barium, cadmium, calcium, cerium, cobalt, copper, didymium, erbium, iron, lanthanum, magnesium, manganese, strontium, zinc.

Again, it is all but settled practically that pure silica or rock crystal, being an acid substance chemically analogous to boric acid, would, if treated as a reagent before the oxy-hydrogen blowpipe (which rapidly fuses it) upon the same support, yield definite silicates analogous to the above-mentioned borates; and thus the chemist would have the pleasure of producing Nature's own products in his laboratory, at the very same time, and by the same process, through which he was enlarging and developing artificial science.

Not having sufficient means to carry out such important experiments myself, I would most respectfully ask the authorities of the following Colleges to do so in the cause of scientific research:—The Royal School of Mines; The London City and Guilds Institute; Owens College, Manchester; The Imperial Mining Academy, Berlin; The Royal University, Freiberg; The French Mining Academy, Paris; Yale College, New Haven, U.S.A.; Columbia College, New York; The College of New Jersey, Princeton, U.S.A.; The Polytechnic Institute, Troy, N.Y.; McGill College, Montreal. Perhaps the following extract from the review of a lately-published popular book of mine on this subject, translated from the "Berg und Hüttenmännischen Zeitung," of which Prof. Bruno Kerl, Imperial Mining Academy, Berlin, is co-editor, may offer some inducement to take the matter up.

"The Blowpipe in Chemistry, Mineralogy, and Geology."

"The author of this work, well known beyond the bounds of his native country by his original works on the art of Blowpipe Analysis, furnishes in the volume before us a new contribution to this science, and gives instructions for the simplest and most efficient methods of determining the chemical nature of inorganic substances, of which only a small quantity is obtainable.

"In consequence of these discoveries blowpipe analysis will become an important factor in the eventual and complete study of chemistry, metallurgy, mineralogy, and geology.

"Besides these novel processes of the author, now familiar to German chemists, many new points of departure from old methods are taken, new reactions and tools described, and surer means of discrimination afforded, by means of a clear and instructive text, copiously illustrated throughout by well-executed wood engravings.

"In twelve chapters are treated—The manufacture of blowing apparatus; the construction of lamps, supports, auxiliary apparatus, and tools; structure and nature of the flame; reagents, special reagents, (boric and phosphoric acids, calcium borate), &c., &c. . . .

"It would be a grateful task to translate this important work into German."

THE ARTIFICIAL PREPARATION OF OPTICALLY ACTIVE SUBSTANCES.

CHEMISTS generally assume that all chemical substances can be made in the laboratory by artificial methods, and certainly when we consider the many syntheses of natural substances that have been effected during the last thirty years, the assumption appears to be justified. Nevertheless, there are some facts which speak against it. Several of the vegetable acids have the power of turning the plane of polarised light either to the right or left. Some of these substances have been prepared artificially, and the products thus obtained have been shown to have all the properties of the corresponding natural substances with the exception of the optical activity. Thus natural malic acid is lævo-rotatory, while the malic acid obtained from

* Made by dipping the red-hot boric acid bead into pure, deliquescent, phosphoric acid.

brom-succinic acid is optically inactive. Such facts have led gradually to the conclusion that artificially prepared substances cannot act upon polarised light, that in order to get an optically active substance we must have the intervention of the life process.

Finally, however, Perkin and Duppa succeeded in making racemic acid from bibrom-succinic acid, and Jungfleisch and Pasteur showed that this artificially prepared racemic acid could be split up into dextro- and lævo-tartaric acids. Thus the artificial preparation of one optically active substance was certainly accomplished, and, while some chemists concluded that the same result would probably in time be reached in connection with all optically active substances, others preferred to suspend judgment and await further developments.

Last December, M. Pasteur in a lecture* before the Paris Chemical Society, called special attention to the subject. The lecture has given rise to an interesting discussion between MM. Wyruboff, Jungfleisch, and Pasteur, the substance of which, together with two papers on the subject by M. Jungfleisch, are published in the *Bulletin de la Société Chimique de Paris*, vol. xl., No. 5 (March 5, 1884). In view of the interest which the subject must have for all chemists, abstracts of M. Pasteur's lecture and the other papers referred to are here given. M. Pasteur began his lecture by describing in detail the crystallisation of the double racemate of ammonium and sodium, and the formation of the two kinds of crystals from it. To use his own words: "A new idea soon occurred to me. These crystals, asymmetric to the right, which I could separate mechanically from the others, proved to be identical in form with those of the dextro tartrate. . . I separated these right-handed crystals from the crystallised racemate; I made the lead salt and isolated the acid. This acid was absolutely identical with the tartaric acid from grapes, and, like it, acted upon polarised light. I was still happier when, on taking in turn the left-handed crystals obtained from the racemate, I obtained a tartaric acid quite similar to ordinary tartaric acid, but having a form asymmetrical in the opposite way, and acting in the opposite direction upon polarised light. The form was identical with that of the image of dextro-tartaric acid placed before a mirror. The principles of 'molecular asymmetry' were thus founded. There are substances of which the atomic grouping is asymmetrical, and this grouping shows itself in an asymmetric form and in an action upon polarised light; besides, these atomic groupings have their possible complements, the forms of which are identical with the images of the first, and with an opposite action upon polarised light. . .

"Now, gentlemen, there is one strange peculiarity about this molecular asymmetry. We find asymmetry established in a very large number of the proximate principles of animals and vegetables, notably in the proximate principles essential to life. All the products, so to speak, of the egg and the seed are asymmetrical.

"There are, without doubt, in animals and vegetables proximate principles, such as urea and oxalic acid, which are not asymmetrical; but these are secondary products, comparable in one sense to our laboratory products, which are not asymmetrical.

"In other words, when a ray of sunlight strikes a green leaf, when the carbon of carbonic acid, the hydrogen of water, the nitrogen of ammonia, and the oxygen of the carbonic acid and of the water form chemical compounds, and the plant grows, the bodies which are thus developed are asymmetrical. You, however skilful chemists as you are, though you bring together the same elements in a thousand different ways, always make products without molecular asymmetry. As far as I know, there does not exist a single product of chemical synthesis, formed under the influence of causes which may be considered peculiar to vegetable life, which is not asymmetrical. . . On the other hand, there is not a single product of synthesis prepared in the laboratory or in dead mineral nature which is not asymmetrical."

* *Revue Scientifique*, Jan. 5, 1884.

The speaker then referred to the synthesis of racemic acid from bibrom-succinic acid, and the splitting up of this artificial product into dextro- and lævo-rotatory tartaric acids. He denied that this synthesis disproved his statement that optically active substances cannot be prepared synthetically. He quoted the words of Le Bel, as follows:—"It is then not only vegetable life which includes cases of asymmetry, and the line of demarcation between vegetable and mineral chemistry pointed out by M. Pasteur does not exist." To this he remarked: "That is an error. I claim to be able to show you that this separation, this barrier, is on the contrary confirmed by the results first observed by myself, and afterwards by M. Jungfleisch and by M. Le Bel.

"We can explain the facts regarding asymmetry in the following manner:—When the proximate principles which are essential to life are formed, it is under the influence of asymmetrical forces, and that is why life produces asymmetrical substances. When the chemist in his laboratory combines the elements or compounds formed from the elements, he does not bring into play the asymmetrical forces. That is why all the substances which he produces by synthesis are devoid of asymmetry. . . . You ask: What then are the asymmetrical forces which preside over the elaboration of the proximate principles of nature? It would be difficult for me to answer with accuracy; but asymmetry I see everywhere in the universe. The universe is asymmetrical. . . . You in your laboratories, with your solvents, your heat and cold, have at your service only symmetrical forces. Is there then an absolute division? Certainly not. Far from saying or thinking so, I first pointed out the means which we might make use of to destroy the barrier. What must we do to imitate nature? We must break loose from our methods, which are from this point of view antiquated and impotent. We must try to bring into action the asymmetrical forces, we must have recourse to the action of the solenoid, of magnetism, of the asymmetrical motion of light, to the action of substances which are themselves asymmetrical. When, carried away by inexorable logic, I passed from researches in crystallography and molecular chemistry to the study of ferments, my thought was to introduce asymmetry into chemical phenomena. . . . On bringing together cinchonine, an active asymmetrical substance, and racemic acid, I saw the cinchonine salt of lævo-tartaric acid deposited, while the dextro-tartrate remained in solution. With an inactive body, racemic acid, I have made lævo- and dextro-tartaric acids. Although I was the first to imitate nature in its methods, and to show the analogy between natural and artificial products, I am careful not to conclude that the barrier between the two chemistries is destroyed. On the contrary, I conclude that the experiment of which I have spoken establishes the proposition, namely, that the forces brought into play in our laboratories differ from those to which vegetable nature is subject.

"In another way, much more interesting, I have introduced asymmetry into chemical actions. I have shown that ammonium racemate can ferment under the influence of microscopic fungi, and that lævo-tartaric acid appears. The dextro-tartrate is decomposed, the lævo-tartrate remains intact. With an inactive racemate I have caused the appearance of simple asymmetry, but why? Because the little ferment is a living body formed of a collection of asymmetrical products, and because for purposes of nutrition the little being finds the dextro-tartrate better adapted than the lævo-tartrate.

"I have gone further: I have caused to grow on the surface of ashes and racemic acid, some grains of *Penicillium glaucum*, that mould which is found everywhere, and I have seen lævo-tartaric acid appear. Here again we have a case of simple asymmetry obtained from an inactive body; but in order to reach this result, it has been necessary, you see, to cause the intervention of the actions of asymmetry, the asymmetry of the natural proximate principles which go to make up the grain of mould.

"These are precisely the methods made use of by M. Le Bel in extracting from his racemates the simple active products. He had recourse to the employment of an asymmetrical substance or of a mould or a microbe.

"Further, these experiments indicate the existence of a line of demarcation between the mineral kingdom and the organic kingdom, since to imitate what nature does, that is to prepare a right-handed or left-handed body, we are obliged to make use of peculiar kinds of action, of the action of asymmetry. The line of demarcation of which we speak is not a question of pure chemistry, of obtaining such and such products, it is a question of forces; life is governed by asymmetrical actions." . . . In a note M. Pasteur adds these words: "I am convinced that the double racemate of sodium and ammonium would not of itself under ordinary circumstances break up during crystallisation unless an asymmetric force were present, and if this is not an action of light or magnetism, I can readily believe that the force is due to some asymmetrical organic dust on the surface of the vessel in which the crystallisation takes place. Nothing would be simpler than to crystallise a solution of sodium ammonium racemate with perfect exclusion of all organic dust. Under such circumstances the unchanged racemate should be obtained."

Discussion.

M. Wyruboff said that the theories put forward by M. Pasteur with so much conviction and talent, in his lecture, appeared to him to be opposed to all that is known to us regarding the properties of crystallised bodies. The theories are based upon a fundamental hypothesis, according to which natural (chemical) phenomena are subject to two kinds of action, symmetrical and asymmetrical; the former governing in the mineral kingdom and in the synthesis effected in our laboratories, the latter pertaining to the life process.

Asymmetrical bodies may be arranged, as is known, in two well characterised classes. Those of the first class, like quartz, sodium chlorate, benzil, cinnabar, are asymmetrical either in their internal structure and their external form, or only in their internal structure, no hemihedral face accompanying the rotatory power. All these bodies can be prepared artificially by starting with the elements; hence we must admit, looking at the matter from M. Pasteur's standpoint, that in our laboratories we have at our disposal at least some of the asymmetrical actions which he attributes exclusively to life; for, how shall we explain, by the aid of symmetrical actions alone, the existence of plagioclinal faces of crystals and their relation to the rotatory power?

"The second category includes those bodies which are not asymmetrical in their internal structure, but have asymmetrical external forms and integrant molecules, or only the latter, for, between the rotatory power of the solution and the hemihedrism of the crystals, there is not that simple and necessary relation which was supposed to exist when only a few facts were known. These bodies have the rotatory power only in solution, and retain the power in all the compounds into which they enter. They are asymmetrical neither more nor less than the bodies of the first category; they are asymmetrical in a different sense.

"The bodies which have molecular asymmetry are the ones which M. Pasteur had in view when he asserted that they cannot be prepared synthetically.

"It should be remarked in the first place, that, among the great number of compounds which chemists have prepared synthetically, only very few have been studied crystallographically and examined with the polariscope. In the second place, the assertion is contradicted by the facts: racemic acid has been prepared synthetically, and it has been split up into dextro-rotatory and lævo-rotatory tartaric acids. To this proof, so clear and definite, M. Pasteur replies by suggesting a new hypothesis. He asserts that we really have to deal with some action of the asymmetrical order, some spiral movement, some magnetic

influence, some organic dust, and he adds: 'Nothing would be simpler than to crystallise a solution of sodium ammonium racemate with perfect exclusion of all organic dust. Under such circumstances the unchanged racemate should be obtained.' But what is the object of trying this experiment, when we consider that twenty years ago the racemate of the formula $C_4H_4Na(NH_4)O_6 + H_2O$ was prepared by M. Scacchi, who, in an admirable memoir, gave the exact conditions of its formation? He showed that the splitting of the acid was occasioned only by the fact that the double ammonium sodium salts of the two tartaric acids are less soluble than the mixture of the two; that in elevating the temperature, the solubility of the dextro acid increases more rapidly than that of the lævo acid, and that there is a limit beyond which the mixture, becoming less soluble, the racemate alone is deposited. The phenomenon is so perfect that we can get it will from the same solution, properly concentrated and containing an excess of ammonium carbonate, either the racemate, or ammoniacal Seignette salt, or crystals of both at the same time. It is only necessary to vary the temperature between 17° and 26° . The racemate of sodium and potassium conducts itself differently: at 26° it always splits up; below this temperature it deposits sodium racemate, then Seignette salt, finally sodium racemate, each one of the deposits corresponding to the solubility of the salt, as M. Scacchi has shown.

"With sodium thallium racemate the case is still different. M. Wyruboff has recently prepared this salt, and will soon describe its form. Seignette salt containing thallium crystallises, as is known, between 20° and 25° in voluminous soluble crystals in about half their weight of water. Neutral thallium racemate requires at these temperatures about nine parts of water to dissolve it; neutral sodium racemate about 2.5 parts.

"According to M. Pasteur, it would be impossible to say beforehand whether or not the racemate will be split into the dextro- and lævo-tartrates, the splitting being a result of mysterious forces acting asymmetrically.

"Nothing is easier, however, than to foresee the course of the phenomenon, if it really depends upon the greater or less solubility of the compounds taking part in the crystallisation. On evaporating at 25° we ought not to get the double tartrate; nor even the double racemate, unless it is—what it is not—less soluble than the neutral tartrate of thallium; we could get only thallium racemate; later, after the liquid is further concentrated, a little of the double racemate, and lastly, sodium racemate. This indeed is what is always observed. And it is so clearly a matter of solubility, that we may get the double racemate of sodium and thallium by two methods, apparently different, but based upon the same principle: we can crystallise the mixture at an elevated temperature, 40° for instance, or at the ordinary temperature, adding an excess of sodium racemate.

"Finally, we have the double racemate of sodium and rubidium, which under the proper conditions always breaks up at ordinary temperatures, and the two simple salts separate at higher temperatures.

"These examples enable us to solve without difficulty the general question as to the causes of the splitting of the racemates, which appear so complex and so mysterious to M. Pasteur, and which is nevertheless so simple. Why do not all the numerous racemates, simple as well as double, known up to the present time, yield tartrates? Why is this action confined to the double salts of sodium, with potassium, ammonium, and rubidium? Because, in these cases alone, one of the tartrates taken separately is less soluble at the ordinary temperature than the mixture of the two.

"We may hence state these rules, to which up to the present there are no exceptions known:—

"1. Every racemate having a solubility less than that of the corresponding tartrate splits up.

"2. Every racemate which is more soluble than the corresponding tartrate does not split up.

"Finally, concerning the case of double racemates, and this applies to double salts of all possible acids:—

"3. When two simple racemates, which are allowed to crystallise together, have very different solubilities, they are deposited separately. To get the double salt, the proportion of the more soluble salt must be increased.

"The solubility being a function of the temperature, it is clear that these rules are valid for any given compound only at a definite temperature."

Apropos of the communication of M. Wyruboff, M. Jungfleisch cited a number of facts which have led him to the opinion that the separation or non-separation of inactive bodies into their constituents is a result of the relations which exist between the solubilities. Thus, in a solution of sodium ammonium racemate, the dextro-tartrate resulting from the splitting up shows itself to be less soluble than the lævo-tartrate. Some experiments have indicated that differences of the same kind exist between the two active tartrates of sodium and potassium. Besides, it is known that the corresponding racemate obtained by M. Delffs was deposited in the neighbourhood of 0°. Further, we may recall the tartrates of cinchonine of M. Pasteur: the marked differences which exist between their solubilities suffice to explain their separation. Finally, the phenomena observed by M. Jungfleisch on para-camphoric acid furnishes new insight from this point of view: during the cooling of a warm solution of this body between 80° and 40°, principally the lævo acid is deposited, while the dextro acid predominates in the crystals formed below 40°; the solubility curves are so different that the two optically active acids can be separated by fractional crystallisation. If the mother-liquor is allowed to stand in the cold, para-camphoric acid is again formed.

M. Pasteur's Reply to M. Wyruboff.

"I am very much surprised that M. Wyruboff should have confused molecular asymmetry and the asymmetry in the arrangement in a crystal. Is not the difference between the two kinds of asymmetry demonstrated by the fact that fused quartz dissolved, sodium chlorate dissolved, strontium formate dissolved, have no action on polarised light; that, on the other hand, an asymmetrical crystal, right or left handed, of one of these substances, as sodium chlorate for example, gives, when crystallised, two sorts of hemihedral crystals?"

"M. Wyruboff objects to the hypothesis which I suggested in a note concerning my communication to the Chemical Society on the 22nd of December, which was to the effect that the splitting of sodium ammonium racemate may be caused by organisms in the solution or on the crystallising dishes. As far as I am concerned that is merely a preconceived notion, but I give it for what it is worth. *A priori* ideas, hypotheses, with all due deference to my opponent, are essential to scientific progress.

"If the experiment which I have referred to should not prevent the splitting of the racemate, I shall try whether the splitting may not be due to some other cause equally asymmetric; for example, light or terrestrial magnetism.

"M. Wyruboff seems to think the matter is settled when he assures that the conditions of the formation of the racemate and of the splitting of the racemate are now well known, and that they depend upon the greater or less solubility of the salts. But M. Wyruboff, in my opinion, seems not to comprehend the fact that the formation of the racemate is only perfectly natural, as all the racemates, with one exception, occur only as such; what is exceptional is that one racemate should split up. I cannot consider the opinion reasonable that finds the cause of the splitting in an influence of solubility. Why does the racemate of sodium and ammonium deposit crystals of two kinds? why does it give rise to the formation of complementary tetrahedrons? Why do these two tetrahedrons exist, and why not the octahedron which corresponds to them, which octahedron would have the solubility of the tetrahedral crystals? These facts, according to my idea, require explanation. I shall continue to believe, as long

as I am not shown to be wrong, that the splitting can take place under the influence of asymmetry.

"M. Wyruboff, in another part of his remarks, calls my attention to the existence of bodies which are active towards polarised light, but which nevertheless have no asymmetry of form. He who reproaches me for not understanding the subject appears not to be aware that I have formerly examined into this fact with much care, and that I have shown that it is easy, by means of artifices in crystallisation, to cause the appearance of asymmetric faces whenever internal molecular asymmetry exists. I cited the case of tartramide, the crystals of which formed in pure water never have hemihedral faces, but which show these faces when they are deposited from an ammoniacal solution. I cited the case of ammonium bimalate, which in crystallising from pure water never has hemihedral faces, and which has them when the liquid in which the salt crystallises is changed by a very simple process to which I refer.

"M. Wyruboff makes a great deal out of the following fact:—On adding ammonium citrate to ammonium (dextro) tartrate, the hemihedral faces appear on the other side of the crystal, and inversely for the lævo-tartrate, and, he adds, the hemihedrism may be made to disappear entirely. But this is only one of the accidents of crystallisation of which I have given many examples; I have proved that crystals of right-handed Seignette salt are sometimes met with which have left-handed hemihedral faces. A crystal may have a number of secondary forms. The hemihedral faces make a part of the secondary forms, and these show themselves or are absent according to the conditions of temperature, of the medium, &c., &c. One cannot see why the external conditions of crystallisation should not overcome the influence of the asymmetric agency upon the internal structure of the molecules."

Experiments of M. Jungfleisch.

M. Jungfleisch describes some new experiments which tend to show that the dextro- and lævo-tartrates of sodium and ammonium have different solubilities in a solution of a mixture of the two salts. He introduced into a super-saturated solution of the racemate a right-handed crystal and a left-handed crystal. The two salts were deposited at once. The crystals were weighed in a number of cases, and constant results were obtained. The following examples will indicate the character of these results:—

- I. Experiment with 1545 grammes racemic acid.
Crystals of the first deposits: left, 557 grms.; right, 585 grms.
Crystals of the last deposits: left, 581 grms.; right, 569 grms.
 - II. Experiment with 1500 grammes racemic acid.
Crystals of the first deposits: left, 561 grms.; right, 577 grms.
Crystals of the last deposits: left, 533 grms.; right, 488 grms.
- In another case, starting with 2 kilogrammes of racemic acid, successive deposits were obtained as follows:—
First crystallisation: lævo salt, 375 grms.; dextro salt, 400 grms.
Second crystallisation: lævo salt, 160 grms.; dextro salt, 181 grms.
Third crystallisation: lævo salt, 165 grms.; dextro salt, 190 grms.
Fourth crystallisation: lævo salt, 115 grms.; dextro salt, 115 grms.
Fifth crystallisation: lævo salt, 185 grms.; dextro salt, 150 grms.

In all the experiments the right-handed salt is at first deposited in greater quantity than the left-handed; its solubility is hence less than that of the left-handed salt. Inversely, in the second phase of the crystallisation, the left-handed salt appears more abundantly than the right-handed.

He has used the apparatus of Berthelot (*Mec. Chim.*, i., 140). He allowed a large quantity of sodium sulphate to effloresce till nearly anhydrous; various portions were then dried at different temperatures. From the author's results it is evident that there are two modifications of sodium sulphate. All the specimens not heated above 150° gave 57 cal. as the value of the equation—

Specimens heated above this temperature up to the fusing-point indicated the existence of a modification dissolving with +760 cal. The existence of the salt in two different forms may explain the discrepancies in the results arrived at by various authors.

The SECRETARY then read a paper "On some Vanadates of the Amines," by G. H. BAILEY. The author has prepared and carefully studied the properties of a considerable number of these compounds. His results may be summed up as follows:—That, considered alongside the vanadates of the alkali metals, the ortho-vanadates of the amines are as difficult to prepare as the corresponding potassium salts, whilst sodium ortho-vanadate crystallises readily. The meta-vanadates of the amines are much more soluble than ammonium meta-vanadate, but in their general characters and reactions they resemble the ammonium salt: the derivatives of the primary amines crystallise well, but the further introduction of alcohol radicals decreases the stability of this series of salts. The salts containing the ethyl radical seem to be at least as stable as the corresponding compounds containing methyl. The optical characters of the red vanadates show that they belong to the monosymmetric system.

The SECRETARY then read a paper entitled "Contributions to our Knowledge of Acet-acetic Ether" (Part I.), by J. W. JAMES. The author commenced this research with a view of obtaining some insight into the reactions of acet-acetic ether, and to establish its formula. The author first gives an account of the action of dilute acetic acid on sodium ethyl-acet-acetic ether: there seems to be no doubt that ethyl-acet-acetic ether is formed. Some mixed dialkyl-acet-acetic ethers were then prepared, with a view of ascertaining whether the order in which radicals were introduced was of importance or not. The author could not prove that allyl-methyl-acetic ether was identical with the methyl-allyl ether, on account of the difficulty of obtaining these bodies in the pure state. The methyl-ethyl derivative seemed to be the same as the ethyl-methyl body. Acetyl-acet-acetic ether was prepared, and also its copper, nickel, and cobalt derivatives. The actions of water and sodium ethylate on this body have been studied. Methyl-acetyl-acet-acetic ether and benzoyl-acet-acetic ether have also been prepared and examined.

The two following papers were also read by the SECRETARY:—

"On Magnesium Hydrosulphide Solution, and its Use in Chemo-legal Cases as a Source of Hydrogen Sulphide," by E. DIVERS and TETSUKICHI SHIMIDZU. The authors, wishing to obtain a regular stream of pure hydrogen sulphide, found that this could be effected by gently heating a solution of magnesium hydrosulphide. Ordinary hydrogen sulphide (from ferrous sulphide and hydrochloric acid) is passed into water containing magnesia in suspension. The gas is absorbed, and the magnesia dissolves. The decanted solution is colourless, and when heated to 60° to 65° evolves a steady stream of hydrogen sulphide, free from hydrogen and hydrogen arsenide. The magnesia which is precipitated during the evolution of the gas can be re-converted by cooling and passing hydrogen sulphide.

"On the Origin of Calcium Thiosulphate, an Emendator. Note to a Paper on the Calcium Hydrosulphides," by E. DIVERS. After a detailed examination of the various reactions in which calcium thiosulphate is formed, the author concludes that there is essentially but one method of forming this salt, viz., the union of sulphur with calcium sulphite.

The Society then adjourned to November 20th, when a

ballot for the election of Fellows will be held, and a paper "On some New Paraffins," by Khan B. B. Sorabji, will be read.

PHYSICAL SOCIETY.

November 8th, 1884.

Prof. AYRTON in the Chair.

MR. KAVARGEE was elected a member of the Society.

Prof. F. GUTHRIE read a paper on "Certain Phenomena attending Mixture." In a previous paper Dr. Guthrie had noticed the increase of volume attending the separation of triethylamine and water effected by heat. The present paper is an account of a more thorough examination of this and allied phenomena. Experiments conducted with a number of different liquids showed that mixtures can be arranged in two distinct classes. Of the first, a mixture of water and ether is an example: When shaken up together they mix, heat is evolved, and a diminution of bulk takes place. If any excess of ether present is poured off, and the lower clear liquid heated in a sealed tube, it becomes turbid owing to the separation of the ether. This is accompanied by an increase of bulk and absorption of heat. Triethylamine and water and diethylamine and water are mixtures belonging to this class; the temperature of separation is a function of the ratio in which the two liquids are present. A typical case of the second class is a mixture of alcohol and bisulphide of carbon. These mix with one another in all proportions above 0° C., with increase of bulk and absorption of heat. Upon being cooled to about -17° C. they separate. The separation of a mixture of ether and water and of a mixture of alcohol and the bisulphide was shown. In these cases the action is regarded as a chemical one, and generally an excess of one liquid or the other is present. To determine the combining proportions two methods were used. In the first a number of mixtures of the same two liquids in different proportions were taken, and the rise or fall of temperature produced by their mixture measured. When this was a maximum there might be assumed to be no "dead matter" present. In the second method, which is more delicate but more laborious, and which was used when the approximate combining proportion had been found by the first, the change of volume produced by mixture was noted; when this increment is a maximum the liquids are present in their combining proportions. These experiments gave very concordant and definite results; for example, that the molecular compound of ether and carbonic sulphide is represented by the formula $\text{C}_4\text{H}_{10}\text{O}_2\text{CS}_2$, and that of chloroform and carbonic sulphide by CHCl_3CS_2 . A striking confirmation of this view is afforded by the behaviour of the vapour tension of a mixture. The temperature being constant if the vapour tension be plotted with the percentages of the more volatile liquid as abscissæ, the curve is, for a mixture of two liquids which have no chemical action upon one another, as the iodide and bromide of ethyl, a straight line. For ordinary mixtures, however, this is not the case. A curve is obtained in which there is observable at a certain point an irregularity. The corresponding abscissa indicates the molecular combination found by the previous experiment.

Dr. C. R. ALDER WRIGHT read a paper by himself and Mr. C. THOMPSON on "Voltaic and Thermo-voltaic Constants." In a former paper the authors had stated that in a cell set up with two metals immersed in pure solutions of their corresponding salts, a given increment in the strength of the solution surrounding the metal acquiring the higher potential causes an increment (a) in the E.M.F. set up (e), while an increment in the strength of the other solution causes a decrement (b) in the E.M.F. This law is now substantiated; it is, however, found that for dilute acids instead of metallic salts b may be negative. The authors also find that it is possible to express

the E.M.F. of a cell by the difference of two quantities, which they term the voltaic constants. These are quantities, one relating to each plate and its surrounding liquid. The voltaic constant of a metal and a liquid is a function of the nature of the metal surface, the strength of the solution, and the temperature, but is independent of the opposed plate and its liquid; it is practically defined as the E.M.F. set up when opposed to a zinc plate in a solution of the corresponding zinc salt of the same molecular strength. The authors further conclude that the E.M.F. of a given combination usually *stands in no simple relationship to the chemical action taking place in the cell*, but that it may be expressed by the sum of the mechanical equivalent of the chemical action per electrochemical equivalent, and the difference of two quantities, one being related to each metal and its surrounding liquid, and being constant for that metal and liquid at a given temperature *termed thermo-voltaic constants*. This thermo-voltaic action may act with or against the chemical action in producing E.M.F. In some cases, as in that of a cell composed of iron in ferrous sulphate and cadmium in cadmic sulphate solutions, the E.M.F. is against and greater than that produced by chemical action; consequently the cell works backwards with absorption of heat.

At the close of the paper Prof. AYRTON and Dr. GUTHRIE remarked upon the apparent exception here shown to the second law of thermo-dynamics.

with Painters' Putty, and with other mixtures of Pigments and Oil." The quantity of this delectable food that mice can consume in a given time is scarcely credible. In one experiment it was found that a mouse would eat as much as 54 grms. of dry whiting made into putty, each day, and thrive upon it, merely for the small quantity of oil it contained—about one-fifth of the weight of the whiting. This is "as if more than 50 lbs. of dry chalk were to pass daily through a man of 150 lbs. weight." Experiments were made with putty consisting of coloured ochres, silica, and other inert materials, but the mice were found to enjoy such messes less than when whiting was used: the addition of a little of the latter, however, made the putty more agreeable to the mice. Among other substances tried were carbonates of lead and baryta. Each of these materials in the pure state proved fatal to the mice, but the addition of a small quantity of whiting served as an antidote against their poisonous action. The physiological reason for this anomaly, as the author points out, is altogether vague.

An index to this work would certainly have been an advantage; possibly, as it forms the continuation of a series of such volumes, a general index to the whole will be given; still each part, we think, might have had this valuable appendix.

NOTICES OF BOOKS.

Bulletin of the Bussey Institution. Vol. II., Part 4, (Jamaica Plain, Boston). 1884. Boston: John Allyn. THE Bussey Institution, or School of Agriculture and Horticulture, apparently in connection with the Harvard University, was established "in execution of the trusts created by the Will of Benjamin Bussey," for giving systematic instruction in agriculture, useful and ornamental gardening, and stock-raising. Owing to the great fire in Boston some years ago, and the commercial depression that followed, the revenue derived from the Bussey Trust was so greatly diminished that the whole available income had to be devoted to the maintenance of the buildings, and for instruction. Before the closing of the research laboratory and the experimental plant-house the work that had been done connected principally with agriculture is brought together in this pamphlet, the majority of the papers being by Prof. Storer. These investigations, although none of them of a purely chemical character, will afford some information to the student of agriculture, especially the rather lengthy papers on "Some Items of American Experience which suggest that Potassic Fertilisers may perhaps act in several different ways," and the "Description of an Attempt to Assay Soils by the Method of Sand Culture." In the latter investigation the plan adopted was to add small portions of the soils to be assayed to some inert material, such as siliceous sand, the young plant being watered with dilute solutions of chemical substances capable of affording food to the growing plant. The author's experiments made in this fashion "show clearly enough that while this method of assay can readily distinguish a true garden soil . . . from the mediocre loams with which it was contrasted, it is incapable of making definite practical distinction between ordinary loams taken from fields and pastures here in Massachusetts." And the author deems the assay "incompetent to give sharp, well-defined results, as between one loam and another."

Among some other papers of minor importance we notice one of a strange character, pointing, however, to facts which may help to explain the sanitary defects occasionally met with in newly-built houses. This paper, also by Prof. Storer, is headed "Experiments on Feeding Mice

CORRESPONDENCE.

SALICYLIC ACID.

To the Editor of the Chemical News.

SIR,—I have not seen any reply to the enquiry of Mr. J. H. Heywood in the CHEMICAL NEWS, vol. I., p. 173, as to the poisonous or non-poisonous effect of salicylic acid. Perhaps it may serve his purpose to learn that much larger doses, up to 80 grains, are successfully administered in the German medical treatment of rheumatism.—I am, &c., J. CRUM.

Workington, Cumberland.
November 6, 1884.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 17, October 27, 1884.

Contaminated Waters and the Cholera.—M. Marey.—The author strongly advocates the theory that the propagation of cholera is mainly due to water contaminated by the excreta of cholera patients, and gives several very important facts in support of this view.

Formation of Saltpetre in Plants.—MM. Berthelot and André.—Potassium nitrate is universally pre-existent in the vegetable kingdom. It does not pre-exist in a sufficient quantity either in the manures or the soil, and must therefore be formed in the plant itself, the stem being the principal seat of its formation. This action is probably due to certain cellulose which behave in the interior of the plant like the nitric ferment which, according to MM. Schloesing and Muntz, produces saltpetre in the soil.

Oxidation of Copper.—MM. Debray and Joannis.—Copper heated with free access of air is generally transformed into cupric oxide without passing through the cuprous stage. This reaction occurs at all temperatures between 350°, and that at which the dissociation-tension

of the oxide formed reaches about the fifth part of the pressure of the atmosphere, *i.e.*, the pressure of the oxygen contained in the air. Above this temperature the black oxide formed at first is partially decomposed. About the melting-point of gold, the mixture of cupric and cuprous oxide fuses. The decomposition ceases when the decreasing tension of the oxygen, liberated from the mixture, reaches that of $\frac{1}{5}$ of an atmosphere. It is evident that the direct oxidation of copper at these high temperatures would have the same final results. Inversely, the refrigeration of the oxide, more or less decomposed, in atmospheric air effects its re-oxidation if the matter is sufficiently porous. When determining copper as cupric oxide, it is necessary not to raise it to a temperature at which it might melt, or even become agglomerated. If the copper is in large excess, as in preparing nitrogen by passing air over copper turnings heated in a tube, there is formed merely cupric oxide if the temperature is sufficiently low. If the middle of the tube is heated more strongly there is formed also cuprous oxide. When the oxygen is insufficient in quantity to saturate all the copper we never obtain an intimate mixture of the two oxides without fusion. On cooling slowly the red and the black oxides are found distinctly separated.

Rapid Preparation of Standard Solutions of Carbon Disulphide.—Ach. Livache.—The author takes a solution of soap, with which he incorporates a certain quantity of petroleum. In this he can dissolve, on stirring, more than 200 grms. disulphide of carbon per litre for 150 grms. of soap. This solution, on adding water, remains perfectly limpid, the disulphide of carbon not separating out.

Certain Reactions of Chloro-chromic Acid.—M. Quantin.—Carbon monoxide acting alone upon chloro-chromic acid transforms it into green chromium sesquichloride and violet sesquichloride. The simultaneous reaction of carbon monoxide and an excess of chlorine transforms the chromium oxychloride into sesquichloride.

Analysis of the Apatite of Logrozan.—A. Vivier.—This mineral contains 41.02 per cent of phosphoric acid combined with lime, besides 4.46 per cent of aluminium and glucinum phosphates. The calcium fluoride is 5.23 per cent.

Combination-heat of Compounds of Hydrogen and Oxygen.—A. Boillot.—Of the number of calories obtained on the combination of hydrogen and oxygen gases to form water, two-thirds are furnished by the former of these gases and one-third by the latter. The water formed does not absorb any latent heat. For 9 grms. of water formed the gm. of hydrogen liberates 23 cal., and the 8 grms. oxygen 11.3 cal. In the formation of oxygenated water each of the component gases liberates the same number of calories, *i.e.*, for 17 grms. of oxygenated water formed, the gm. of hydrogen gives 11.85 cal., and the 16 grms. of oxygen also 11.85 cal. The latent heat of this quantity of oxygenated water is 22.3 cal., of which the half comes from each of the elements. The author deduces from his investigations the density of liquid oxygen as = 0.888. M. Wróblewski found this density as intermediate between 0.89 and 0.90. M. Gérardin addresses a note on the use of hydrosulphurous acid, as a bleaching agent. In opposition to chlorine it acts by reduction, and is capable of important industrial applications.

Journal de Pharmacie et de Chimie.
Series 5, Vol. x., Aug., 1884.

Universal Presence of Nitrates in the Vegetable Kingdom.—M. Berthelot.—Already noticed.

Chemical Detection of Nitric Acid and Nitrates in Vegetable Tissues.—A. Arnaud and L. Paul.—Already noticed.

New Means of Detecting Chlorates in Solution.—M. Fourmont.—If we treat a chlorate with copper turnings and sulphuric acid, hydrochloric acid escapes and there is

formed copper chloride, which tinges the solution green. Consequently, after having proved the absence of the acids which are precipitated by silver nitrate, the chlorates can be very quickly distinguished from the nitrates. In case of a mixture of chlorate and nitrate the liquid is also heated with copper turnings and sulphuric acid. The chlorate is first decomposed, hypochloric acid escapes, and the liquid turns green; then hyponitric acid follows, and the green colour is succeeded by the blue characteristic of copper. These characters are easily recognised within two minutes' time. When chlorates and chlorides are mixed, after having thrown down the chlorides with silver nitrate the chlorate is detected by means of copper turnings and sulphuric acid. When chlorides, chlorates, and nitrates exist in mixture, the chlorides are first removed with silver acetate and the other acids are then detected as above by means of copper and sulphuric acid.

Volumetric Determination of Alumina in Limes and Cements.—H. Prunier.—The author takes finely powdered cement 0.428 gm., water and pure nitric acid each 2 grms. He stirs up the cement in the water in a tared flask, adds the acid, heats to render the solution as complete as possible, adds 20 grms. water, and colours the liquid with ten drops of tropoline Oo (orangé Pourrier, No. 4). He then pours in by degrees strong ammonia until the original red colour of the mixture is reduced to a faint rose tint. The decoloration is then completed by adding by drops ammonia free from carbonate and diluted with four times its volume of water, until the solution if tested on a white plate with orange No. 4 gives a colourless mixture, or simply a pale yellow without the mixture of any reddish grey tint. All the free nitric acid is thus saturated. The alumina is then precipitated by an excess of standard alkali, say 10 to 15 c.c. of semi-normal ammonia. Water is added to make up a total weight of 50 grms. and the whole is mixed up and filtered. Two c.c. of the filtrate (= 0.1712 gm. cement) are taken, coloured with 3 or 4 drops tincture of litmus, and the excess of alkali is titrated with decinormal nitric acid until it turns to the red shade of an onion skin. The volume of semi-normal ammonia (4 or 6 c.c.) contained in the 20 c.c. of the filtrate corresponding to 20 or 30 per cent of alumina, each c.c. of deci-normal acid employed would indicate 1 per cent of alumina if no iron was present. But as cements always contain more or less iron, to find the exact proportion of alumina it is necessary to deduct Fe_2O_3 from the gross sum of $\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$, as shown by the above alkalimetric determination. This result is obtained by determining previously the percentage of Fe_2O_3 by means of potassium permanganate, basing upon the fact that 1 per cent of $\text{Fe}_2\text{O}_3 = 0.642$ c.c. decinormal acid.

Crystalline Colchicine.—A. Houdé.—Colchicine crystallises in prisms which turn litmus-paper slightly blue. It is very slightly soluble in water, ether, and glycerin, but dissolves in all proportions in alcohol, chloroform, and benzol.

Colchicine.—M. Zeisel.—From the *Comptes Rendus*.

Synthesis of Xanthine.—M. Armand Gautier.—Already noticed.

The Elixir of Pepsine.—P. Vigier.—A purely pharmaceutical paper.

Detection of Albuminose or Peptone in Urine.—C. Méhu.—The author makes use of an acetic solution of potassium-mercuric iodine.

Detection of Starch in Gluten Bread.—A. Mallat.—The author concludes that the only exact method is the determination of the nitrogen in a given weight of the bread by the soda-lime process.

The Composition of Cork.—Ch. Kugler.—The characteristic component of cork is suberine, a true fat, saponifiable by alkalis and oxidisable by nitric acid, which converts it into a mixture of suberic and ceric acids.

Suberine is composed of the mixed glycerides of phellonic and stearic acids.

September, 1884.

The Preparation of Hydrated Chromic Acid and on Certain Novel Properties of Chromic Anhydride.—M. H. Moissan.—The author fuses the chromic acid of commerce in a platinum capsule at a very gentle heat, when, with care, the greater part of the sulphuric acid present is volatilised. The contents of the vessel are then poured into a flat porcelain capsule. The sulphuric acid, which is much the more liquid, flows out first. The chromic acid solidifies quickly in little red rods, which are broken up rapidly, selecting such as have not been touched by the sulphuric acid and preserved in dry bottles. Chromic anhydride rapidly absorbs hydrochloric acid gas, giving off red fumes and condensing to chlorochromic acid. Hydrobromic and hydriodic acids do not, under similar circumstances, form analogous compounds.

Poisoning by Nicotine.—Dr. Rabot.—An account of a poisoning case and of the autopsy, &c.

The Falsification of Pepper by Means of Olive Kernels.—E. Landrin.—Not capable of useful abstraction.

A New Alcohol from Bird-lime.—J. Personne.—Already noticed.

October, 1884.

Purification of Methyl Alcohol.—MM. J. Regnaud and Villejean.—In the alcohol regenerated from methyl-oxalic acid the authors dissolve about 10 per cent of iodine. To this liquid they add, little by little, an aqueous solution of caustic soda in quantity sufficient to produce an entire decolouration and a distinct alkaline reaction. On being submitted to careful distillation this mixture yields methyl alcohol not convertible into iodoform, and which, if rectified over quick-lime, has the sp. gr. 0.810 at +15°.

Wood Oil of Cochin China.—J. Leon Soubeiran.—A pharmaceutical paper.

Purification of Arseniferous Zinc.—L. L'Hôte.—Already inserted.

A Process for Determining the Specific Gravity of Porous Bodies.—G. Fleury.—This memoir cannot be intelligibly reproduced without the accompanying illustration.

The Kola Nut.—M. Naton.—A pharmaceutical paper.

Determination of Silver and Copper in one and the same Solution.—J. Quessaud.—The author standardises his solutions with a liquid (normal solution) containing silver and copper in known proportions, and then repeats the same operation upon an equal volume of an unknown solution. Three solutions are necessary:—(1.) A normal solution composed of 1 grm. of pure silver and 0.10 grm. of pure copper to 400 c.c. of distilled water, of which 40 c.c. are taken. The solution is made with 3 grms. pure nitric acid and 1 grm. distilled water. It is evaporated to dryness on the water-bath, and re-dissolved in distilled water. The unknown substance is dissolved in the same manner. (2.) A solution of potassium ferrocyanide at 1 per cent. (3.) A decolourising solution composed of potassium sodium tartrate, 10 grms.; soap-boiler's lye, 25 grms.; distilled water enough to make up 550 c.c. (The soap-boiler's lye is probably caustic soda lye at sp. gr. 1.310, but lyes of different strength are used in different processes for soap making.) The operation must be conducted in a neutral or faintly acid liquid, since the ferrocyanide does not precipitate copper from an alkaline solution, and the decolourising liquid is more or less neutralised according to the proportions of excess of acid. In standardising the normal solution the author takes 40 c.c. (representing 0.10 grm. of silver and 0.01 grm. of copper). The solution of ferrocyanide is run into the metallic solution drop by drop from a burette

graduated into tenths of a c.c., with constant stirring until the last drop produces a faint, permanent, flesh-coloured tint. The number of degrees necessary to produce this result for 0.10 grm. silver is noted as the standard of the silver. For copper we continue to add the same solution of ferrocyanide until, by an excess of the reagent which dissolves the last traces of copper ferrocyanide, the liquid has a reddish colour after the precipitate has subsided. When this result is obtained the alkaline solution of tartrate (decolourising solution) is added drop by drop from a burette graduated into tenths of a c.c. until this red colour has disappeared, and a bluish white tint appears. We note the number of degrees of the decolourising solution necessary for transforming the copper ferrocyanide formed in a solution containing 0.01 grm. of copper. In operating upon an unknown solution 40 c.c. are taken and treated precisely as above.

Analysis of Blood which had remained for some Years in a Cavity excluded from the Air.—E. Leidié.—This paper is chiefly of physiological interest.

Second Memoir on Flour.—M. Balland.—Already noticed.

Detection of Tartaric Acid in Citric Acid.—Vulpis dissolves 0.5 grm. of the sample in question in 10 grms. of distilled water, and adds 5 drops of the solution drop by drop to 15 grms. of lime water. If the citric acid contains mere traces of tartaric acid, in a few moments there is produced a distinct turbidity, which increases on adding more of the acid solution and stirring. In this manner 1 per cent. of tartaric acid can be detected. M. Pusch puts 1 grm. of the sample, ground up, in a dry test-tube along with 10 grms. pure colourless sulphuric acid, and suspends the tube in a beaker containing water which is kept at a temperature close upon boiling. If the citric acid is pure the liquid takes and retains a lemon-yellow colour. But if only $\frac{1}{4}$ per cent. of tartaric acid is present the mixture becomes brown in twenty-five to thirty minutes.

Moniteur Scientifique, Quesneville.

Vol. xiv., November, 1884.

Address delivered before the Chemical Section of the British Association.—Prof. H. Roscoe.—Already inserted.

Review of Foreign Researches in Organic Chemistry.—G. de Bechi.—This "review" consists of extracts from the *Berichte der Deutsch. Chem. Gesell. und Liebig's Annalen*.

Industrial Review and Patents.—Brief notices of patents for the manufacture of metallic nickel and cobalt; of aluminium, of solidified mineral acids, of soluble glass; for the purification of alcohol, and for improvements in the manufacture of sugar.

Patents concerning Colouring Matters.—These consist of a process for the preparation of double compounds of the azo colours with the bisulphites, and a process for the separation of the azo colours formed by the combination of the diazo derivatives of the β -naphthylamine-mono-sulphonic acids with the α -naphthol-mono-sulphonic acids.

Patents in the Chemical Arts taken out in France in 1884.—A classified patent list for the month of September last.

Selection of Patents obtained in France, 1884, relating to the Chemical Arts.—This list refers also to the month of September last.

The Solutions of Cupro-ammonium and their Applications.—Dr. C. R. Alder Wright, F.R.S.—From a well-known English source.

Degeneration of Yeast and the Means for making it Disappear.—J. C. Jacobsen.—Not adapted for abridgment.

Critical Study on the Analysis of Superphosphates.—N. Grignon.—In this memoir the author discusses principally the methods for the determination of reverted phosphates.

Industrial Society of Mulhouse: Session of the Chemical Committee, September 10, 1884.—The Secretary read certain letters from G. Witz, of Rouen, concerning the action of gaseous chlorine upon colouring matters or alkaloids in presence of soda. A yellow printed discharge with chromate of lead succeeded perfectly on blues and reds in seventeen seconds in chlorine previously mixed with air. White discharges required further purification. With aniline hydrochlorate the following facts were noted:—First, the instantaneous and successive production of reddish colours, turning to violet, blue, and green, more or less soluble, then blacks passing gradually through all the known phases, including an ungreenable black, and lastly a permanent orange or Bismarck brown. The whole of these changes does not require more than one or two minutes. The simple aqueous solution of aniline hydrochlorate gives absolutely distinct and different results according to its concentration, as soon as it is introduced into chlorine gas. Up to 130 grms. per litre we obtain an insoluble bright rosy chamois (which ultimately turns brown when dry); whilst with 150 grms. or upwards of the same salt there are obtained blacks with a narrow orange margin. M. Schmid has succeeded in effecting a discharge on the chrome mordant described by H. Kœchlin at the last meeting. It is merely necessary to print potassium ferricyanide and to pass the pieces into caustic soda, when the chromic oxide is converted into sodium chromate. By steaming, the same end may be gained by printing a mixture of ferricyanide and of an alkaline carbonate.

Phenic Acids of Commerce.—O. Castelha.—The author endeavours to distinguish "crude carbolic" acid from the varying grades of "liquid carbolic" acid, and gives processes for their commercial analysis.

The Iridium Industry.—A notice of the improvements introduced by Mr. John Holland, of Cincinnati.

Antipyrine, a New Febrifuge.—An account of another attempt to supersede quinine.

Vermilion and its Manufacture in China.—From the CHEMICAL NEWS.

A New Antiseptic, Aseptol.—E. Transer.—The scientific name of this compound is orthoxy-phenyl-sulphurous acid. It is an acid phenol, capable of neutralising ammoniacal bases. It is said to be preferable as an antiseptic to phenol, having the advantage of not being poisonous.

Certain Processes for the Analysis of Water.—A notice of a work by M. Roques, in which the method of Wanklyn, Chapman, and Smith is recommended.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale. 3rd Série. Tome xi., August, 1884.

Manufacture of Aluminium.—Mr. James Weldon.—This memoir appeared in the *Journal of the Society of Chemical Industry* for September, 1883, and has been reproduced and commented upon in various English papers.

On Vaseline.—J. Otto.—Taken from the *Moniteur Scientifique* Queneville for April, 1883.

Utilisation of Burnt Pyrites.—J. Creutz.—Already noticed under the *Moniteur Scientifique*, from which it is taken.

Cosmos les Mondes.
No. 5, October 9, 1884.

This number contains no chemical matter.

No. 7, October 25, 1884.

Determination of the Quantity of Organic Matter Contained in Water.—M. Limousin.—The author merely acidulates the water with a trace of sulphuric acid, heats it to 80° or 90°, and drops in a solution of permanganate until a permanent rose colouration is obtained. He adds that if the water is very highly charged with organic matter it need not be acidified, unless alkaline, or even heated!

Archives Néerlandaises des Sciences Exactes et Naturelles.
Tome xix., Part 3.

Filtration of Liquids through Fibrous Membranes.—J. C. Van Beek.—In this long and illustrated paper the author comes to the conclusion that the changes observed under the influence of pressure of the duration of the experiments in the filtration of water and of matters in solution or in a very fine state of division through fibrous membranes must be ascribed to changes in the reciprocal distance of the fibres constituting the membrane.

MEETINGS FOR THE WEEK

THURSDAY, Nov. 20th.—Chemical, 8.—Ballot for the election of Fellows.—"On Some New Paraffins," by Khan Bahadur Dr. Bomanji Sorabji. "On Additive and Condensation Compounds of Di-ketones with Ketones," by Dr. F. R. Japp and Dr. N. H. Miller. "On a New Method of Determining the Vapour Pressure of Solids and Liquids," by Dr. W. Ramsay and Sydney Young. "Action of Halogens on the Salts of Trimethyl-sulphine," by Dr. L. Dobbin and Orme Maason, M.A., D.Sc. "Note on the Sulphates of Potassium and Lithium," by Spencer U. Pickering. "Researches on the Application of Iron Sulphate in Agriculture," by A. B. Griffiths. **SATURDAY, 22nd.**—Physical, 3. "Note on a Point in the Theory of Pendent Drops," and "On a Capillary Multiplier," by A. M. Worthington.

SPLENDID BARGAIN.

For Disposal, through death, Twelve First Mortgage Debenture Bonds, or part, of £25 each, fully paid, bearing 10 per cent interest, and paid off at £20 15s. per Bond.—Address, "Executor," Mason and Co., 56, Coleman Street, London.

TECHNICAL CHEMIST, with a long practical experience in the manufacture of ANILINE DYES, is open for an engagement. First-class references.—Address, CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

To SODA and CHLORIDE OF LIME Manufacturers, and Others.

Wanted, Wholesale Prices for large quantities of Hypochlorite of Lime, Hypochlorite of Soda, caustic Soda, Hydrochloric Acid, Peroxide of Manganese, and Eau de Javelle.—Address, A. H. S., CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Wanted, the method for making ROSANILINE BASE by the Nitro-benzol Process. Also the best mode of manufacturing SAFFRANINE.—Address, stating terms to "Rosine," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Wanted, Quotation for 2000 to 3000 tons of VITRIOL, of good colour, 148° Tw., delivered at a Works in South Lancashire during 1885.—Apply to the CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

SALE OF FOOD AND DRUGS ACTS, 1875-9.

The Board of Works for the Plumstead District intend to appoint a person possessing competent knowledge, skill, and experience, as Analyst for the district. Salary £100 yearly. Application for the appointment must be in writing (on a form which can be obtained here by letter), and left at this Office not later than 20th November, 1884.

Candidates are requested not to canvass the members of the Board.

By order, **GEORGE WHALE, Clerk.**
The Board's Offices, The Village, Old Charlton,
3rd November, 1884.

be secured by teaching well some one branch of science. Admitting that this has been the case, however, there is no reason why it should be in the future: if while developing the intellect it be possible—and it certainly is—to impart much valuable information; and if—as it certainly is—the teaching be rendered easier and more attractive because it has direct reference to the familiar objects and operations of Nature. We cannot, indeed, any longer afford to grow up ignorant of all that is going on around us, and without learning to use our eyes and our reasoning powers; we cannot afford to be unacquainted with the fundamental laws of health; but we must ever remember “that knowledge of Nature is the guide of practical conduct,” and no effort must be spared to render our system of education an effectual preparation and truly adapted to the exigencies of practical life. The female educators appear already to have grasped the importance of such teaching, and under the guise of domestic economy much that I advocate is being taught in girls' schools; it is to be hoped that ere long something akin to the domestic economy course in girls' schools will find a place in boys' schools.

To pass now to the consideration of the mode of teaching my own special subject in science classes, such as those held under the auspices of the Science and Art Department, and in the introductory course for students in science schools and colleges generally. To deal first with the former. Inspection of the syllabus for the elementary stage, together with the study of the examination papers of the past few years, will show that the student is mainly required to have an elementary knowledge of the methods of preparing, and of the properties of the commoner *non-metallic* elements and their chief compounds. There is thus practically no distinction to be drawn between the knowledge required of students under the Science and Art Department, and of those who are making the study of chemistry the business of their lives. But surely it is not the function of the Science and Art Department to train up chemists, and I am satisfied that it is neither their desire nor their intention to do so; their object undoubtedly is to encourage the teaching of chemistry as a means of cultivating certain faculties, and in order that the fundamental laws of chemistry may be understood and their commoner applications realised. It is not difficult to understand how the system has grown up and why it is maintained; I do not believe it is because the Department consider it a satisfactory one; but they know full well that a better system is not yet developed and that it would be unwise to legislate far in advance of the intelligence and powers of the majority of the teachers. With all deference, however, I venture to add that the programme has been drawn up too much from the point of view of the specialist, and that too little attention has been devoted to it from the point of view of the educationalist. The course I am inclined to advocate would be of a more directly useful character. There is no reason why in the beginning attention should be confined to the non-metals, especially when certain of the metals enter so largely into daily use; and provided that it involve no sacrifice of the opportunities of developing the faculties which it is our special object to cultivate by the study of chemistry, there is no reason against, but every reason for, selecting subjects of every day importance rather than such as are altogether outside our ordinary experience, such, for example, as the oxides of nitrogen; even chlorine, except in relation to common salt, might be omitted from special study. The presumed distinction between so-called inorganic and organic chemistry should be altogether put aside and forgotten, and the elements of the chemistry of the carbon compounds introduced at a very early stage in order that the phenomena of animal and plant life might come under consideration. To give the barest possible outline of a programme, I would include such subjects as the following in the syllabus:—

The chemistry of air, of water, and of combustion.

The distinction between elements and compounds. The fundamental laws which regulate the formation of compounds and the chemical action of bodies upon one another (*i.e.*, the nature of so-called chemical change). The chemical properties of the metals in ordinary use, with special reference to their uses and the action upon them of air, water, &c. The composition of natural waters. The distinction between fats, carbohydrates, and albuminous substances in so far as is essential to the understanding of the relative values of different foods and respiration and growth in animals and plants (outlines of the chemistry of animal and plant life, in fact); the nature of the processes of fermentation, putrefaction, and decay.

The instruction in these subjects should in all cases be imparted by means of object-lessons and tutorial classes; lectures pure and simple should, as far as possible, be avoided. The students should by themselves go through a number of practical exercises on the various subjects. I would abolish the teaching of tables for the detection of simple salts, the teaching of analysis, as at present conducted, being, I believe, in most cases, of very little if any use except as enabling teachers to earn grants.

In schools and colleges in which chemistry is taught as a science, and ostensibly with the object of training young people to be chemists, it is the almost invariable practice that the student first devotes more or less time to the preparation of the commoner gases, and then proceeds to study qualitative analysis; quantitative determinations are made only during the later period of the course. I believe that the system has two great faults: it is too mechanical, and does not sufficiently develop the faculty of reasoning from observation; and actual practice in measurement is introduced far too late in the course. It is of great importance that the meaning of the terms equivalent, atomic weight, molecular weight, should be thoroughly grasped at an early stage, but according to my experience this is very rarely the case; there is no such difficulty, however, if the beginner is taught to make a few determinations himself of equivalents, &c., as he very well may be. It is not necessary here to enter into a more detailed criticism, but I propose instead to give a brief description of a modification of the existing system which in my hands, in the course of about four years' experience, has furnished most encouraging results, and which I venture to think is worthy of an extended trial.

Instead of merely preparing a variety of gases, the student is required to solve a number of problems experimentally: to determine, for example, the composition of air and of water; and the idea of measurement is introduced from the very beginning, as the determination is made quantitatively as well as qualitatively. Each student receives a paper of instructions—two of which are printed as an appendix to this paper—which are advisedly made as bare as possible so as to lead him to find out for himself, or enquire, how to set to work; and he is particularly directed that, having made an experiment, he is to enter in his notebook an account of what he has done and of the result, and that he is then and there to ask himself what bearing the result has upon the particular problem under consideration, and having done so, he is to write down his conclusion. He is thus at once led to consider what each experiment teaches; in other words, to reason from observation. Apart from the mental exercise which this system affords, if the writing out of the notes be properly supervised, the literary exercise which it also affords is of no mean value.

In illustration, I may here very briefly describe the manner of working out the second problem in the course. The problem being: To determine the composition of water, the student receives the instruction: 1. Pass steam over red-hot iron brads, collect the escaping gas, and apply a light to it. (N.B. The gas thus produced is called hydrogen). He is provided with a very simple apparatus, consisting of a small glass flask containing water, joined by a narrow bent glass tube to an iron tube (about 9

inches long and $\frac{1}{4}$ to $\frac{3}{4}$ inch wide) in which the brads are placed, a long glass tube suitably bent for the delivery of the gas being attached to the other end of the iron tube. Plaster-of-Paris is used instead of corks to make the connections with the iron tube. The iron tube is supported over a burner, and heated to redness; the water in the flask is then heated to boiling, and the steam thus generated is passed over the brads; the escaping gas is collected over water in the usual manner. Having made this experiment, and observed that on passing steam over red-hot iron the gas hydrogen is produced, the student proceeds to consider the bearing of this observation. The hydrogen must obviously be derived either from the water or from the iron, if not from both. Those who already know that iron is iron, so to speak, at once infer that the hydrogen is derived from the water: it is, however, pointed out that even if it be known that iron is a simple substance, this observation taken alone does not prove that hydrogen is contained in water.

2. The student next learns to prepare hydrogen by the ordinary method of dissolving zinc in diluted sulphuric acid, and makes a few simple experiments whereby he becomes acquainted with the chief properties of the gas.

3. Having done this, he is instructed "to burn dry hydrogen at a glass jet underneath a cold surface and to collect and examine the product." The product is easily recognised as water, and the immediate answer to the question, "What does this observation teach?" is, that since iron is absent, taken in conjunction with experiment 1, the production of water on burning hydrogen in air, the composition of which has already been determined, is an absolute demonstration that hydrogen is contained in water.

4. Having previously studied the combustion of copper, iron, and phosphorus in air, and having learnt that when these substances burn they enter into combination with the oxygen in air, the student is also led to infer from the observation that hydrogen burns in air producing water, that most probably it combines with the oxygen, and that water contains oxygen besides hydrogen. It may be, however, it is then pointed out, that the hydrogen, unlike the phosphorus, &c., combines with the nitrogen instead of with the hydrogen, or perhaps with both. He is, therefore, instructed to pass oxygen over heated copper, weighing the tube before and after the operation, and subsequently to heat the "oxide of copper" in a current of hydrogen. He then observes that water is formed, the oxygen being removed from the copper: and since nitrogen is absent, it follows that water consists of hydrogen and oxygen, and of these alone.

5. By repeating this experiment so as to ascertain the loss in weight of the copper oxide tube and the weight of water produced, the data are obtained for calculating the proportions in which hydrogen and oxygen are associated in water.

In practice, the only serious difficulty met with has been to induce students to give themselves the trouble to consider what information is gained from a particular observation; to be properly inquisitive, in fact. I cannot think that this arises, as a rule, from mental incapacity. When we consider how the child is always putting questions, and that nothing is more beautifully characteristic of young children than the desire to know the why and wherefore of everything they see, I fear there can be little doubt that it is one of the main results—and it is indeed a lamentable result—of our present school system that the natural spirit of enquiry, inherent to a greater or less extent in every member of the community, should be thus stunted in its growth, instead of being carefully developed and properly directed.

Having in the manner which I have described studied air, water, the gas given off on heating common salt with sulphuric acid, and the ordinary phenomena of combustion, the student next receives a paper with directions for the comparative study of lead and silver (see Appendix). The experiments are chosen so as to afford an insight into the

principles of the methods ordinarily employed in qualitative and quantitative analyses, and the student who has conscientiously performed all the exercises is in a position to specialise his studies in whatever direction may be desirable.

The system I have thus advocated undoubtedly involves far more trouble to the teacher than that ordinarily followed, but the student learns far more under it, and I assert with confidence that the training is of a far higher order, and also of a more directly useful character. I believe it to be generally applicable, and that it would be of special advantage in those cases in which only a short time can be devoted to the study of chemistry, as in evening classes and medical schools. At present the only practical teaching vouchsafed to the majority of students in our large medical schools is a short summer course, during which they are taught the use of certain analytical tables: as a mental exercise, the training they receive is of doubtful value; the knowledge gained is of little use in after life, and the course certainly ought not to be dignified by being spoken of as a course of Practical Chemistry: *test-tubing* is the proper appellation. It is not a little remarkable also that even the London University Syllabus nowhere specifies that a knowledge even of the elements of quantitative analysis will be required of candidates either at the Preliminary Scientific or First M.B. Examination, and this too when, as is well known, an analysis to be of any practical value must almost invariably be quantitative. It is little less than a disgrace to the medical profession that a subject of such vital importance as chemistry should be so neglected.

If, however, we are to make any change in our method of teaching Science; if we are to teach Science usefully throughout the country, two things are necessary:—Teachers of Science must take counsel together, and the Examining Boards must seriously consider their position. There can be little doubt that in too many cases the examinations are suited to professional instead of to educational requirements: and that the professional examinations are often of too general a character, and do not sufficiently take into account special requirements.

APPENDIX.

Problem: to Determine the Composition of Air.

N.B.—Immediately after performing each experiment indicated in this and subsequent papers, write down a careful description of the manner in which the experiment has been done, of your observations and the result or results obtained, and of the bearing of your observations and the result or results obtained on the problem which you are engaged in solving. Be especially on your guard against drawing conclusions which are not justified by the result of the experiment; but, on the other hand, endeavour to extract as much information as possible from the experiment.

1. Burn a piece of dry phosphorus in a confined volume of air, i.e., in a stout Florence flask closed by a caoutchouc stopper. Afterwards withdraw the stopper under water, again insert it when water ceases to enter, and measure the amount of water sucked in. Afterwards determine the capacity of the flask by filling it with water and measuring this water.

N.B.—The first part of the experiment requires care, and must be done under direction.

2. Allow a stick of phosphorus lashed to a piece of stout wire to remain for some hours in contact with a known volume of air confined over water in a graduated cylinder. After noting the volume of the residual gas, introduce a burning taper or wooden splinter into it.

N.B.—The residual gas is called *nitrogen*.

3. Burn a piece of dry phosphorus in a current of air in a tube loosely packed with asbestos. Weigh the tube, &c., before and after the experiment.

4. Repeat Experiment 2 with iron-borings moistened

with ammonium chloride solution. Preserve the residual gas.

5. Suspend a magnet from one arm of a balance; having dipped it into finely divided iron, place weights in the opposite pan; and, when the balance is in equilibrium, set fire to the iron.

6. Pass a current of dry air through a moderately heated tube containing copper. Weigh the tube before and after the experiment; also note the alteration in the appearance of the copper.

7. Strongly heat in a dry test-tube the red substance obtained by heating mercury in contact with air. At intervals plunge a glowing splinter of wood into the tube. Afterwards note the appearance of the sides of the tube. (Before performing this experiment ask for directions.)

N.B.—The gas obtained in this experiment is named oxygen.

8. Heat a mixture of manganese dioxide and potassium chlorate in a dry test-tube, and at intervals plunge a glowing splinter into the tube. This experiment is to acquaint you with an easy method of preparing oxygen in quantity.

9. Prepare oxygen as in Experiment 8, and add it to the nitrogen from Experiment 4 in sufficient quantity to make up the bulk to that of the air taken for the latter experiment. Test the mixture with a burning taper or splinter.

10. Dissolve copper in nitric acid and collect the escaping gas (nitric oxide); add some of it to oxygen and some of it to air.

11. Fill a large flask, provided with a well-fitting caoutchouc stopper and delivery tube, with ordinary tap water, and gradually heat the water to the boiling-point; collect the gas which is given off in a small cylinder, and add nitric oxide to it. Also collect a sufficient quantity in a narrow graduated cylinder, and treat it as in Experiment 2.

Comparative Study of Silver and Lead.

Silver.—Symbol, Ag. (Argentum). Atomic weight, 107.67. Specific heat, 0.05701.

Lead.—Symbol, Pb. (Plumbum). Atomic weight, 206.47. Specific heat, 0.03140.

1. Determine the relative density of lead and silver at a known temperature by weighing in air and in water.

2. Separately heat known weights of lead and silver for some time in the air, allow to cool, and weigh.

3. Separately convert known weights of lead and silver into nitrates, and weigh the latter. From the data thus obtained calculate the *equivalents* of lead and silver.

4. Convert the known weights of nitrates thus obtained into chlorides, and weigh the latter.

5. Compare the action on lead and silver of chlorhydric acid; of dilute and concentrated sulphuric acid, using the acid both cold and hot; and of cold and hot nitric acid.

6. Using solutions of the nitrates, compare their behaviour with chlorhydric and sulphuric acids, hydrogen sulphide, potassium iodide, and potassium chromate. Ascertain the behaviour of the precipitate formed by chlorhydric acid when boiled with water, and when treated with ammonia solution.

7. Compare the behaviour of lead and silver compounds on charcoal before the blowpipe.

8. Tabulate the results of your experiments with lead and silver in parallel columns.

9. Ascertain whether the substances given you contain lead or silver.

10. Determine silver in an alloy of lead and silver by cupellation.

11. Study the method of determining silver volumetrically by means of a *standard solution* of ammonium thiocyanate. Determine the percentage of silver in English silver coinage.

12. Determine silver as chloride by precipitation.

13. Dissolve a known weight of lead in nitric acid, precipitate it as sulphate, collect and weigh the latter.

14. What are the chief ores of lead and silver? How are lead and silver extracted from their ores? How is silver separated from lead? How is it separated from burnt Spanish pyrites? What are the chief properties and uses of lead and of silver? State the composition of the chief alloys of lead and silver.

A NEW REACTION FOR THE ALBUMENOIDS AND THEIR NITROGENOUS AND SULPHURETTED DERIVATIVES.

By W. MICHAÏLOW.

THE substance in question is added to a solution of ferrous sulphate, treated with sulphuric acid (undiluted), and then cautiously mixed with a very small quantity of nitric acid. If nitrogen and sulphur are present there appear, along with the well-known brown rings, also rings of a blood-red colour, formed apparently at the expense of the nascent ferric oxide and of the hydrosulphocyanic acid formed simultaneously from the albumenoids of the action of the sulphuric acid. The appearance of a faint rose colour must be disregarded, as it is produced on merely mixing the reagents without any albumenoid body.—*Journal Russ. Phys. Chem. Gesellschaft*.

THE PERIODIC LAW AND THE OCCURRENCE OF THE ELEMENTS IN NATURE.

By T. CARNELLY.

THE theory concerning the occurrence of the elements in nature is based upon the periodic law. Hence it is necessary to keep in view three facts which have been mentioned by Mendeleeff in his original communication on the periodic law (*Annal. Chem. Pharm. Suppl.*, 8.)

a. That although all elements belonging to the same group evince close relations to each other, yet the elements of the even series are more closely connected with each other than with those of the odd series, and in like manner the elements pertaining to the odd series are far nearer to each other than to those of the even series.

b. In the elements of the second series from carbon to fluorine, and in the third from sodium to silicon, the rule a is often inverted. This appears evident when considering Lothar Meyer's "curve of the elements" (see "Modern Chemical Theories") which, as soon as it has reached carbon, rises until it meets sodium, instead of descending regularly, and then falls from sodium to silicon, instead of rising. The inverted character of the curve represents accurately many properties of the elements which lie within the limits above mentioned.

c. The elements belonging to the eighth group are in many respects peculiar. Without doubt they form links between the even series on the one hand and the odd series on the other,—a fact which is rendered manifest by Lothar Meyer's curve, according to which it appears quite evident that it forms a gradual transition from the even to the odd series, or rather from the descending to the ascending parts of the curve. The elements of this group are always to be found at the minimum points of the curve.

After the above necessary explanations the author proceeds to the immediate object of the communication, which he divides into three parts, that is to say:—

1. *Reducibility of the Elements*.—Elements which belong to odd series are, as a rule, readily brought into the free

condition. On the other hand, those elements belonging to the even series are only set free with difficulty.

The only exceptions to this rule are carbon, nitrogen, oxygen, sodium, magnesium, and silicon, which find an explanation in *b*, and likewise the elements of group VIII. (compare rule *c*.)

2. *Occurrence of the Elements in Nature in a Free State.*—This point, indeed, is closely connected with the reducibility already considered.

Elements belonging to the even series, with the exception of carbon, nitrogen, oxygen, and the group VIII., never occur in nature in a free condition. The elements belonging to odd series are frequently met with in this condition.

Thus we often find the following members of the uneven series in the free condition:—Copper, silver, gold, mercury, arsenic, antimony, bismuth, sulphur, selenium, tellurium; lead and tin occasionally occur in the free state in nature. Gallium, indium, thallium, and cadmium are so sparingly distributed that we can scarcely determine whether they occur in the free condition or not.

Among the elements which belong to uneven series and are yet not met with free, the only noteworthy exceptions are chlorine, bromine, iodine, fluorine, zinc, and phosphorus, whilst sodium, magnesium, aluminium, and silicon are explained by rule *b*. As for the exceptions among the even series, carbon, nitrogen, and oxygen, rank under *b*, and the elements of group VIII. under *c*.

3. *Occurrence of the Elements in Nature in a Combined Condition.*—Here the elements chlorine, bromine, iodine, fluorine, and the group VIII., must be reserved for future consideration.

The elements belonging to the odd series occur in nature ordinarily as sulphides or double sulphides (or selenides, tellurides, or arsenides), *i.e.*, in combination with a negative element belonging to an odd series, in rare instances only as oxides. Elements belonging to the even series are commonly found as oxides or double oxides (with formation of silicates, carbonates, sulphates, aluminates, &c.), that is to say in combination with a negative element belonging to an even series, and never (with two exceptions) as sulphides.

Thus elements of the even series are met with as oxides or double oxides:—

Commonly: lithium (in lepidolite, &c.), potassium (in saltpetre, felspar, &c.), rubidium, caesium, beryllium, calcium, strontium, barium, boron, scandium, yttrium, lanthanum, ytterbium, carbon, titanium, zirconium, cerium, thorium, vanadium, niobium, didymium, tantalum, oxygen, chromium, tungsten, manganese.

Frequently: nitrogen (in saltpetre), molybdenum. Seldom or never: none.

As sulphides:—Commonly: molybdenum. Very rarely, manganese (also oxygen as sulphurous acid in volcanic gases).

Elements belonging to the uneven series occur:—

As sulphides, selenides, and tellurides. Commonly: copper, silver, zinc, cadmium, mercury, gallium, indium, thallium, lead, antimony, sulphur, selenium, tellurium.

Frequently: arsenic, bismuth, tin. Never: gold, sodium, magnesium, aluminium, silicon, phosphorus (see rule *b*.)

As oxides:—Commonly: sodium, magnesium, aluminium, silicon, phosphorus (see *b*), and tin.

Frequently: zinc and copper. Rarely: lead, antimony, bismuth, and arsenic.

Group VIII. The elements of this group, save iron, cobalt, and nickel, never occur in combination. Hence we need merely take into consideration the first three elements of this group.

Iron occurs mostly as oxide, but frequently as sulphide, Cobalt occurs mostly as sulphide, but often as oxide.

Nickel is almost always met with as sulphide and arsenide, and very rarely as oxide.

Iron, the first member of the triad, much resembles the elements of the even series, whilst nickel, the last member, approaches closely to the elements of the odd series. This shows in a very striking manner that in the group VIII. we have a gradual transition from the even to the odd series.

The halogens, chlorine, bromine, iodine, fluorine, the most electro-negative elements, occur in nature in combination with the most electro-positive metals, as chlorides, bromides, iodides and fluorides, and (if we omit certain metallic oxy-chlorides and sulpho-chlorides) in combination with oxygen or sulphur.

The above-mentioned facts may be thus expressed with reference to Lothar Meyer's curve of the elements.

Elements whose place is on falling parts of the curve are difficult to reduce, and never occur in nature in a free condition, or in combination as sulphides, but always in combination with oxygen as oxides or double oxides (silicates, sulphates, carbonates, &c.); whilst the elements whose place is on ascending parts of the curve are easily reduced, and occur almost always—more or less—in a free condition, and also in combination with sulphur, and very rarely with oxygen.—*Berichte der Deutsch. Chem. ischen Gesellschaft.*

ON THE DIAMOND-BEARING ROCKS OF SOUTH AFRICA.*

By Professor H. E. ROSCOE, LL.D., F.R.S., &c.

THE communication opens with an account of the general features of the diamond-bearing region, based chiefly on the papers of Mr. Dunn and Mr. W. H. Huddleston, with special reference to the theory of the volcanic origin of the "pipes" in which the diamonds occur, first advanced by Prof. E. Cohen, of Strasburg.

The strata at Kimberley Mine (from which the specimens referred to in this paper were kindly sent by Mr. Loewenthal) are then described; two shafts which have been sunk there—one in the "pipe," the other in the shale near it—passed through the following strata:—

(1) "Pipe."

Red sand	3 ft.
Tufaceous limestone	15 "
Soft yellow earthy diamond rock ..	30 "
Soft blue diamond rock, proved to ..	282 "
Total excavated	330 "

(2) "Outside the Pipe."

Red sand	3 ft.
Tufaceous limestone	5 "
Yellow shale	20 "
Black carbonaceous shale	10 "
Two thin bands of black dust in shale	1 "
Black shale	236 "
Dolerite	2 "
Total excavated	277 "

The diamonds are found in the yellow and blue "stuff" along with garnets, mica, bronzite, ilmenite, pyrite, &c., and are separated by washing the broken-up earth in sluices similar to those used in gold mining. The annual value of the diamonds from Kimberley is said to be £3,750,000, and the total amount raised since 1870 to reach the enormous sum of £40,000,000.

The specimens forwarded were as follows:—

* A Paper read before the Manchester Literary and Philosophical Society, October 21, 1884.

I. A compact greenish-grey rock, labelled "The Hard Rock."

II. A compact rock of dull rusty brown colour, labelled "Layer of Ironstone."

III. A friable earthy rock of greenish-blue colour in which the diamonds occur.

IV. A mixture of several minerals, in pieces about the size of a pea, labelled "Coarse heavy Deposit, Kimberley blue ground."

V. A similar mixture, in much finer grains, labelled "Fine heavy Deposit, Kimberley blue ground."

Sections of the first three specimens were cut and sent to Professor Bonney, F.R.S. An abstract of his report upon them is as follows:—

I. This rock is an actinolitic diabase, and could not be distinguished from specimens obtained from various British localities, where rocks of paleozoic or greater age occur.

II. This is rather a decomposed basalt belonging to the same group as I., but probably from a different mass and altered in a different way.

These two specimens were analysed with the following results:—

	I.	II.
SiO ₂	58.03	48.47
Al ₂ O ₃	15.53	16.33
Fe ₂ O ₃ ..	—	9.85
FeO	9.64	1.65
MnO	4.54	0.48
CaO	6.99	8.43
MgO	4.55	7.38
Loss on ignition....	—	7.44 { 5.55% at 120° 1.89 at red heat

It will be observed that these have a very similar composition, the second differing from the first in containing a considerable percentage of water, and in the fact that its iron is almost entirely in the peroxidised condition.

III. Of this specimen, the diamond-rock itself, Prof. Bonney reports as follows:—

"No. III. is evidently a breccia composed of a compact serpentinous rock, of dark colour; the fragments and the paste in which they are embedded apparently being similar in character; one or two scales of bronzite and a black mica are scattered in the matrix with some small grains of a black mineral of irregular fracture, and one of a brown mineral. Microscopic examination does not enable me to come to a definite conclusion as to the nature of this earth. So far as I can make out, the ground mass consists of a very minute aggregation of doubly refracting crystallites of no very definite but rather fibrous shape, and specks of ferrite. Here and there (and these patches have rather definite outlines and an approach to crystal form) the colouring mineral is opacite. Frequent cracks appear to traverse the slide, occupied by a clearer mineral similar to that disseminated through the slide. There is a small crystal resembling a hydrous bronzite. I cannot recall ever having seen a slide exactly of this character, but I have several that throw some light upon it, and I have a very strong suspicion that the fragments have been a basalt-glass or an olivine-glass, more probably the latter, converted by hydration into a kind of serpentine. As a rule the peridotites appear to be deep-seated rocks, but it is quite possible that there may be occasional exceptions. I do not see anything specially characteristic of a breccia of volcanic origin, but there is nothing incompatible with this."

An analysis of the earth gave the following numbers:—

SiO ₂	46.16
Al ₂ O ₃	10.00
FeO	6.71
MnO	0.34
CaO	3.84
MgO	16.63
Loss on ignition.. .. .	15.43 { 9.75 at 120° 5.68 at red heat

It was noticed that a peculiar smell, somewhat like that of camphor, was evolved on treating the soft blue diamond-earth with hot water, and an attempt was made to isolate the aromatic body. A quantity of the earth was powdered and digested with ether. On filtering and allowing the ether to evaporate, a small quantity of a crystalline, strongly aromatic body was obtained. The substance was very volatile, burned easily with a smoky flame, and melted at about 50° C.

The presence of this carbonaceous substance in the diamond matrix is most interesting, and tends to confirm Professor Cohen and Mr. Dunn's hypothesis that the carboniferous shales that are penetrated by the diamond-bearing "pipes" have been the source of the carbon which is now found in the crystalline form as diamond. It is unfortunate that the quantity of the substance obtained was too small to admit of a full investigation of its composition and properties.

The results of the examination of the remaining specimens, which are samples of the deposit obtained by washing the "stuff" at Kimberley, are interesting, as showing the minerals which accompany the diamond in the matrix:—

100 grms. of the "fine heavy deposit" contained—

	Grms.
Garnet	10.76
Bronzite	3.64
Ilmenite	54.80
Pyrites	0.14
Mica	0.20
Limonite	16.12
Pieces of the rock which have escaped disintegration with some limonite ..	10.84
Coarse sand—a mixture of all the above..	3.46
	99.96

The composition of the limonite and bronzite are given below:—

	Limonite.	Bronzite.
SiO ₂ per cent	6.93	55.17
Al ₂ O ₃	6.85	2.95
Fe ₂ O ₃	71.40	—
FeO	—	5.76
CaO	0.71	3.64
MgO	0.86	32.83
H ₂ O	12.53	—
	99.28	100.35

A CONSTANT LEVEL STEAM-OVEN AND STILL.

By ALEX. J. ATKINSON.

THE accompanying sketch of a combined steam-oven and distilled water apparatus, so arranged as to be left to itself for a long period of time without the risk of the boiler going dry, may perhaps be of interest to many chemists, and it is hoped that a few words only will be necessary to describe its working. The steam-oven, A, is of the ordinary construction, but is fitted at the side with a tube connecting it with the condenser, B. Heat is applied to A by means of a radial burner, connected with the gas supply by metallic tubing; the steam generated circulates round the drying chamber, escapes through the copper tube, C, thence through block-tin worm, and falls as distilled water in the receiver, D. The cistern, E, fitted with a Mariotte's tube, holds cold water, which falls through the tube, F, enters the condenser, where it rises slowly, absorbing heat from the condensing-worm, until it reaches the tube leading to the boiler at a high temperature. For a cistern, an eighteen-gallon ale cask, supported on a stool, has been found to answer admirably, having the advantage of

holding sufficient water on the top to secure the two corks being air-tight. By a suitable adjustment of the Mariotte's tube, M, the rate of flow of the water can be so regulated that the level of the water in the condenser is constant, or, if desired, allowed to drop slowly into the waste pipe, while the water evaporated from A is replaced by water already near boiling. In practice it has been found necessary to allow the water to waste at the rate of about two drops per minute, the eighteen gallons lasting for over seventy-two hours, during which time ten to eleven gallons of distilled water are collected. When this apparatus was first fitted up in this laboratory it was intended to have connected the condenser directly with the town water supply, but as the water works' authorities would sanction no such connection we had recourse to the cistern, with the satisfactory result that we are in this respect quite independent of the caprice of the water-works' turn-cock. The several connections are made by union joints at *u u* to allow the apparatus to be taken to pieces and the boiler freed from scale. The whole apparatus may be supported upon a strong shelf, which should be protected from the heat of the burner by means of slates or asbestos

indicate that every element moves with a velocity independent of the nature of the acid residue with which it is associated, from which physicists conclude that an electrolyte contains a great number of free elementary atoms and free acid radicles,—an idea which is repugnant to the chemist, as such free atoms could not remain in the solution producing chemical decomposition.

ROYAL DUBLIN SOCIETY.

ON Monday, the 18th, at the evening meetings the following papers were read in the Physical and Experimental Section:—

"On the Aspect of the Planet Mars," by Mr. OTTO BOEDDICKER. It described a series of observations made with a three-foot reflector at Lord Rosse's Observatory.

"On the Volatilisation of Zinc from German Silver Alloys," by A. R. HASLAM. He stated that his experiments in connection with the volatilisation of zinc from German silver were undertaken first to find the rate at which the alloy loses zinc by heat, and secondly the

millboard. With this arrangement bulky precipitates may be allowed to remain in the steam-oven all night and found ready for further treatment next morning.

44, Loudoun Square, Cardiff.

PROCEEDINGS OF SOCIETIES.

UNIVERSITY COLLEGE, LONDON,
CHEMICAL AND PHYSICAL SOCIETY.

Thursday, October 23.

DR. MORLEY gave an account of the researches of Hittorf and Kohlrausch "On the Motion of the Ions in a Liquid undergoing Electrolysis." Their experiments seem to

action of the nickel constituent on retarding this volatilisation. Three specimens of German silver were obtained and analysed. Their composition being then known they were heated for six hours in a current of hydrogen, weighings being taken of the alloy at the end of each hour. The results thus obtained show that the greatest amount of loss occurred in every case during the first hour of experiment, after this there is a rapid decrease in the loss sustained by the alloy. The effect of the nickel contained in the alloy on the volatility of the zinc is very striking. It was found that the alloy containing the most nickel was also the one in which the volatilisation of the zinc proceeded slowest. A specimen of brass containing the same percentage of zinc as the German silver alloys, when heated for the same time, lost nearly double the quantity of zinc. This would also tend to show that German silver appears to have much more the character of a perfect

alloy than brass. The conclusions drawn from these experiments are that the nickel retards the volatilisation of zinc in German silver alloys, and that this volatilisation is determined by the proportion of nickel present.

In the Natural Science Section, Prof. HADDON read a paper on a "*New Species of Halcampa from Malahide.*"

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, October 7th, 1884.

Professor W. C. WILLIAMSON, F.R.S., President,
in the Chair.

"*The Pink Sun-Glow.*" by ALFRED BROTHERS, F.R.A.S.

In the *Photographic News* for September 12th, Mr. C. RAY WOODS writing from the Rifel, in Switzerland, where he has been stationed for some months for the purpose of photographing the corona, says, "But the most interesting sight to me . . . was the remarkable haze round the sun. A pink glow extended for some twenty degrees around the sun, and at the extremity of this glow was a vivid and well-defined red ring . . . On every clear day we have had here this peculiar haze has been more or less apparent."

In the *English Mechanic*, a few weeks since, a letter on the same subject appeared, written, I think, from Canada, and gave very much the same description of this very curious phenomenon.

As this pink glow has attracted attention from places widely separated, it may be of some interest if I state that many times during the present year I have noticed the same effect. As early as January I saw at mid-day the pink tint extending to at least 15° or 20° from the sun. I saw the same thing again from the East coast of Anglesea about 5 o'clock in the afternoon of the 5th July, and at the same time some of the clouds near the pink part of the sky showed the most beautiful nacreous tints, this effect lasting for a few minutes only.

About the end of August, and lasting for at least an hour after sunset, this pink tint was visible as a broad band of light, bounded at right and left by a green tint exactly complementary to the pink. Taking the place of the sun as a centre this pink light had about the breadth of the zodiacal light and extending in the same direction as when that phenomenon is seen in the western sky. By this I do not wish it to be inferred that I think the zodiacal light has anything to do with the matter, and merely refer to it to indicate the appearance of the pink light on the evening named. On the following morning there was a fainter pink tint in the sky near the sun, and several times since the same appearance has been visible at different times of the day.

It is a singular fact that some persons fail at first to see the pink colour.

It may be stated that the pink colour of the sky is not always visible when the atmosphere seems favourable for its appearance, the neighbourhood of the sun having the usual grey tint. The times when the pink colour is best seen are when there are masses of white cloud near; the colour of the sky then becomes most apparent.

Since writing the above paragraph has appeared in "*Knowledge*" of September 26th, in which the writer calls attention to an unusual glow around the sun, and suggests that the effects may be cosmical and a real appendage of the sun. That the effect referred to is not connected with the sun seemed to me easy to prove, as, if belonging to our atmosphere, a clear moonlight night might reveal the same effect, but in a fainter degree. This supposition has proved to be correct, as on the evening of October 3rd there was an exact repetition of what I had so often seen during the year at mid-day, and at other times of the day. The coloured sketch shows very roughly the

effect when the sun is seen partly surrounded by cloud, and it may be taken to show sunlight or moonlight allowing only for the different intensities of the light.

The pink glow is not persistent on any day when it may be visible. The colour may be as bright as I have attempted to show it for half an hour or more, and then all colour may quickly disappear and only the usual grayness surrounding the sun may be visible; and again the pink colour may reappear as quickly as it vanished. The colour is often seen to increase in intensity in a few moments, and always appears of a darker tint if the sun is obscured during the observation.

Mr. R. F. GWYTHER, M.A., described an Aurora seen on the night of September 13th, off Rimouski, on the St. Lawrence. When first seen the arch passed through the zenith, and stretched to the horizon on either side. The phenomenon remarked upon was that in the final stage in place of the usual streamers the light flashed across the sky, presenting the appearance of a border to hanging drapery (represented by dark sky). Of this border, the uppermost part was distinctly green in colour, whereas the lower fifth or sixth part (in breadth) was distinctly purple.

Ordinary Meeting, October 21st, 1884.

Professor W. C. WILLIAMSON, F.R.S., President,
in the chair.

"*Note on the Visibility of the Moon during Total Lunar Eclipses.*" by JOSEPH BAXENDELL, F.R.S., F.R.A.S.

It has been generally supposed by astronomers since the time of Kepler that the visibility of the moon during total lunar eclipses is due to light refracted by the earth's atmosphere; but in considering the phenomena of the late eclipse, and endeavouring to estimate the amount of light which could be bent by the atmosphere of the earth into its shadow. I was led to doubt whether this light was sufficient to illuminate the eclipsed moon to the extent observed in many total eclipses; and this view appeared to me to be supported by the faintness of the illumination of the dark part of the moon by the reflected light from the whole, or nearly the whole, of the disk of the earth a little before or after new moon. This illumination is not much greater than that observed in some total eclipses, but it seems difficult to suppose that the light of the narrow ring or thread of sunlight round the earth's disk as seen from the moon, and greatly subdued as it must undoubtedly be by passing through the earth's atmosphere, could be comparable with the light from an almost fully illuminated hemisphere of the earth, and it therefore became necessary to inquire whether any other source existed which would contribute light sufficient to render the moon so distinctly visible as it sometimes appeared during total eclipses.

At the time of maximum phase during the late eclipse, or when the centre of the moon was nearest to the central line of the earth's shadow, the apparent diameter of the earth as seen from the moon would be $1^\circ 26' 41''$ greater than that of the sun, and therefore, besides the whole of the disk of the sun, the whole of the lower corona, or corona proper, would be covered by the earth, but according to the statements of observers of total solar eclipses, the outer corona extends to a much greater distance on each side of the sun than the semi-diameter of the earth as seen from the moon, and from the estimations of the brightness of this uncovered portion by some observers it seems probable that to it may be due a not inconsiderable portion of the light which renders the moon visible when immersed in the earth's shadow; and this probability is increased when it is considered that the intensity of the light of the corona, as seen from the earth, is much reduced by the absorption of the atmosphere, an effect which would not be produced in the case of the moon.

"On the Diamond-bearing Rocks of South Africa," by Professor H. E. Roscoe, LL.D., F.R.S., &c. See page 243.

NOTICES OF BOOKS.

The Science of Agriculture. By F. JAMES LLOYD, F.C.S., Lecturer on Agriculture, King's College, London. London: Longmans, Green, and Co.

The title of this book, if not absolutely incorrect, is unguarded. "Science," according to the highest authorities on method, merely notes, declares, and co-ordinates natural phenomena, and traces them to their causes. To give directions for producing any results is the duty of industrial art. That Mr. Lloyd is fully aware of this distinction may be gleaned from the preface, in which he speaks of a work "from which they (farmers) could learn some of the bearings of modern science upon their art." It is the more to be regretted that he did not adopt some such title as "the scientific principles of agriculture."

In his introduction he complains, and not without grounds, that "agriculture alone, of all the arts cultivated in England, is still supposed to be best learnt by practice without either the previous or simultaneous study of the principles upon which it is founded." This prejudice he ably combats. He mentions as a natural result of the prevailing ignorance that "many farmers are ignorant of the value of the analysis of a manure, and buy anything so long as it has a powerful smell and is cheap."

This is error No. 1, and it is naturally followed by No. 2. "Finding but little benefit from the use of their artificial manure, they jump to the conclusion that artificial manuring is altogether a mistake."

The author does not overlook,—though he mentions it without any marks of regret or any inkling of its ultimate consequences—the decrease of arable land and the increase of "permanent pasture." Considering that this change means the depopulation of the agricultural districts, inventors surely ought to put forth all their efforts so as to make farming, as distinguished from grazing, more profitable.

In a well written chapter on the origin of soils, in which we find a brief abstract of Darwin's researches on the soil-forming operations of the earthworm, Mr. Lloyd expresses a very justifiable regret that we have as yet no geological map of the surface of Britain. Hence, owing to the frequency of transported soils the ordinary geological maps are of little use to the farmer.

As the essential mineral constituents of a soil the author enumerates three—lime, potash, and phosphoric acid. He does not, however, with Ville, recommend the addition of lime in all cases. On the contrary, after giving the analysis of certain soils, he remarks that they "possess sufficient lime, and to add more would be a waste of money."

In the chapter on the physical properties of soils a common confusion is pointed out. Sandy soils are really heavier than clays—a cubic foot of the former weighing more than the same bulk of the latter. Yet farmers are in the habit of calling sandy soils light, because they are easily worked, and clay soils, for the contrary reason, heavy.

The relation of different classes of soils to heat are fully explained. The fact is cited that at noon, on a July day, the temperature of the air being 90°, a thermometer placed about an inch below the following soils gave these readings:—Quartz-sand, 126°; garden soil, 115° F.; yellow sandy clay, 100° F., and chalk soil, 87° F.

The presence of an excess of moisture in keeping down the warmth of a soil, and "indirectly, therefore, its plant producing power," is fully admitted.

Among the physical causes of barrenness we find mention of ferruginous pans, such as may be seen in the

neighbourhood of Wellington College. Iron sulphide and sulphate (ferrous) the author considers as not merely injurious in themselves, but as indicators that the soil is not sufficiently aerated.

In discussing the improvement of soils Mr. Lloyd decidedly traverses the notion of Sir J. B. Lawes that "profitable agriculture involves a slow but continuous exhaustion (of the fertility) of the soil."

The loss of combined nitrogen in the drainage-water issuing from the soil is duly recognised. According to an analysis by Professor Frankland, here quoted, such drainage water contained 21.03 parts per million ($=1.472$ grains per gallon) of total nitrogen, of which 20.40 was in the state of nitrates and nitrites. Hence it is recommended that the land should never be left without a crop longer than is absolutely necessary, as the drains discharge much less water whilst the land is under crop.

We perceive a slight discrepancy: In Prof. Frankland's analysis just referred to we find that the drainage waters contain 0.08 part per million of ammonia. But two pages further we read:—"As no traces of ammonia can be discovered in drainage waters, &c."

In speaking (p. 111) of the improvement of soils, Mr. Lloyd writes:—"If lime, however, is at times beneficial it is not always so, and even upon land where in moderation it would be advantageous, its application is capable of being carried to excess." Soils containing 2 per cent. of lime the author holds will not require liming except for special purposes. Gypsum, it is here stated, is used as a means of giving lime to grasses, clovers, and mustard, but "apart from the lime which it contains there are no facts to show that it possesses peculiar properties." Is there any reason why, as regards the use of gypsum, the experience of British farmers should differ so greatly from that of their neighbours across the Channel?

In considering farmyard manure we find Dr. Voelcker's analysis quoted, in which the total nitrogen = ammonia 0.780, whilst the total phosphate of lime is given as 0.955 per cent. To these figures we may have occasion to return.

The result of liquid manure is said to have been "not a success, either in the crops or financially."

Concerning the utilisation of human excreta, especially in the form of sewage, Mr. Lloyd speaks unfavourably:—"As no system has yet been discovered of taking out of solution the valuable portion of the sewage, viz., its nitrogen, consequently all sewage manures are of necessity poor manures, and seldom worth the price given for them."

To this somewhat rash statement may be opposed the analysis of a sewage manure by Dr. Voelcker:—"Containing nitrogen = ammonia 3.41 per cent, and phosphate of lime 2.35 per cent." If no means has yet been devised of taking out of sewage its organic nitrogen, whence came the above nitrogen? Further, if this manure, which contains nearly five times as much nitrogen as farmyard manure (see Dr. Voelcker's figures above cited), and more than twice as much phosphate of lime, is a "poor" manure, what must farmyard manure be?

A little further Mr. Lloyd says:—"The most recent and one of the best methods of utilising the sewage farm is in the cultivation of vegetables. Many of the most flourishing market-gardens around Paris are sewage farmed." These gardens certainly produce heavy crops of strawberries, lettuces, cabbages, &c. But all these come in late, when the markets are well stocked, and prices rule low. This is exactly what must happen if the principles which Mr. Lloyd has laid down on the temperature of damp soils as compared with dry soils are correct. Hence it is only in tropical and subtropical regions where there is heat enough and to spare that irrigation really works well.

The author's remarks on ensilage are excellent, and as far as England is concerned will go far to dispel the nimbus in which this novel process has been enshrouded. He shows that silage is less valuable than hay, and adds "that the farmer must still endeavour to make hay while the sun

shines." If the sun does not shine he can make hay of superlative quality by means of the Gibbs drying machine.

We regret that we cannot carry further our examination of this excellent work, and can merely express our conviction that it will be productive of the greatest service to the British farmer.

Annual Report of the Board of Regents of the Smithsonian Institution, showing the Operations, Expenditures, and Condition of the Institution for the year 1882. Washington: Government Printing Office, 1884.

THIS report, like the proceedings of great public bodies in most countries, has the disadvantage of appearing considerably after date. Hence the records of "recent scientific progress," though ably drawn up, have lost much of their interest. The summary of chemical discovery is from the pen of Professor H. Carrington Bolton. He notes as a proof of the increasing activity in research that "the fifteen principal chemical journals of America, England, France, and Germany publish annually about 18,000 pages; in this rough estimate journals of physics and transactions of societies are not included, and both classes of serials contain much chemical matter.

Dr. Bolton refers to the syntheses of tyrosine and uric acid, to the activity shown in the revision of the organic weights, and to the progress made in unravelling the knotty problem of the rare earths in cerite, samarskite, and gadolinite.

Professor G. F. Barker, of the University of Pennsylvania, reports on physics. He remarks that of the four hundred and thirty memoirs which he has abstracted in drawing up his report, two hundred and four, or nearly one half, refer to subjects connected with electricity and magnetism.

Mr. Cleveland Abbe furnishes an elaborate, we might even say voluminous, report on meteorology, a subject which, from its obvious practical importance, commands a great and increasing interest in America. His abstracts have the disadvantage of being drawn from one sole source.

The general activity of the Smithsonian Institution is great and most satisfactory.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 18, November 3, 1884.

Conditions of Equilibrium of a Liquid Plate submitted to Electro-magnetic Actions.—G. Lippmann.—Whatever may be the form of the space occupied by the liquid in the distribution of the electric currents there is required for an equilibrium that this space should be limited by partitions arranged as sections, so as to render uniform the conjugated function of the electric potential. The law of the pressures developed along the outline is the following:—These pressures have the conjugated values of those of the electric potential along the outline.

Portable Electric Lamps.—G. Trouvé.—This paper requires the two accompanying illustrations.

Decomposition of Copper Oxide by Heat.—E. J. Maumené.—The author criticises the paper of MM. Debray and Joannis, and contends that when the temperature is raised to the point of fusion a new chemical action is set up. The cuprous oxide formed by the heat combines with the cupric oxide not yet decomposed, so as to form a saline oxide. In a former paper submitted to the

Academy of Sciences, April 8th, 1844, he gave various proofs that Cu_2O_3 is a compound. This oxide on dissolving in acids gives a brown colour, whilst cupric oxide gives a blue and cuprous oxide a colourless solution. Cuprous oxide, if dissolved in melted glass, gives a colourless mass, cupric oxide a fine green, but Cu_2O_3 that splendid red so much admired in the windows of old churches.

Biedermann's Central-Blatt für Agrikultur-Chemie, Vol. xiii., Part 3.

Relative Heat-Conductivity of Different Soils.—Dr. F. Wagner.—The author's conclusions are that the heat-conductivity of a soil is so much the greater the more densely its particles are packed together. The difference thus occasioned is the more considerable the higher the proportion of water. In a dry soil the heat conduction rises with an increase in the size of the particles of the soil. Water increases the conductivity of the soil considerably, the more the larger its proportion in the soil, other circumstances being equal.

Influence of the Stratum of Vegetation and of Shade upon the Physical Properties of the Soil.—Prof. E. Wollny.—Soil covered with living herbage or dead vegetable matter (leaves, straw, dung, wood, &c.), is colder in summer and warmer in winter than bare soil under otherwise similar conditions. The difference of temperature is greatest in summer and least in spring and autumn. Bare soil heats more quickly in spring and cools more quickly in autumn than that covered with living or dead vegetable matter. The fluctuations of temperature are much smaller in covered than in bare soil.

On Manuring with Sulphuric Acid.—Dr. H. Fresenius.—Schröder, of Berlin, has some time ago advised farmers to apply sulphuric acid in a direct manner to their fields. Fresenius points out that a dressing of sulphuric acid might render phosphates soluble in a soil free from lime, but that in general no action would be visible. In experimental trials the result never covered the cost of the acid.

Manuring with Nitrogen and Phosphoric Acid for Barley and Oats.—Prof. Maercker.—With barley phosphoric acid was most effective, whilst nitrogen had little action. With oats the result was reversed.

Manurial Experiments with Superphosphate containing Crude Ammonia.—Prof. Wollny.—The superphosphate was prepared by Bolton and Wanklyn's process, the gas, freed from tar, being allowed to pass through chests in which the superphosphate is supported on hurdles. Superphosphate thus prepared containing 0.7 to about 1 per cent ammonium sulphocyanide, used in the ordinary proportion of 500 kilos. per hectare has upon almost all plants the same effects as ammoniacal superphosphate containing the same proportions of nitrogen and phosphoric acid, but free from sulphocyanides.

The Physiology of the Formation of Milk.—Hans Thierfelder.—Serum-albumen is probably the material from which casein is formed by a ferment present in the milk-glands.

Influence of Unpeeled Cotton Seed Cake upon the Production of Milk.—Prof. M. Sievert.—The result of the author's experience was unfavourable.

Researches on the Influence of Heat and Light upon the Development of Plants.—Prof. Hellriegel.—At a constant temperature of 40° in the soil the roots of barley cannot develop themselves. A constant temperature of 30° is not destructive, but decidedly injurious. A constant temperature of 20° is the best adapted to the wants of the plant, but one of 10° is not distinctly injurious.

On Blue Milk.—Dr. Schmäger. The author ascribes blueness in milk not always to bacteria but to the presence of iron.

Examination of the Elementary Composition of Certain kinds of Wood in Connection with Calorimetric Experiments on their Combustibility.—E. Gottlieb.—From the *Journal für Praktische Chemie*.

Cosmos les Mondes.

No. 6, October 18, 1884.

This number contains no chemical matter.

No. 8, November 1, 1884.

Determination of Temperatures at a Distance by Means of the Telephone.—Dr. Lenz.—Let there be two stations, M and N, connected by two wires, one of iron and the other of silver, soldered together at both ends. If the soldering of the station M is at a different temperature from that at the station N a thermo-electric current is produced in the wires. If a telephone and an interruptor are introduced into the circuit the telephone will speak until the moment when the observer at N has raised or lowered the temperature of the soldered junction so as to render it identical with the other at M. The thermo-electric current ceases, and the telephone is silent. The exactitude of the method depends on the precision with which we determine the instant when the telephone ceases to speak—not an easy thing, for a certain resonance remains in the apparatus after the equalisation of the temperature at the two extremities. In a first series of experiments, the stations M and N being only one metre removed from each other, Dr. Lenz determined the difference of temperatures to from 1-100th to 1-200th of a degree. He concludes that with wires of iron and silver of 2 millimetres in thickness the determinations might be made at a distance of 5 kilometres, and with wires of bismuth and antimony the distance might be carried to 25 kilometres.

No. 9, November 8, 1884.

The Pollution of the Seine.—An anonymous writer suggests that the fumes and waste waters of the works of St. Denis may destroy disease-germs. It is proposed that sewage and industrial refuse should no longer be poured into the Seine, but turned into the plain of Achères. M. Després affirms that the water of the Seine contains above Paris 12 per cent (?) of microbia, and below the city 17 per cent, and recommends that towns above Paris should be prevented from turning their sewage into the Seine.

The Bouquet of Cider.—The cider-makers of Normandy are said to add pond-water to the crushed apples, and even a little of the drainage of dunghills, in order to hasten the fermentation and develop the bouquet of the cider.

The Waters of Paris: a New Process for the Analysis of Water.—Dr. Ménard.—The author complains of the polluted character of the water, rich in fecal matter, which the inhabitants of Paris have to drink. River-water is supplied at the cost of 60 francs per cubic metre. The spring-water is charged at 120 francs, and, though originally pure, is contaminated by passing through dirty pipes, and when scarce is often enriched with more or less Seine water. The new method of analysis is the gelatin process.

Constitution of Clouds.—M. le Goarant de Tromelin.—The author denies that clouds and fogs consist of hollow spheres of water.

No. 10, November 15, 1884.

Liquefaction of Gases.—Dr. Tommasi.—From a note inserted in the "Antologia" di G. P. Viessieux (vol. xxvii., 1827, Florence) it would appear that the first to liquefy air and hydrogen was Perkins, who had at command a machine exerting a pressure of 2000 atmospheres. Viessieux does not state his authority. Dr. Tommasi

raises the important question whether the air operated on was absolutely dry.

History of the Germ Theory.—It appears that the celebrated Athanasius Kircher, in his work on the plague (*Scrutinum physico-medicum Contagiosa Luis quæ pestis dicitur*), published at Rome in 1658, attributed the origin of epidemic diseases to germs, or, as he called them, animalcules. He contended that each kind of putrefaction gives rise to a special virus which produces a definite species of malady.

Journal de Pharmacie et de Chemie.

Series 5, Vol. x., November, 1884.

The Volumetric Determination of Manganese.—M. Schlagdenhauffen.—An examination of the method of Leclerc. The author shows that it is essential to operate on a concentrated solution, with the aid of heat and in presence of an excess of nitric acid.

Second Memoir on Flour.—M. Balland.—A continuation, nor susceptible of useful abstraction.

MEETINGS FOR THE WEEK

MONDAY, 24th.—Medical, 8.30.

Geographical, 8.30.

London Institution, 5.

(CARR'S PATENT),

BAILEY'S LABORATORY MILLWith Wedgwood-ware Pan and Runner. For Hand or Power.
*Suitable for Levigating Chemicals, Drugs, Powders, Minerals, Paints
and for General Laboratory Purposes.*Approved by some of the most eminent Chemists, and awarded
the Silver Prize Medals of the Manchester and Liverpool, and the
Middleton Agricultural Shows.

The chief feature in this machine is, that although it can be turned with ease, it has immense frictional power for levigating purposes. This is caused by the runner being driven at a much greater speed than the bowl. The surfaces are clean, smooth, and durable.

Dia. of Bowl, 18 ins. Price, £11 nett cash, delivered in Manchester. This Levigator is also suitable for triturating and mixing Medicines, Vegetable Powders, Ointments, Paints, Sugar, Salt, Spices, Herbs, Mineral Ores, &c., and will grind the coarsest emery into a nearly impalpable powder in a few seconds. The Pan can be tilted for emptying.

W. H. BAILEY & Co., Albion Works, Salford, Manchester.

A RE-DETERMINATION OF THE ATOMIC WEIGHT OF CERIUM.

By HENRY ROBINSON, B.A.,
Assistant to the Professor of Chemistry in the University of Cambridge.

HAVING worked a good deal during the last few years on the preparation of pure compounds of the cerium and yttrium metals, I was led to seek some method by which I might obtain their anhydrous chlorides in such a state of purity that it would be possible to make from them re-determinations of the atomic weights of the metals. In April last year, I succeeded in preparing anhydrous cerium chloride (and in this paper I shall confine myself to that metal) by passing dry hydrochloric acid gas over what I may call air-dry cerium oxalate, heating it at first gently, so as not to char the oxalate, and then, as the operation proceeded, increasing the temperature to a full red heat. The chloride so obtained was perfectly white, and, when thrown into water, dissolved with a hissing noise and a considerable evolution of heat, to a clear and colourless solution. I obtained the chloride so easily on the first attempt, I supposed I could repeat the experiment at will, but such did not prove to be the case, and, being much occupied with other duties, not much more was done towards the attainment of my object until the commencement of the present year. I had previously prepared a considerable quantity of pure cerium oxalate, in the following manner, from a crude yellow sulphate obtained from Schuchardt. It contained much didymium and a smaller quantity of lanthanum, besides other metals. About 250 grms. of the crude material were taken at once, and the lumps were broken down in a mortar, then it was transferred to a flask of about 3 litres capacity and 100 cub. centims. of strong nitric acid were added to it, afterwards gradually water until the bulk was about 3 litres. After shaking frequently for a day, it was allowed to settle all night, and next morning the clear liquid was syphoned into another flask. Any undissolved was left in the flask to go on with the next lot, to be treated in the same way. The clear liquid which had been syphoned off was saturated with sulphuretted hydrogen, then filtered from the reddish brown precipitate thrown down. To the filtrate oxalic acid was added, until there was no further precipitate formed; the precipitated oxalate was allowed to settle down, and the clear liquor was syphoned off and thrown away. The oxalate was then well washed with water made slightly acid with nitric acid on a filter, using a Bunsen pump, dried over a water-bath and then ignited. The oxides thus obtained were dissolved in nitric acid; the solution was transferred to a dish and evaporated down on a water-bath to a thick syrup, until it would scarcely pour from the basin. It was then transferred to two large beakers, each containing 1500 cub. centims. of boiling dilute sulphuric acid—20 cub. centims. of sulphuric acid, sp. gr. 1.84, in 1000 cub. centims. of water—well stirred and allowed to settle. There was a considerable precipitate of basic cerium sulphate; after it had settle down well, the clear liquid was syphoned off, precipitated with oxalic acid, and the above process was exactly repeated to obtain more of the basic cerium sulphate. After syphoning off as much as possible of the clear liquid from the second precipitate, both precipitates were thoroughly drained together on a filter at a Bunsen pump, and washed with dilute sulphuric acid. The washings and the clear liquid from the second precipitate were precipitated with oxalic acid, and the oxalates obtained, principally of didymium and lanthanum, were reserved for further treatment.

Bunsen's process was now to dissolve the basic sulphate, and re-precipitate as such, repeating the process until he obtained a small quantity of the pure sulphate; but I found it better from this stage to adopt Gibbs's method of treatment with lead peroxide. Accordingly I dissolved the washed and drained basic sulphate in strong nitric acid, added to the solution some lead peroxide, and boiled the whole until a small quantity of the solution diluted with water gave no precipitate with barium nitrate. If properly done, the cerium was now peroxidised and in solution as nitrate. I now allowed the excess of lead peroxide and the lead sulphate formed during the process to settle down, then decanted the clear liquid into an evaporating basin, and heated it on a water-bath until it became a thick syrup. This syrup was treated with boiling dilute nitric acid—25 cub. centims. of strong acid in 1000 cub. centims. of water—by which the cerium nitrate was decomposed into a basic nitrate which generally settled down readily, leaving only a small quantity of cerium in solution. The clear liquid was syphoned off and saved for further treatment. The basic nitrate was thrown on a filter, drained at the pump, and slightly washed with dilute nitric acid. It was removed from the filter-paper, transferred to an evaporating basin, and thoroughly heated on a water-bath until quite dry and hard, then broken up with a pestle in the dish, again set on the water-bath and heated, and, while there, drenched with boiling dilute nitric acid of the same strength as that used before. It was kept hot on the water-bath for some time and constantly stirred, then, after standing a short time, the greater part of the nearly clear supernatant liquor was poured away and the precipitate transferred to a filter, where it was drained by means of the pump and thoroughly washed with dilute nitric acid until some of the basic nitrate taken from the filter and dissolved in hydrochloric acid, so as to make a very concentrated solution, showed no trace of the didymium absorption bands. When this point was reached the basic cerium nitrate containing a little lead was removed from the filter and put in a flask, hydrochloric acid was added, and the whole heated on a water-bath until the nitrate was converted into chloride and dissolved. The greater part of the excess of hydrochloric acid was evaporated away, as the oxalate of cerium, to be obtained subsequently, was found to be rather soluble when much of that acid was present. The cerium chloride was dissolved in water and the solution saturated with sulphuretted hydrogen, then filtered from the lead sulphide; the filtrate was boiled to get rid of the sulphuretted hydrogen, and again filtered to remove the small quantity of sulphur which separated out. The warm solution was then saturated with chlorine, and left to stand all night, so that if any iron was present it might be peroxidised. The cerium was then precipitated from the acid solution by well purified oxalic acid; the oxalate was allowed to settle down thoroughly, and the clear liquor was poured away. After several washings by decantation, using a dilute solution of hydrochloric acid containing about 2 per cent of hydrochloric acid, the oxalate was transferred to a funnel which held a perforated platinum plate in its neck, and well washed with boiling water, then dried on the water-bath. All the cerium oxalate I have used in my experiments was prepared in the way just described. When I had obtained a sufficient quantity, the whole was well mixed in a mortar and then placed in a rather loosely stoppered bottle. From time to time a quantity sufficient for each experiment was taken from this bottle. When I had prepared all the pure oxalate I required, I hit accidentally on a simpler mode of separating cerium from lanthanum and didymium. Instead of precipitating the cerium as basic sulphate, I evaporated the solution of the mixed nitrates of cerium, lanthanum, and didymium, obtained in the first instance, to complete dryness; then heated the brown mass over a naked flame until the brown colour entirely disappeared, and the residue became a pale yellow. On treating this yellow residue with boiling dilute nitric acid, the whole of

the lanthanum and didymium was dissolved, and nearly all the cerium was left as basic nitrate.

When preparing the chloride I weighed out for each experiment about 10.5 grms. of the air-dry oxalate, and put it in a rather wide glass-tube about 18 inches long. The tube was then placed in a paraffin bath and dry hydrochloric acid passed through it. The hydrochloric acid gas was prepared in the following way:—20 parts of oil of vitriol were mixed with 8 parts of water, and the mixture was allowed to cool; it was then poured on to 12 parts of common salt. The gas is not produced when the acid is thus diluted until a gentle heat is applied, but when it is it comes so easily that it may be regulated to come at any desired rate. The gas was first passed through a Woulff's bottle containing oil of vitriol, and with three tubulures, the third one being connected with an apparatus for producing carbon dioxide, so that when necessary that gas could be admitted without disconnecting any part of the apparatus, next through two large U-tubes containing calcium chloride, then again through a bottle containing oil of vitriol, and lastly through a U-tube filled with asbestos to catch any spray of sulphuric acid which might be produced. The gas now entered the tube containing the oxalate, and the excess, after passing through a sulphuric acid wash-bottle, was absorbed in water. Soon after the hydrochloric acid began to pass over the oxalate, water made its appearance at the exit end of the tube. When the air was expelled heat was applied to the bath, much water continued to come off, and was driven away by heating the end of the tube. When the temperature of the bath rose a little above 120°—generally at 123°—the oxalic acid began to sublime to the end of the tube and condensed there in crystals; this in its turn was driven away by heating the tube. As long as oxalic acid was seen to come off the bath was kept between 120° and 130°, and all that did show itself as oxalic acid did so between these limits.

Afterwards the temperature of the bath was allowed to rise gradually to 200°; there was no advantage in going higher, as the paraffin evaporated away and a gas furnace can easily be regulated to this temperature. I now transferred the substance, not yet completely converted into chloride, to another tube and continued the process in an ordinary gas combustion furnace. The object now was to so regulate the temperature that water was kept coming off without increasing the heat so rapidly as to char the oxalate left undecomposed. When a low red-heat was reached a slow current of carbon dioxide was passed in along with the hydrochloric acid to burn the little carbon left from a small quantity of the oxalic acid nearly always charring. When the slightly grey appearance of the chloride due to this small quantity of carbon disappeared the current of carbon dioxide was stopped, that of the hydrochloric acid was continued for an hour longer, while the chloride was kept at a full red-heat. With the hydrochloric acid still flowing over the chloride the furnace was gradually cooled until it was safe to handle the glass-tube; the exit end of the tube was then plugged, then the other end, and the tube was removed from the furnace and wiped clean from the magnesia it had been lying in. The cork of the tube was then withdrawn and the chloride slipped into the weighing flask, which was securely closed by a glass-cap well ground on to its neck. It was then quickly weighed while still quite warm. The object in weighing the chloride at this stage in the process was to make quite sure no water was absorbed before the final weighing was made, and such was found to be the case, for although there was always a small increase in weight, about 0.0025 gm. on 6.5 grms. of the chloride, it was no more than was easily accounted for by the loss that would arise from weighing the body warm. When weighing the chloride it was placed in a small flask with a closely fitting cap, and an exactly similar flask was used as a tare; the latter required the addition of 0.0005 gm. to balance the weighing flask; whatever was done to the one flask was always done to the other, and they were always kept

beside one another. To avoid repetition, I may say here that in all the other weighings the body to be weighed was placed in one vessel, and another vessel as similar in material and weight as possible was used as a tare. The weight having been taken, in order to remove extraneous hydrochloric acid, the flask containing the chloride and the tare were placed over sulphuric acid and surrounded by quick-lime under the receiver of a large air-pump, which could be exhausted very rapidly to within 3 millims. of a vacuum. This was usually done during an afternoon; they were left here the whole of the two following days, and on the morning of the fourth day air, dried by passing through sulphuric acid and phosphoric anhydride, was let into the receiver. This treatment was found to completely free the chloride from adhering hydrochloric acid, as when it was dissolved its solution was perfectly neutral. The two flasks were now removed from the receiver, securely closed, and the final weighing of the chloride made; it was then cautiously dissolved in water.

In making the following determinations pure silver was used, prepared, according to Stas's directions, by precipitation from an ammoniacal solution of the nitrate by ammonium sulphite. For each experiment, after making the first weighing, I calculated how much silver was required to precipitate the chlorine of the cerium chloride, assuming at the outset the atomic weight of cerium was 141.0. I then weighed in a porcelain crucible that quantity, less about 10 m.grms., and ignited it in a current of dry and purified hydrogen, keeping it some time at a red-heat, allowed it nearly to cool in hydrogen, and then heated it again nearly to redness in air. After cooling over sulphuric acid the silver was weighed and transferred to a 20-oz. bottle, and the empty crucible was again weighed. A sufficient quantity of nitric acid, sp. gr. 1.42, was added to the silver, and the stopper of the bottle, which had been previously well ground in with emery, was tied down fast. The bottle was then placed in a water-bath, and the water was heated gradually until it boiled. It was kept at this temperature nearly an hour. There was no escape of gas at the stopper; if the stopper ever did slip, the silver being dissolved was rejected, and a fresh quantity was weighed. The solution of the silver was made some time before it was required, so that the bottle and contents were quite cool when opened. After carefully cleaning the neck and stopper of the bottle on the outside the stopper was loosened and washed down into the bottle, a little more water was added when the silver was found to be completely dissolved, and the solution to be perfectly clear. The succeeding operations were performed in a room from which daylight was excluded. The solution of cerous chloride was poured into the solution of silver nitrate in the bottle in which it was prepared, and the whole was well shaken. The additional quantity of silver required for the complete precipitation of the chlorine was added by means of an approximately centinormal solution of silver nitrate, 1 gm. of which contained 0.001064 gm. of silver. As I did not measure the quantity of the solution used, but weighed it, I discarded the ordinary forms of burette in favour of a convenient sized bulb which I fused on to a glass stop-cock; in this shape it was more easily weighed. The titration was made in an oblong box, divided into two compartments by a partition. The inside of the box was well blackened. In the partition a round hole was bored $1\frac{1}{4}$ inch in diameter; in the right-hand compartment a lamp was placed, and between it and the hole in the partition a spherical flask containing a solution of potassium chromate, so that the light from the lamp before passing through the hole had to pass through the yellow liquid in the flask. In the left-hand compartment the bottle containing the chloride was placed in such a position that the upper portion and surface of the liquid it contained was illumined by the pencil of yellow light proceeding through the hole. The burette was fixed in a stand in the box, so that it dropped the solution of silver nitrate into the bottle when the latter was in the best light. By this arrangement the

11	9 ¹³ 930	9 ⁶⁰ 00	81 ⁹⁸ 81	46 ⁶¹ 81	82 ¹⁹ 37	46 ⁷³ 67	139 ⁸⁵ 43	140 ²¹ 01

lightest turbidity produced in the liquid by the silver chloride is at once detected. The credit of originating it is due to Stas. With a little practice it soon becomes easy by observing the amount of turbidity produced by each addition of the silver nitrate to the chloride to know how many drops may be added the next time with safety, and as one drop of the solution of silver nitrate I used contained only 1-20th of a m.grm. of silver there was not much danger of adding an appreciable excess.

I have made seven determinations of the chlorine in cerous chloride by the method I have just described. The mean of these determinations gives 139⁸⁵84 as the atomic weight of cerium when the atomic weight of hydrogen is taken as 1; if that of oxygen is taken as 16, then the number for cerium becomes 140²¹54.

I have taken the specific gravity of cerous chloride by weighing it in carefully purified benzene, and I find it to be 3⁸⁸ compared with water at 15⁵. Then making corrections for weighing in air, for both the brass and platinum weights and for the cerous chloride, I find the atomic weight in vacuo when hydrogen is 1 to be 139⁹⁰35, and when oxygen is 16 to be 140²⁵93. I thus find the atomic weight of cerium to be lower than Böhlig did, but I defer making comments on the work of others who have preceded me until I have made some determinations of cerous bromide. This latter compound I have already succeeded in making by passing hydrobromic acid over cerium oxalate.

The ratios I have employed in this paper are those of Stas, and are as follows:—If the atomic weight of hydrogen is 1, that of oxygen is 15⁹⁶, silver is 107⁶⁶, and chlorine 35³⁷.

The atomic weight of oxygen being 16, that of silver is 107⁹³, and of chlorine 34⁴⁵7.

The table above shows the quantities of silver and cerous chloride used in each experiment, and the ratios obtained.

REPORT OF THE COMMITTEE ON INDEXING CHEMICAL LITERATURE.*

THE Committee on Indexing Chemical Literature appointed in 1882 respectfully presents the following report of progress.

We have the pleasure to announce that since our last Report the following Indexes have been published by their authors, the arrangement of material being uniform with that of those previously issued.

Ozone, *second index*, by Prof. Albert R. Leeds.
Peroxide of Hydrogen, *second index*, by Prof. A. R. Leeds.

Speed of Chemical Reactions, by Prof. R. B. Warder.
Starch Sugar, by Dr. E. J. Hallock.

Besides these a valuable contribution to chemical bibliography has been independently published on a somewhat different plan by Professor Albert B. Prescott

and Mr. J. W. Baird. The full titles of the above will be found at the close of this Report.

Two hundred and fifty copies of our Report for 1883 have been sent to chemists throughout the United States, the Smithsonian Institution having kindly attended to the distribution by mail without expense to the Committee. This led to correspondence with several chemists who regarded the scheme of co-operative indexing favourably, and resulted in several offers of assistance.

Professor Wm. Ripley Nichols offers an Index to the Literature of Carbon Monoxide.

Professor L. P. Kinnicutt offers an Index to the Literature of Meteorites.

Dr. Henry Leffmann reports progress on his Index to the Literature of Arsenic.

Professor C. E. Monroe does likewise with reference to an Index to the Literature of Explosives.

Professor A. B. Prescott and Mr. J. T. Craig offer an Index to the Literature of Phosphorus.

Dr. H. Carrington Bolton has in preparation a second index to the Literature of Uranium.

An offer was also received of an Index to an element already on the list of those published, but was withdrawn as soon as the author had his attention called to the existing publication. This circumstance shows forcibly the advantage of co-operation through this Committee.

We are pleased to announce that in consequence of our representations the Smithsonian Institution has consented to Publish Indexes to Chemical Literature which shall be endorsed by this Committee. The Smithsonian places a limit to the number of pages which will be printed per annum, but the limit is a generous one.

By thus securing the assistance of the Smithsonian Institution, chemists are assured of a reliable and authoritative channel of publication, together with a wide circulation, and the plan of co-operative indexing will undoubtedly receive a great stimulus.

Finally, to extend more widely acquaintance with the existing Indexes, we append a complete list of those printed. A limited number of those published by the New York Academy of Sciences can be had by addressing the Chairman of the Publication Committee of the Academy, Prof. D. S. Martin, 236 West 4th Street, New York City.

Respectfully submitted,

H. CARRINGTON BOLTON, Chairman.

IRA REMSEN.

F. W. CLARKE.

ALBERT R. LEEDS.

ALEXIS A. JULIEN.

Sept. 4, 1884.

List of Indexes to Chemical Literature.

Uranium, Index to the Literature of. By H. Carrington Bolton. Annals of the New York Lyceum of Natural History, vol. ix., February, 1870. 15 pp. 8vo.

Manganese, Index to the Literature of; 1596—1874. By H. Carrington Bolton. Annals of the Lyceum of Natural History, New York, vol. xi., November, 1875. 44 pp. 8vo.

Titanium, Index to the Literature of; 1873—1876. By Edw. J. Hallock. Annals of the N. Y. Academy of Sciences, vol. i., Nos. 2 and 3, 1877. 22 pp. 8vo.

* Advance Proofs from the Proceedings of the American Association for the Advancement of Science, vol. xxiii., Philadelphia Meeting, September, 1884.

- Vanadium*, Index to the Literature of. By G. Jewett Rockwell. Annals of the N. Y. Academy of Sciences, vol. i., No. 5, 1877. 13 pp. 8vo.
- Ozone*, Index to the Literature of; 1875—1879. By Albert R. Leeds. Annals of the N. Y. Academy of Sciences, vol. i., No. 12, 1880. 32 pp. 8vo.
- Peroxide of Hydrogen*, The Literature of; 1818—1878. By Albert R. Leeds. Annals of the N. Y. Academy of Sciences, vol. i., No. 13, 1880. 11 pp. 8vo.
- Electrolysis*, Index to the Literature of; 1784—1880. By W. Walter Webb. Annals of N. Y. Academy of Sciences, vol. ii., No. 10, 1882. 40 pp. 8vo.
- Speed of Chemical Reactions*, Literature of. By Robert B. Warder. Proceedings of the Am. Assoc. Adv. Science, vol. xxxii., 1883. 3 pp. 8vo.
- Starch Sugar*, Bibliography of. By Edw. J. Hallock. Appendix E to Report on Glucose prepared by the National Academy of Sciences in response to a request made by the Commissioner of Internal Revenue. U. S. Internal Revenue, Washington, D. C., 1884. 44 pp. 8vo.
- Ozone*, Index to the Literature of (1879—1883); accompanied by an Historical-Critical Résumé of the Progress of Discovery since 1879. By Albert R. Leeds. Annals N. Y. Academy of Sciences, vol. iii., p. 137, 1884. 16 pp. 8vo.
- Peroxide of Hydrogen*, Index to the Literature of; 1879—1883. By Albert R. Leeds. Annals N. Y. Academy of Sciences, vol. iii., p. 153, 1884. 3 pp. 8vo.
- Dictionary of the Action of Heat upon Certain Metallic Salts*, including an Index to the principal Literature upon the Subject. Compiled and arranged by J. W. Baird, contributed by A. B. Prescott. New York, 1884. 70 pp., 8vo.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING OCTOBER 31ST, 1884.

By WILLIAM CROOKES, F.R.S.

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford.

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To COLONEL SIR FRANCIS BOLTON, *Water Examiner*,
Metropolis Water Act, 1871.

London, November 7th, 1884.

SIR,—We submit herewith the results of our analyses of the 188 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily from October 1st to October 31st inclusive. The purity of the water, in respect of organic matter, has been determined by the Oxygen and the Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter, and the quantities of free oxygen present in the whole of the samples submitted to analysis.

Of the 188 samples subjected to examination, three were found to be "very slightly turbid." The remaining 185 samples were perfectly clear, bright, and well-filtered.

As regards degree of freedom from organic matter, the water supplied to the Metropolis during the past month

has more than maintained the character it has now exhibited continuously for a long time past. Thus, while the mean proportion of organic carbon in the water supplied by the Thames Companies during the previous three months was 0.128 part in 100,000 parts, the mean proportion in the Thames-derived water supplied during the past month was only 0.118 part in 100,000 parts; corresponding to about two-tenths of a grain of organic matter per gallon; this excessively low proportion of organic matter being, it must be said, quite unusual for the period of the year.

We are, Sir,

Your obedient Servants,
WILLIAM CROOKES,
WILLIAM ODLING,
C. MEYMOTT TIDY.

THE LATE MR. FRANK HATTON, F.C.S.

A MOVEMENT has been set on foot, with the approval of the Council, to found a memorial prize at the Royal School of Mines and Normal College of Science, South Kensington, in honour of the late Frank Hatton.

This gentleman, who so untimely met his end by a sad accident last year while acting as scientific pioneer in the service of the British North Borneo Company, was for some years a student at the above Institution. The energy and enthusiasm he displayed in the laboratory and his spirit and tact as an explorer in the wilds of Borneo show that Science has cause to regret the loss of a youthful worker full of promising usefulness. Mr. Hatton's contributions to chemistry, work done whilst a student at South Kensington, comprised papers "On the Action of Bacteria on Gases," "On the Oxidation of Organic Matter in Water by Filtration through Various Media, and on the Reduction of Nitrates by Sewage, Spongy Iron and other Agents," and one "On the Reduction of Amylic Alcohol," which were published in the *Journal of the Chemical Society*.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, Thursday, November 20, 1884.

Dr. W. H. PERKIN, F.R.S., President, in the Chair.

DURING the evening a ballot was held, and the following gentlemen were declared by the scrutators (Messrs. Davies and Greenaway) duly elected Fellows:—F. Broughton, F. J. Down, L. Ehrmann, F. G. Holmes, J. Hulme, C. Thompson, W. F. Wyley.

The following certificates were read for the first time:—W. P. Ashe, J. Ballard, H. M. Chapman, J. D. Johnstone, G. F. Kendall, P. C. Porter, W. C. Wise.

Dr. THORNE then communicated the substance of a paper by KHAN BAHADUR BOMANJI SOBRABJI "On some New Paraffins." The reaction used by the author is the one proposed by Wurtz—

The author gives an account of the preparation and properties of the following bodies:—Cetane, $C_{16}H_{34}$; boils at 278° , melts at 18° to 20° ; its vapour density was found by Meyer's apparatus 7.9 to 7.85 ; theory requires 7.84 . Dicyetyl, $C_{32}H_{66}$, crystallising in glistening scales which melt at 70° . Ethyl-cetyl and diheptyl, boiling-point 245° .

Dr. JAPP then read a paper "On Additive and Condensation Compounds of Diketones with Ketones," by F. R. JAPP and N. H. J. MILLER. In a former communication

it was shown that phenanthraquinone, acetone, and ammonia react according to the equation—

and that the resulting compound, acetone-phenanthraquinon-imide, when treated with aqueous acids, takes up water and parts with ammonia, yielding a compound of the formula $C_{17}H_{14}O_3$, which may be named acetone-phenanthraquinone. A further study of this body has led the authors to abandon the formula which was at first given, and to believe that the constitution of this substance is—

In the imide mentioned above the authors consider that the imido group attaches itself to the phenanthraquinone residue and not to the acetone residue, because when a mixture of phenanthraquinone and acetone is acted on by potash, both carbonyl groups take part in the reaction, and an additive compound of one molecule of phenanthraquinone with two molecules of acetone is obtained (diacetone-phenanthraquinone). Under other conditions an additive compound of two molecules of phenanthraquinone with one molecule of acetone was obtained. The authors also describe condensation compounds formed from the above additive compounds by the abstraction of the elements of water. They have extended the application of these reactions to the action of potash upon mixtures of benzil with acetone and with aceto-phenon respectively, and have obtained the compounds acetone-benzil and aceto-phenone-benzil. The substance obtained from acetone-benzil by the abstraction of water possesses considerable theoretical interest, since the hydroxyl group appears to be eliminated along with a hydrogen atom from the methyl group to form a closed-chain compound, whereas aceto-phenone-benzil parts with its hydroxyl group along with a hydrogen atom from the contiguous methylene group, yielding an unsaturated compound. The authors then describe in detail the action of potash of various strengths upon mixtures of phenanthraquinone and acetone; the action of acetic anhydride upon diacetone-phenanthraquinone, which gives rise to dehydro diacetone-phenanthraquinone, $C_{20}H_{18}O_3$; the action of nascent hydrogen upon acetone-phenanthraquinone; the action of dilute potash upon monacetone-phenanthraquinone; of strong potash upon a solution of acetone-phenanthraquinone in acetone. The authors find that the action of diethylamine on acetone-phenanthraquinone is identical with that of potash. The authors then give a detailed account of the action of potash upon mixtures of benzil and acetone: three distinct products may be obtained according to the conditions of the experiment. By acting with a small quantity of potash upon benzil dissolved in an excess of acetone, acetone-benzil is formed, $C_{17}H_{16}O_3$. If an excess of potash be employed a condensation product, dehydracetone-benzil, $C_{17}H_{14}O_2$, is obtained: by acting with a small quantity of potash upon acetone mixed with an excess of benzil a condensation product, dehydracetone-dibenzil, $C_{37}H_{24}O_4$, is formed. These reactions are described in detail, and also the action of heat, oxidising agents, ammonia, and hydroxylamine upon acetone-benzil. Similar reactions with the two other products were studied. The action of potash in the cold upon a mixture of benzil and acetophenone was investigated. The products were dehydracetone-phenone-benzil, $C_{22}H_{16}O_2$, and aceto-phenone-benzil, $C_{22}H_{18}O_3$. By the action of bromine on the first of these two bodies a tetrabromide, $C_{22}H_{16}O_2Br_4$, was obtained.

Dr. RAMSAY then read a paper "On the Vapour-pressure of Acetic Acid, and on a New Method of Determining the Vapour-pressures of Liquids," by W. RAMSAY and SYDNEY YOUNG. The vapour-pressures of acetic acid, which have given very discordant results in the hands of other observers, have been found to be perfectly concordant

and regular by the authors. They use for the purpose of determining the vapour-pressure of liquids a species of still into which a thermometer dips; the bulb of the thermometer is covered with cotton-wool or other suitable substance. Liquid can be admitted from time to time from a reservoir to moisten the cotton-wool. Heat is applied to the tube surrounding the thermometer, and the liquid evaporates from the cotton-wool without entering into ebullition. By altering the pressure in the apparatus the temperature registered by the thermometer correspondingly alters. By this means the determination of vapour-pressures is easy and exact. The results obtained by this method have been shown, by exceedingly numerous observations, to be coincident with the vapour-pressures measured in the ordinary way.

Dr. MASSON then read a paper "On the Action of the Halogens on the Salts of Trimethyl-sulphine," by L. DOBBIN and ORME MASSON. When dry trimethyl-sulphine iodide is shaken up with an ethereal solution of iodine, a black tarry liquid was produced, which did not crystallise. By the action of iodine on the bromide and chloride reddish black crystals were obtained, which were, however, unstable in air and so were not analysed. By the action of bromine vapour on the iodide a red oil was formed, which after exposure for a short time to the air solidified. The mass was washed with ether, and crystallised from hot alcohol. Orange-red crystals separated, which analysis proved to be trimethyl sulphine dibrom-iodide, Me_3SIBr_2 . Its properties and those of the platinum salt are given. The crystals are converted by ammonia solution into iodide of nitrogen. Ammonia-gas, however, forms an addition product, $Me_3SIBr_2NH_3$, an amorphous, non-explosive, light green solid, stable only in an atmosphere of ammonia. Chlorine forms with trimethyl-sulphine iodide a substance crystallising from hot alcohol in canary-yellow crystals, Me_3SICl_2 . The platinum and silver salts were prepared. With ammonia it behaves like the dibrom-iodide mentioned above. Iodine monochloride also forms with the chloride trimethyl-sulphine-dichlor-iodide. Iodine monochlor-iodide forms with the bromide the substance $Me_3SIBrCl$. Similar bodies are formed by the action of bromine on the bromide, bromine on the chloride, chlorine on the bromide, chlorine on the chloride. The authors have also partly investigated the action of the halogens on trimethyl-sulphine sulphate. From their results they conclude that all the haloid salts of trimethyl-sulphine combine directly with chlorine, bromine, iodine, and iodine monochloride. In no case is one halogen replaced by the other. The product of each reaction may be formulated as Me_3SX_3 ($X = Cl, Br, \text{ or } I$). The constitution of these bodies the authors consider to be—

in which the sulphur is hexad. In conclusion, the authors point out the analogy of these bodies to the poly-iodides and bromides of the nitrogen bases. They purpose making a complete investigation of the halogen compounds of the tetramethyl-ammonium salts, which has been commenced.

In answer to Dr. Armstrong,

Dr. MASSON did not think that the bodies were molecular compounds, $Me_3SX(X_2)$, because of the comparatively high temperature (180°) necessary to effect their decomposition.

Dr. JAPP said that S was already known to combine with 6 monads in the body Si_6 , and that Lothar Meyer had also suggested the possible heptadic character of nitrogen.

Mr. S. U. PICKERING then read a "Note on the Heats of Dissolution of the Sulphates of Potassium and Lithium." This paper is similar to the paper on sodium sulphate read at the last meeting, but the potassium and lithium salts do not seem to form isomeric modifications.

Dr. ARMSTRONG said that when potassium displaced the hydrogen in sulphuric acid more energy seemed to be lost

than when the hydrogen was replaced by sodium, and it was interesting to find the sodium salt forming combinations which did not exist with the potassium salt.

Dr. HODGKINSON, in confirmation of Dr. Armstrong's remark, stated that zinc dissolved in sodium sulphate, but was unacted upon by the potash salt.

"On the Application of Iron Sulphate in Agriculture, and its Value as a Plant Food," by A. B. GRIFFITHS. This paper contains an account of further researches on this subject (*Chem. Soc. Trans.*, 1884, 71). The author has grown duplicate crops of beans, turnips, and wheat under similar conditions, excepting that one set was manured with half a hundred-weight of ferrous sulphate per acre, the other having no iron salt added. With the beans the crop with the iron yielded 44 bushels of grain; without the iron only 28 bushels were procured. The plants and the pods in the first case (with iron) contained more iron and phosphoric acid than in the second (without iron). No difference as regards these constituents was found in the seeds. In the case of wheat no very marked increase in the weight of the crop was observed, but the wheat grown with the iron seemed to be healthier, and completely resisted "rust," which attacked the crop grown without iron. With the turnips, the plot manured with ferrous sulphate gave 16½ tons, the unmanured 13 tons of roots. The former contained markedly more iron and phosphoric acid. From some estimations of chlorophyll made by Dr. Russell it appears that the use of sulphate of iron increases the amount of chlorophyll in the leaves. An excess of sulphate of iron acts as a poison to plant life.

"Notes on the Chemical Alterations in Green Fodder during its Conversion into Ensilage," by C. RICHARDSON, U.S. Department of Agriculture. Prof. Kinch and Dr. Kellner have already published some observations which prove that during the conversion of grass, &c., into ensilage a considerable increase in the quantity of non-albumenoid nitrogen takes place. The author of the present paper has confirmed this result in the case of maize. Thus in a sample of original maize the percentage of the total nitrogen which existed in the non-albumenoid condition amounted to 21.2, in ordinary dried fodder 15.6, in ensilage 44.6 to 49.6, in ensilage from young maize 53.3, from older maize 47.1; so that in silos a large portion of the albumenoids is converted into non-albumenoid nitrogenous substance, while in the ordinary drying of fodder no such change takes place. This loss, according to the author, is due to the comparatively large amount of ammonia combined with the acids produced during the fermentation, and which is lost in drying the specimens for analysis. Thus from 4000 parts by weight of ensilage he obtained 8.66 of ammonium chloride = 2.266 of nitrogen. The remaining non-albumenoid nitrogen is probably present as an amide. The ensilage contained about 2 per cent of acids, of which 0.6 is lactic, the rest acetic acid. The author gives many analyses of maize and ensilage, which exhibit great variations in composition, and show how unsafe it is to generalise from one experiment.

"On the Decomposition of Silver Fulminate by Hydrochloric Acid," by E. DIVERS and MICHITADA KAWAKITA. In a previous note the authors stated that silver fulminate differed from the mercury salt in yielding much less than the full amount of hydroxy-ammonium chloride, and in yielding ammonium chloride. The present communication contains the results of a further examination of the action of hydrochloric acid upon silver fulminate, and in addition an investigation of the action of dilute hydrochloric acid upon mercury fulminate, and of the action of this acid upon fulminates in relation to the production of hydroxy-ammonium chloride, formic acid, and ammonia, and of Steiner's production of oxalic acid from mercury fulminate. The silver fulminate was found to contain 71.79 and 71.76 per cent of Ag. Unlike the mercury salt, silver fulminate is fiercely attacked by concentrated hydrochloric acid, it shrivels up and decomposes with a loud hissing noise into very hot products. The authors have carried out this reaction without accident. If the

heating be not checked, the silver chloride is at first orange, but rapidly loses this colour, imparting it to the acid mother-liquor. An unstable colourless substance is formed, giving an intense wine-red colour with ferric chloride in acid as well as neutral solutions. This substance is completely decomposed by heating. In all cases a small quantity of hydrocyanic acid was formed. The hissing noise of the decomposition is attended with the escape of carbon dioxide. The yield of hydroxy-ammonium chloride depends for its amount on the strength of the hydrochloric acid used. With strong acid in large excess, the temperature being allowed to rise, only 21.55 per cent was obtained out of the full yield 46.33; with dilute acid 43.52 per cent was formed. Formic acid seems to be produced in about the same ratio as the hydroxy-ammonium chloride. The yellow colouring matter mentioned above seems to be formed at the expense of that portion of the fulminate which would otherwise become hydroxylamine and formic acid. The quantity of ammonium chloride formed varies inversely as the quantity of hydroxy-ammonium chloride. If the hydrochloric acid be dilute, no ammonium chloride is produced, so that with dilute hydrochloric acid the action on silver fulminate does not differ from that on the mercury salt. The authors could not form any hydroxy-ammonium chloride or formic acid by the acid of hydrochloric acid on potassium or silver fulminate. They have also repeated Steiner's reaction, i.e., decomposing mercury fulminate by hydrogen sulphide in ether, but could not detect a trace of oxalic acid. The paper concludes with a brief discussion on the constitution of the fulminates, by Dr. Divers.

The Society then adjourned to Dec. 4, when the following papers will be read:—"Calorimetric Determinations of Magnesium Sulphate," by S. U. Pickering. "Fluorenes," by Dr. Hodgkinson.

PHYSICAL SOCIETY.

November 22nd, 1884.

Prof. GUTHRIE in the Chair.

MR. JAMES BEWSHER was elected a member of the Society.

The following notes were read by Mr. R. T. GLAZEBROOK, M.A., F.R.S., "On the Permanence of some Standards of Electrical Resistance." The author has had occasion to compare with ten standard B.A. units a coil which had been tested by Lord Rayleigh in 1882, the coil then being two years old. He found that its resistance was 9.98335 B.A.U. at 14° 05 C., while Lord Rayleigh found the value 9.98330 B.A.U. Thus, either the coil and the standards have changed by exactly the same amount, which is improbable, for they are wires of different thickness, or they have all remained permanent.

"On the Effect of Moisture in Modifying the Refraction of Plane Polarised Light by Glass." The author described some experiments he had been engaged in lately at the Cavendish Laboratory. Plane polarised light is made to fall on a plate or a wedge of glass at various angles and the position of the plane of polarisation determined. It is found that this depends greatly on the hygrometric condition of the air in the neighbourhood of the glass. If moist air be blown on to perfectly clean glass the plane of the polarisation of the emergent light is displaced from its normal position in one direction, while if dry air be blown it is displaced in the opposite direction. At an angle of incidence of 60° the difference between the two positions is from 6' to 8'. If, however, the glass be not perfectly clean the effect of moisture is at first the same as that of dry air, though on stopping the draught an opposite effect is observed. The author assigns as the cause of this the heating of the surface which, as Magnus discovered, is

produced by a draught of moist air. He finds on repeating Magnus's experiment that the heating is not produced if the glass be clean, and he shows by an independent experiment that slight local heating does produce an effect on the plane of polarisation in the same direction as that due to the dry air.

Mr. Glazebrook also exhibited a Spectro-photometer, described by him in a paper read before the Cambridge Philosophical Society (*Proc. Phil. Soc.*, vol. iv., pt. vi.) and made by the Cambridge Scientific Instrument Company from his design.

A note "*On a Point in the Theory of Pendent Drops*," by Mr. A. M. WORTHINGTON, was read by the Secretary, Mr. WALTER BAILY. This was a note upon a paper recently communicated by the author to the Royal Society upon the measurement of the surface tension of a liquid from observations of the forms assumed by pendent drops. By making a measurement of a horizontal section of such a drop, and of the angle made by the tangent plane to the surface at the line where the section meets the surface with the horizontal, and knowing the density of the liquid, sufficient data are obtained to determine its surface tension.

Prof. PERRY, remarking upon this paper, gave an account of some researches upon the subject in which some years since he had assisted Sir William Thomson. On the usually accepted theory of surface tension, based upon the behaviour of liquids in capillary tubes, at every point of the surface of a liquid the equation—

$$k p = \frac{1}{R} + \frac{1}{R'}$$

must hold, where p is the pressure at that point and the difference of pressure on the two sides of the surface, R and R' two principal radii of curvature, and k a constant. In the case of a drop, whose surface is one of revolution about the vertical, the contour may be drawn from the equation; this was done, and the theoretical drawings were made of a number of drops. These have since been compared by Sir W. Thomson with enlarged photographs of actual drops, and the results are highly satisfactory. This law no longer holds in the case of a drop at its "critical point," or that point when it is about to fall, since here dynamical action comes in.

Mr. BAILY also read a paper by the same author "*On a New Capillary Multiplier*." This is an apparatus for the measurement of surface tension, and is a modification of one used by M. Despretz. From one extremity of the arm of a balance is suspended a roll of platinum foil, consisting of a strip 50 centims. long, and 5 or 6 centims. broad, rolled up, the successive convolutions being prevented from touching by rolling up with the foil a number of small pieces of hard glass tubing about two millims. diameter, which occupy the upper part of the helix, and preserve the form of the lower. The coil is cleaned by igniting it in a Bunsen flame, and then suspended with its lower end in the liquid to be examined. The increase in weight corrected for the part of the coil immersed is due to the fluid rising between the convolutions. From this the surface tension is readily calculated.

Mr. HILGER described a new Solar Eye-piece. In Prof. Pickering's eye-piece there are two rectangular prisms of glass of slightly different refractive indices. The light of the sun undergoes partial reflection at the surface separating the two prisms, the ratio of the reflected to the incident light diminishing with the difference between the refractive indices. It is found, however, that such a prism under a high power always gives a double image, due to the two glass surfaces, it being practically impossible, even under enormous pressure, to bring them into true contact. To obviate this, Mr. Hilger makes the second prism of Canada balsam, which gives the most satisfactory results, the image being pure and single.

UNIVERSITY COLLEGE, LONDON,
CHEMICAL AND PHYSICAL SOCIETY.
Thursday, November 6.

C. E. CASSAL, F.I.C., F.C.S., President, in the Chair.

Mr. A. H. FISON read a note on "*Electrolysis*," in which he maintained that the ordinarily received chemical theories of electrolysis are not substantiated by any known fact, and are in direct antagonism with the fact that electrolytes obey Ohm's law, and with the migration of the ions. The theory which presents least difficulty is the physical theory of Clausius.

Dr. MORLEY replied at some length to the arguments from a chemical point of view.

Mr. E. ERNEST GRAVE, F.C.S., then read a paper on the "*Estimation of Carbon in Phosphorus*." He commenced with a brief history of this subject, and stated that Leeds was first led by theoretical considerations to the belief that carbonic oxide would be oxidised by nascent oxygen; both he and Baumann stated that experiments verified this theory. On the other hand, Profs. Remsen and Southworth asserted that carbonic acid was not oxidised in the slightest degree by ozone. Recently Remsen and Reiser have described apparatus which they have constructed so as to be entirely free from organic matter. It consists in a combustion-tube containing cupric oxide heated to dull redness; then two wash-bottles containing sodic hydrate, and a third wash-bottle filled with baric hydrate; then a bell-jar containing phosphorus in convex discs, the curved surface just showing above a solution of potassic bichromate and hydric sulphate; air was passed in through the copper oxide tube on to this bell-jar, the air being kept as near 24° C. as possible. In this case white fumes were abundant during the course of an experiment, indicating the efficient working of the phosphorus. From this bell-jar the ozonised air was washed by means of a bottle containing pure water, and was then passed into a bottle containing concentrated baric hydrate, and this in turn protected from the external air by a sodic hydrate tube. Air alone, when passed through this apparatus for a sufficiently prolonged period, gave a precipitate—diminutive though it might be—in the baric hydrate solution. Ten litres of air gave a turbidity; twenty to thirty a precipitate. Phosphorus was considered a likely source of the carbon; for is not phosphorus isolated by methods similar to boron, silicon, and iron, in which carbon occurs as an impurity? Attempts to estimate the carbon in phosphorus at first failed, but the conclusion was arrived at that the carbon *must be* in chemical combination. The carbon has since been quantitatively determined. The method consists in oxidising a known weight of phosphorus by means of pure hydric nitrate, removing the oxides of nitrogen from escaping gases, and estimating carbonic acid. The quantity of carbon found was about 0.04 per cent. While the absolute quantity is small, it is sufficient to account for the results obtained, and the conclusion is that carbonic oxide is not oxidised by moist air in contact with phosphorus. Since Remsen published the above, Baumann has again affirmed that oxidation does take place, and the matter is now open to other workers to decide.

Action of the Active and Inactive Amyl Chlorides and of Amylen upon Toluene in Presence of Aluminium Chloride.—J. C. Essner and E. Gossin.—Active amyl chloride loses hydrochloric acid and yields amylen, which is immediately fixed so as to yield tertiary iso-amyltoluene. The inactive amyl chloride loses not merely the elements of hydrochloric acid, but undergoes a molecular transformation to yield this body. The constitution of this iso-amyltoluene may be easily deduced from this manner of formation. This body is a dimethyl-ethylmetacresyl-methane.—*Bull. de la Soc. Chim. de Paris*.

NOTICES OF BOOKS.

London Water Supply. By Colonel Sir FRANCIS BOLTON, C.E., Water Examiner, "Metropolis Water Act, 1871." Published for the Executive Council of the International Health Exhibition and for the Council of the Society of Arts, by William Clowes and Sons, Limited, 13, Charing Cross, S.W.

THIS publication, which may be classed among the results of the late International Health Exhibition, is of very great importance not alone to municipal and sanitary authorities, but to the general public. It must, however, be duly noted that the author deals only with the existing water supply, and throws out no suggestions as to its possible extension, modification, or supercession. He describes merely what is without any reference to what might or what probably will be.

In the General Introduction we find a notice of the possible sources of supply, classed under the heads of rivers, lakes,—natural or artificial—and wells. Processes of purification are next referred to as necessary in most cases. As additions to mere mechanical filtration we find mention of the methods of Spencer and Bischoff, without any discussion of their value, relative or absolute, and of the well-known Clark process, now in successful operation in some towns for softening waters which are hard in consequence of the presence of lime as carbonate.

On the comparative advantages of the "intermittent" and the "constant" systems of supply, Sir F. Bolton speaks decidedly, giving, as we are glad to find, the preference to the latter, which is, we believe, universally in use where the water supply is in the hands of the municipality. Where cisterns are necessary the water is unavoidably contaminated by impurities suspended in the atmosphere.

Under the head of "Average Consumption" we find an interesting table of the consumption—or perhaps rather the supply of water per head in a number of the principal cities of the world. At the head of the list stands Rome, with a flow of 160 gallons per head daily. Next comes a city, not in other respects a sanitary model, *i.e.*, Marseilles, with 158 gallons. The cities of the United States are copiously supplied, Washington receiving 143 gallons, Chicago 102, Boston 73, and San Francisco 64. London receives 312, which is below the Paris standard (36 gallons), but far in excess of the quantity distributed at Amsterdam, Berlin, St. Petersburg, Stockholm, or Madrid. The worst supplied cities here quoted are Sanjago, with 5 gallons, Venice with 8, Seville with 7.26, Pernambuco with 7.3, Madrid with 3.3, and Durban with 2.1. We need not wonder that the recent fire at the last-mentioned town proved so disastrous.

The mode of charging consumers is next discussed. The author evidently prefers the system of a rate upon the annual value of the premises supplied, advancing in its favour the somewhat socialistic argument that by this method "the use of water is not restricted by any motives of economy, and the rates charged to houses of the better class admit of water being supplied to dwellings of the poorer class at a rate below what would otherwise be possible." We strongly doubt that such is the case. But however this may be, a rate upon the supposed annual value involves, in London at least, the possibility of an increase in the cost of water [every five years. Surely there can be no equity in allowing a company or a municipality to charge a higher price for water without giving either a better or a more abundant supply, and without incurring any additional outlay. This very obvious contention is referred to in a subsequent chapter (p. 13). The reply of the companies is that "when the value of house property in any part of London declines they are compelled to take a reduced payment." Such cases, however, are rare. The surveyors employed in the quinquennial valuations [are, we understand, paid by a percentage on the increased value which they can attach to the parish.

A further grievance is that, whilst any arrangement in a house which can lead to an increased water consumption—such as bath, fountains, stand-pipes for washing house fronts and watering gardens, &c.—is made the subject of a higher charge, there is no decrease in case of a greatly reduced consumption. We have heard of the following instance:—A tradesman, who previously lived over his shop, took a house in the country, and used the rooms formerly occupied by his family as a warehouse. He and his assistants took their meals at an adjacent restaurant. In consequence the consumption of water at the shop was reduced to a minimum. Yet the Company concerned refused to allow the smallest reduction. Perhaps the most equitable system, as far as dwelling-houses are concerned, would be to base the charge on the number of inmates. Such questions, however, scarcely fall within the purview of the *CHEMICAL NEWS*.

One of the proposals mooted from time to time is that of a dual water supply. It is obvious that for watering the streets, extinguishing fires, flushing sewers, raising steam for manufacturing purposes, &c., water may be used which is by no means sufficiently pure for domestic use. Sir F. Bolton thinks—and upon careful consideration we must agree with him—that an inferior water might be safely supplied for the purposes above enumerated. But he does not hold that a dual household supply of a pure and an impure water would be judicious. He points to the expense of duplicate pipes and fittings in every house. In addition there would be the danger that from mistake or carelessness the inferior water might be used for drinking or cookery. It might also happen that in a dry season the Company or the Municipality would be tempted to make an unsuspected communication between the two mains. Paris enjoys a dual supply; there is a supposed pure water from certain springs, and an inferior quality from the river, but there the complaint arises that the two qualities are not always kept absolutely apart.

In the second chapter, the subject of filtration which was touched upon in the introduction, is resumed at greater length. The questions, however, in how far any practicable process of filtration will remove not merely lifeless suspended impurities, but living organisms, such as disease germs and liquid pollution, is overlooked. The former merit is claimed for spongy iron and for the porcelain filter, whilst of others it is asserted that they withdraw soluble matter, such as dissolved mineral salts. But our author is perfectly justified in reminding the public that a filter will not remain for ever serviceable. He concludes this chapter with the remark that:—"The Water Companies are frequently blamed for delivering unpotable water, when if the true delinquent were sought it would be found to be the water consumer himself, whose lack of attention to his cisterns and filters has created the evil of which he complains." Again we read (p. 21) that "an inspection of the cisterns in houses too generally shows that they are in a state of foulness generally attributable to neglect." To this plea the reply is very obvious: were it not for the refusal, or at least delay, of the Companies to provide a constant service the cisterns would be non-existent, as, *e.g.*, in Manchester. It is not uncommon for 38. 6d. to be charged for cleaning out a cistern. If the process is to be repeated every two months, as some experts recommend, here is a very serious addition to the cost of the water.

The proportions of the London water supply drawn from different sources for the present year are stated as follows:—From the Thames and certain chalk springs in its valley about 50 per cent of the whole; from the Lea and certain springs in its valley about 38, and from eighteen chalk wells 12 per cent. It appears that, as compared with 1866, the river-supply now forms a smaller proportion of the whole, whilst that obtained from the wells has increased. It is, however, an open question whether the water drawn from wells in the valleys of the Thames and the Lea is not ultimately obtained at the cost of these two rivers. The total quantity allowed to be drawn from

the Thames by the Companies is 110,000,000 gallons daily; the demands which may be made upon the Lea by the New River and the East London Companies is unrestricted.

The fourth chapter defines the duties of the Metropolitan Water Examiner, and enumerates the points on which he is required to report. Here we find a fact which certainly is not generally known. "None of the Companies are under any obligation to provide water sufficient for the extinction of fires; all that is required of them being to allow the gratuitous use of their water for this purpose and to grant certain special facilities, such as keeping for inspection maps showing their pipeage and the spots where the screw-cocks are placed for regulating the service and depositing keys of the fire-plugs at places prescribed by the Metropolitan Board. Sir F. Bolton remarks, with justice, that the value of constant supply for the purpose of fire extinction has been said with truth to be of even greater moment than its convenience to ordinary consumers." A delay of five minutes may make all subsequent exertions useless.

The sixth chapter discusses the quality of the water with especial reference to the reports on the one hand of Professor Frankland, and on the other by Messrs. W. Crookes, W. Odling, and C. Meymott Tidy. The author here states at the outset—"It should not be forgotten with regard to organic impurity, that not only is the amount present in filtered Thames water infinitesimal in actual quantity, but we have the distinct opinion of the last Royal Commission on Water Supply—an opinion arrived at after hearing very varied and often contradictory evidence—that the presence of a small quantity of organic matter in drinking-water is not necessarily prejudicial."

Professor Frankland, in his report, written apparently this year—complains that as far as the Thames and Lea are concerned "it is sewage purification which has been attempted and not sewage exclusion. We have the *banal* laudation of irrigation and intermittent downward filtration followed by a condemnation of chemical treatment as effecting comparatively little improvement in the sewage, excepting so far as the coarser matters in suspension are concerned" (1). But there is the admission that "none of these processes, even when carried out with the greatest care and efficiency, offers any sort of guarantee against the admission into the Thames and Lea of noxious ingredients which may at any time be present in the sewage and which are capable of spreading zymotic disease." Thus the chief superiority claimed at one time for irrigation as against precipitation is virtually abandoned.

Prof. Frankland, before proceeding to his figures and tables, points out that the protection from pollution which is afforded by law to rivers is denied to underground waters. "That the latter may now be polluted to an unlimited extent without remedy was shown by the judgment of Mr. Justice Pearson in an action *Ballard v. Tomlinson*, recently heard in the Court of Chancery." Surely such a state of things should not be allowed to continue.

Prof. Frankland also states that it is only during the autumn and winter months that the total combined nitrogen can be regarded as any measure of pollution, whilst in the summer months it is considerably reduced by the presence of active vegetable and animal life. All the water delivered in London, excepting that of the Colne Valley Company, is pronounced unsuitable for washing.

Turning to the joint report issued by Messrs. Crookes, Odling, and Tidy, we find that these chemists have made a full analysis of one sample daily, whilst Prof. Frankland reports only on samples collected on one single day in each month. They take exception not to Prof. Frankland's methods or results, but they "protest most strongly against the peculiar modes of statement and comparison employed by him with obvious intent to disparage the river-water supply and exalt the well-water supply of the metropolis." Prof. Frankland's reports "suggest the

notion that the wholesomeness and desirableness of different water supplies are inversely as the ascertained quantities of organic matter which they contain—that a water containing two-tenths of a grain of organic matter per gallon is twice as unwholesome as a water containing only one-tenth, and a water containing one-tenth twice as unwholesome as a water containing only one-twentieth of a grain—and this irrespective of any ascertainment of the chemical nature and the hygienic character of the organic matter, and irrespective of any regard to the absolute smallness, one might almost say insignificance, of even the largest quantities habitually met with. If the statement has not this implied meaning it would seem, as we take it, to have no meaning at all.

Messrs. Crookes, Odling, and Tidy further compare the mean quantity of organic matter per gallon as given in Prof. Frankland's monthly analysis of the water of the five Thames Companies for the year 1883, with the mean determinations of the Birmingham water by Dr. Hills, and of the Loch Katrine water supplied to Glasgow, by Dr. Mills. It is interesting to find that whilst the water of the five Companies contained 0.287 grain per gallon, that of Birmingham contained 0.259, and that of Loch Katrine 0.250. The difference is certainly very trifling. Furthermore, the water of the Lea, as supplied by the East London Company, contained only 0.235, and that of the New River Company, which is also largely Lea water, only 0.173. Both these river waters are therefore purer than the Loch Katrine supply.

Sir F. Bolton does not undertake to decide the questions here at issue.

The remaining portion of the work, though invaluable as a book of reference to local officials, has no direct scientific interest. In it the author gives a description of the London water works, with maps and tables of capital, income, expenditure, profits, &c.

Appendices contain the rates empowered to be charged for supply by the eight Companies, statutory powers as to dividends, and regulations under the metropolis. Finally comes an account of the display made by the London Water Companies at the late International Health Exhibition.

This work undoubtedly fills up an important vacancy in our sanitary literature.

CORRESPONDENCE.

SCIENCE TEACHING IN SCHOOLS.

To the Editor of the Chemical News.

SIR,—With reference to Dr. Armstrong's paper on the above in the *CHEMICAL NEWS* (vol. 1., p. 239), I would ask chemists to consider whether it is desirable that further provision should be made for this teaching.

Surely the number of technical colleges now in existence is more than sufficient to supply any probable demand for technical instruction, and it should be remembered that the result of this wide diffusion of knowledge is to render it of less commercial value.

What has been the result (so far as chemists are concerned) of the opening of so many Science Colleges in recent years in this country? In my opinion simply to lower the rate of remuneration for work done till in many cases it is little better than that of an ordinary labourer. We have been told very often indeed during the past twelve months of the incalculable value this technical instruction was to the community at large, but very little has been said about the remuneration received by the pupils after the conclusion of their studies.

The matter is one of great importance, especially to the younger generation of chemists, and has not received the consideration it deserves. I should therefore be glad if

others would take the matter up and favour the readers of the CHEMICAL NEWS with their views on the subject.—I am, &c.,

Nov. 24th, 1884.

A CHEMIST.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Journal de Pharmacie et de Chimie.
Series 5, Vol. x., November, 1884.

Note on Sulphocyanic Urine.—H. Bretet.—The substance in certain urines which causes them to turn red with ferric chloride is commonly supposed to be potassium sulphocyanide. The author maintains that it is more probably ammonium sulphocyanide formed by a molecular transformation of sulph-urea.

The Preparation of Sodium Monosulphide.—A. Damoiseau.—Of 100 parts of soda lye at 45° (probably Beaumé) the author takes 45 parts, which he dilutes with twice the bulk of water. He then passes into the solution a rapid current of sulphuretted hydrogen, letting the mixture heat. When it is saturated the other 55 parts of lye are added and the whole is well shaken together.

The Bark of *Piscidia Erythrina*.—M. Limousin. A purely pharmaceutical paper.

Filters.—MM. Chamberland and Maigren.—The Chamberland filter consists of a porous cylinder of ground porcelain burnt at such a heat that it is capable of transmitting liquids but not solids. It is used in Pasteur's laboratory for separating microbes from their culture-liquids. He has found that on filtering the most impure waters neither microbes nor their germs pass through. In the Maigren filter the acting medium is a mixture of powdered hydrate of lime and of bone-black. This apparatus is said to remove not merely suspended but dissolved impurities.

Bulletin de la Société Chimique de Paris.
Vol. xlii., No. 4 and 5.

The Compounds Formed by Chromium Sesquichloride with other Metallic Chlorides.—M. l'Abbé Godefroy.—Chromium sesquichloride forms with the other metallic chlorides definite crystalline compounds. These compounds are all formed under identical circumstances; they are all decomposed by water with formation of hydrochloric acid, and the decomposition ceases when the liquid contains 32½ per cent of this free acid. Under corresponding conditions double chromium bromides and iodides are obtained.

On the Fat of Saint.—A. Buisine.—The author finds in this fat, in addition to the fatty ethers of the cholesterines, cerotate of ceryl, and other compounds of alcohols of the fatty series.

Extraction of the Amines Contained in Commercial Methylamine.—A. Müller.—Methylamine contains some very volatile amines—those of methyl, and others less volatile,—compounds of higher amines beginning with propylamine. The author gives distinct methods for the separation of these two classes.

On Certain Colloidal Compounds Derived from Ferric Hydrate.—E. Grimaux.—A great number of ferric derivatives constitute colloidal bodies feebly soluble and capable of coagulating under the influence of heat or of salts. It is already known that the nitrate, the acetate, and the ferric oxychlorides present this character, which

is also recognised in the alkalino-ferric derivatives of the polyatomic alcohols and in certain salts, such as potassium ferri-tartrate and the compounds obtained with arsenic and arsenious acids. The author examines in detail the alkalino-ferric derivatives of the polyatomic alcohols, the colloidal ferric salts, amongst others the arsenite and arsenate, the borate, phosphate, and silicate. The number of ferric derivatives giving colloidal solutions coagulable by heat is very great. The reason must probably be sought in the polyatomic character of ferricum Fe₂ and of the normal instable hydrate, which easily loses water and forms polymers.

A New Proof of the Non-Existence of Ammonium Hydrate.—Dr. Tommasi.—The author's view that ammonium hydrate does not exist in the so-called liquid ammonia, and that it cannot be properly compared with a solution of potassa or soda has been recently confirmed by M. Bouty in his researches on the conductivity of saline solutions. According to this savant the solution of an anhydrous alkali does not conduct electricity, whilst, on the contrary, the solution of a hydrated alkali conducts in the manner of salts. M. Bouty then observes that liquid ammonia conducts 110 times less than a salt of the same molecular weight, whilst potassa, soda, lithia, lime, and thallium oxide when dissolved in water conduct the current well. This fact cannot be explained save by admitting that the soluble metallic oxides form with water true hydrates, whilst ammoniacal gas, on the contrary, does not form with water any definite compound of a constitution analogous to the alkaline hydrates. According to the law of thermic constants it results that hydroxylamine, ethylamine, and trimethylamine, when dissolving in water, behave like ammoniacal gas, not forming true hydrates. Their solutions, therefore, should conduct the current very badly.

Note on "Dry Extract."—M. Jay.—Dry extract is a product sold for the purpose of sophisticating wines. Its chief constituents are commercial glucose, glycerin, tannin, dextrin, boric acid, and mineral salts. It may be detected by evaporating the wine to dryness and incinerating the ash, when the flame appears tinted with green, and by determining the glucose with the polarimeter according to Neubauer's method—the strong deviation to the right indicates dextrin.

Note on "Vinicolore."—M. Jay.—Vinicolore is a product sold at Toulouse, Agen, &c., for giving a factitious colour to red wines. It consists of elder-berries mixed with Biebrich red.

On Obtaining the Ash of Vegetable Liquids and Especially Wine.—M. Jay.—The author dries at 110° the extract obtained in a platinum capsule from 20 c.c. of wine. He ignites slightly so as to obtain a charred mass but not ash. He then adds a few drops of water and places it on the water-bath. The water acts upon the carbon in such a manner that it falls to a powder spontaneously, whilst the alkaline salts leave it and deposit themselves on the sides of the capsule. The desiccation is then finished at 110° to 115°, and the residue ignited. The author thus quickly obtains a very white ash without any loss of the alkaline salts.

Biedermann's Central-Blatt für Agrikultur-Chemie,
Vol. xiii., Part 4.

Report on Field Experiments with Summer Corn.—Prof. Emmerling.—Not calculated for useful abridgment.

Fermentation of Cellulose and its Solution in the Intestine.—H. Tappeiner.—The principal products of the fermentation of cellulose in the intestines of the ruminants, &c., are carbonic acid, hydrogen sulphide, and methane. It is not truly digested like the carbohydrates.

Motion and Milk-secretion.—Prof. H. Munk.—Moderate muscular exercise increases the yield of milk, but strong motion reduces the quantity.

Chemical Researches on the Development and Nourishment of the Silk-worm (*Bombyx Mori*).—Dr. O. Kellner.—Not adapted for abstraction.

Influence of Heat and Light on the Development of Plants.—Prof. Hellreigel.—In this concluding portion of his memoir the author discusses the comparative action upon plants of direct and diffused light and their development in coloured light.

Researches on Chlorophyll.—A. Tschirch.—From the *Berichte der Deutsch. Chem. Gesellschaft*.

A New Saccharine from Lactose.—Dr. H. Kiliani.—The compound in question, isosaccharine, is obtained by the action of lime upon milk-sugar.

MISCELLANEOUS

Cantor Lectures.—A Course of three Cantor Lectures on "The Use of Coal-Gas" will be delivered at the Society of Arts, by Mr. Harold B. Dixon, M.A., on Dec. 1st, 8th, and 15th. The subject of the first lecture will be on "The Composition of Coal-Gas, its properties, its combustion"; the second, "Coal-Gas as a source of Light"; and the third, "Coal-Gas as a source of Heat."

Commercial Arbitration.—At the request of the Council of the London Chamber of Commerce, the London Jute Trade Association has nominated the following seventeen gentlemen to act as Arbitrators in difficulties which may arise suitable for arbitration in the various branches of the jute trade, in connection with the Arbitration Scheme of the London Chamber of Commerce:—As Brokers—Messrs. F. J. Barber (Barber Bros.), J. C. Duncan (J. C. Duncan and Co.), F. Ferrier, J. Johnson (Rouse and Co.), C. Patterson (Cox, Patterson, and Co.), D. Falconer (D. Falconer and Co.), and J. Scott. As Merchants—Messrs. J. Douglas (Robinson, Fleming, and Co.), Gastav Green (Rehder and Co.), G. Henderson, Jun. (G. Henderson and Co.), F. Eisenlohr (Oesterley and Co.), E. E. Petrocchino (Petrocchino Bros.), J. A. Ralli (A. Agelasto and Co.), A. A. Vlasto (Ralli Bros.), and W. F. Malcolm (W. F. Malcolm and Co.). As Dealers and Manufacturers—Messrs. J. T. Ritchie (W. Ritchie and Sons), and W. H. Hindley (W. H. Hindley and Co.). List of arbitrators are now complete for the Chemical, Leather, Coal, Printing and Allied, Textile, Wine, Carriage Building, South African and West African Trades, and are at the disposal of merchants and traders of the City of London (whether members of the Chamber or not) who may desire to submit their disputes to the jurisdiction of the London Chamber of Commerce.

NOTES AND QUERIES.

*. Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

A New Method of Making the Purple of Cassius.—An alchemist named Cassius, living at Leyden, discovered in the year 1683 that a certain mixture of the solutions of tin and gold produced a fine purple-coloured precipitate, which has ever since been known by the name of "Purple of Cassius," and is much used to give a ruby colour to earthenware, glass, and artificial stones. Attempts almost innumerable have been made to ascertain the nature of this singular compound, but the results have been so contradictory as tended rather to mystify than explain the origin of its peculiar colour. Moreover, all the efforts used to produce a similar colour by other means have totally failed; so that at the present time the greatest uncertainty exists concerning its true nature, for some chemists regard the colour as an effect of metallic gold in the compound, and this is the most common view of the matter; whilst others suppose the colour to be due to an imaginary oxide of gold not yet isolated: but all chemists agree in considering tin indispensable necessary to the formation of the purple. I am about, however, to show that this latter opinion is incorrect, because a beautiful purple having the properties of the Purple of Cassius can be made without the use of tin, and perhaps the few observations which I shall add concerning the composition of this new purple may tend to elucidate the nature of

the Purple of Cassius, though it must be borne in mind that the said observations are the result of very small experiments, and require to be confirmed upon a larger scale. The principal agent employed in the new process is a fluid, to which, for want of a better term, I employ the name Phosphuretted Water, since it appears to be merely a solution of phosphorus in water, though no such solution is mentioned in any book that I know of. It does not affect the colour of neutral litmus-paper, nor does it act upon sulphurous acid when heated; consequently it contains neither hypo-phosphorous acid, phosphorous acid, nor the mixture usually called phosphatic acid, because all these acids decompose sulphurous acid when heated with it. To make phosphuretted water, a large glass bottle, such as a Winchester quart, having a well-ground stopper, is to be filled with recently boiled but cold distilled water, and an ounce or so of phosphorus being added, the bottle is to be closed and left for twenty-four hours in a cool place, after which the phosphuretted water may be poured out into a proper vessel, and the process repeated upon the same phosphorus as often as may be necessary. Thus furnished with phosphuretted water, we must next dissolve 7 grains of pure gold* and 2 grains of iron in aqua regia, and evaporate the solution to dryness by a steam heat; then re-dissolve the residue in 2 ounces of distilled water, and add this metallic solution solution gradually to any given quantity of the phosphuretted water until the mixture becomes slightly red, when the whole must be set aside and freely exposed to the air, by which it slowly assumes a rich ruby colour, and after a time lets fall a fine purple precipitate, which is the purple spoken of. There occasionally happens in this process, exactly as sometimes happens in the process of Cassius, an unaccountable slowness in the precipitation, and the fluid remains for days, or even weeks, of a clear crimson hue, very much resembling a solution of permanganic acid, nor will agitation, or even warmth, always put an end to it, though I once observed an obstinate solution of the above kind precipitated in a few minutes by a severe thunderstorm. It will be noticed that the proportions of gold and iron directed to be used are in the proportion of one atom of each metal, which is the ratio I have always found in the precipitate, even when the iron has been in very great excess in the solution. With regard to the composition of this new purple, I offer my opinions very modestly, for the observations I have made scarcely deserve the name of experiments. When a portion of the new purple is acted on by dilute hydrochloric acid a part is dissolved, and this part consists of the basic phosphate of the sesquioxide of iron, after the removal of which the residuum has a dark colour with an obscure tinge of purple; and if it is exposed for some time to the direct rays of the sun it becomes coated with gold as if gilded; but if without this exposure we boil the residuum in concentrated hydrochloric acid a part of it is dissolved into a solution of the perchloride of gold, and the insoluble part assumes a jet-black colour, and is but very slightly acted on even by boiling concentrated nitric acid. If, however, we heat it to a dull red heat in the open air it is converted into metallic gold and phosphoric acid, and from the relative proportion of the substances thus separated I have been induced to think that the composition of the new purple is as follows:—

	Atoms.	Grains.
Proto-phosphuret of gold..	One	228
Aurate of the protoxide of gold ..	One	424
Basic phosphate of the sesquioxide of iron..	Three	456

—L. THOMPSON.

* The presence of copper, and also of some other metals, totally prevents the desired effect.

MEETINGS FOR THE WEEK

MONDAY, Dec. 1st.—Medical, 8.30.

Society of Arts, 8. (Cantor Lectures.) "The Use of Coal-Gas," by Harold B. Dixon, M.A.

London Institution, 5.

on receipt of Order.

ST HELEN'S ENGINE, BOILER, AND BRIDGE WORKS
AND FOUNDRY,
LANCASHIRE

BICHROMATE OF SODA.

Potter and Higgin's Patent

A complete substitute for Bichromate of Potash in Dyeing,
Calico Printing, Colour Making,
and all other manufactures
where Chromic Acid is a necessary element.

*It contains as much Chromic Acid as
Bichromate of Potash.*

It is cheaper than Bichromate of Potash.

*It is more soluble than Bichromate of
Potash.*

It is of uniform strength and purity.

SOLE MAKERS—

LITTLE LEVER, NEAR BOLTON.

THE CHEMICAL NEWS.

VOL. L. No. 1360.

THE COMPOSITION AND METHODS OF ANALYSIS OF HUMAN MILK.*

By Prof. ALBERT R. LEEDS, Ph.D.

In a previous paper, "On Infant Foods," which I read before the College of Physicians of Philadelphia, May 2nd, 1882, I alluded briefly to the investigation then in progress upon the Composition of Human Milk, and gave a tabular statement of the minimum, maximum, and average results of the analyses of forty-three samples, the total number of analyses which I had made up to that date. Since then I have analysed thirty-seven more samples, and have verified the results by a critical examination of the various methods of analysis which are in use at the present time.

In the beginning of my previous paper I asked the question, "What is human milk?" and stated that to answer this question satisfactorily we should know at least three things:—1st. All the constituents. 2nd. Their relative proportion. 3rd. Their chemical and physiological properties. It is not my present object to discuss the first and third points, except in the light of the following isolated results which were only incidental to the main object of the present inquiry.

The albumenoids and fat of a large number of samples, as obtained by precipitation with Ritthausen's solution, were extracted with ether, until the albuminate of copper ceased to give up any further traces of fat to the solvent. It then became, after drying, a very light green amorphous powder.

In order to separate the albumenoids, this powder was digested with very dilute hydrochloric acid, which carries some of the organic matter into solution along with the copper. The residue, after washing and drying at 100°, formed brownish, somewhat brittle, amorphous masses.

The percentage of cupric oxide contained in this albuminate of copper was found, in two analyses, to be 20.93 per cent and 20.63 per cent. The ultimate analyses of the albuminate, after deducting cupric oxide, yielded the following results:—

	I. Per cent.	II. Per cent.
Carbon	49.07	49.17
Hydrogen	7.15	7.22
Nitrogen	14.67	—
Sulphur	1.08	1.15

Two analyses of the total albumenoids, left behind after the foregoing treatment of the albuminate of copper with dilute hydrochloric acid, gave the following figures:—

	I. Per cent.	II. Per cent.
Carbon	52.39	—
Hydrogen	7.02	—
Nitrogen	13.64	13.50
Sulphur	1.49	—

The albumenoids, separated by hydrochloric acid from the copper albuminate, were digested with 50 per cent alcohol, at the boiling-point. On cooling, the filtered solution deposited a white, flocculent, voluminous precipitate, whilst the residue on the filter formed a somewhat brownish mass.

This precipitate would correspond to the "caseo-protalbin" of Danilewsky (*Jahresb. der Thierch.*, 1880, 1886), and the residue, which was much the larger in amount, to his "caseo-albumen."

An analysis of the caseo-protalbin gave:—

	Per cent.
Carbon	55.86
Hydrogen	6.07
Nitrogen	17.17

An analysis of the "caseine," obtained by Makris in quite a different manner from Woman's Milk, yielded for its composition:—Carbon, 52.35 per cent; hydrogen, 7.27 per cent; and nitrogen, 14.65 per cent.

The foregoing analyses render evident that the bodies examined are not homogeneous, and in every case the process of separation left behind mixtures of substances the true nature and composition of which are at present unknown. Moreover, the deportment and properties of the bodies examined are such as to lead one to the conclusion that the investigation was being conducted not upon bodies in the condition and with the properties which they possessed originally in woman's milk, but upon substances whose composition and properties had been altered by the operation of the reagents employed.

It had been the intention of the author to endeavour to isolate the various constituents, at present very imperfectly known, of the fat of human milk. This desire had been increased by the fact that the ethereal extract of the copper albuminate obtained from numerous samples, although not by any means from all, was coloured emerald-green by some copper salt. As to the chemical nature of this copper salt, going as it does in perfect solution in ether, I have no knowledge. Unfortunately the entire mass of fats was lost by accident in the early stages of manipulation, and I shall have considerable difficulty in again procuring sufficient material to work upon. No sample of cow's milk which I have analysed yielded to ether an emerald-coloured solution. The unknown body is peculiar to woman's milk.

Methods of Analysis.

Passing by the methods of analyses which were employed when the nature of the difficulties to be overcome was imperfectly understood, and omitting from discussion in this paper the earlier results as obtained by Meggenhofen, Payen, Henri and Chevallier, L'Héritier, Quevenne, Simon, Clemm, Sherer, Donné, Heilen, Regnault, and Lehmann, the first method claiming our attention is that made use of by Vernois and Becquerel, in their essay "Du Lait chez la Femme," Paris, 1853.

Although regarded by the authors of the process as the smallest which they could employ, the amount of milk regarded by Vernois and Becquerel as necessary for analysis is excessive, being 60 grms.

Total Solids.—Of this 30 grms. are taken for determination of total solids, which are found by evaporation to constant weight at 80° C. It is evident that the evaporation of so large an amount at so low a temperature not only requires so very many hours, but presents great difficulties in the way of expelling the last traces of moisture.

Fat.—The total solids are exhausted on a filter with ether. The loss in weight is set down as fat. Or the ethereal extract after evaporation gives the weight of fat directly.

The estimation of fat by loss of weight involves numerous sources of error. And even the direct estimation according to this method is erroneous, inasmuch as ether very partially exhausts a dried residue of this nature. Consequently, the figures obtained by Vernois and Becquerel for fat are much too low, the average in 89 samples being only 2.67 per cent.

The other 30 grms. are coagulated by boiling with some drops of acetic acid. The filtrate contains sugar, extractive matters, and soluble salts.

* Read, by invitation, before the College of Physicians of Philadelphia, May 7th, 1884, and reprinted by permission from advance sheets of its Transactions.

Milk Sugar.—Its determination by the saccharimeter, as performed by Vernois and Becquerel, gives less accurate results than those obtained by direct chemical methods.

Albumenoids.—The authors regard the nature of the extractive matters as so entirely unknown as to make their determination by analysis impossible, and set down under one head what they denominate "caseum and extractive matters." Its amount is found by subtracting the sum of the weights of fat, sugar, and ash from the total solids. If it were possible by their method to determine these four quantities correctly, the difference, which they style caseum united with extractive matters, would be the albumenoids. But, otherwise, the difference represents the algebraic sum of the errors committed in the various determinations, and this difference, in the present instance, the amount of fat and sugar as stated by Vernois and Becquerel being much too low, is correspondingly too high, being 3.92 per cent.

Analysis by the same Method as that usually employed for Cow's Milk.—This method, which is practised by some of the public analysts of New Jersey and New York, and which is a somewhat modified form of Wanklyn's, will be found stated in Cairns's "Quantitative Analysis," p. 204.

The results obtained on sample of woman's milk, Laboratory No. 1133, were as follows:—

	Per cent.
Ash	0.21
Fat	2.62
Albumenoids	2.60
Milk sugar	8.19
Total solids by summation	13.62
Total solids by evaporation	13.63

The fat, as thus determined, is too low, although it was extracted by digesting the solids left after evaporation with boiling ether six times, and with cold ether as many times more.

The sugar is too high. After weighing it was re-dissolved in water, and the amount of albumenoids contained in it determined. This was 0.78 per cent. which, subtracted from the sugar, as determined in accordance with the method, left 7.41 per cent, which is the correct result.

The albumenoids are also too high, and the excess is still greater when the albumenoids contained in the sugar are added to those as determined in accordance with the method, the total being 3.38 per cent. This excess is due to fat.

Correcting the results, as found directly by the method, by the results obtained by separately analysing the various extracts, we have:—

	Per cent.	Per cent.
Fat, determined by method	2.62	
Fat, extracted from casein residue	2.18	
Actual Fat	—	4.80
Albumenoids, determined by method	2.60	
Albumenoids, contained in sugar	0.78	
Sum of albumenoids	3.38	
Deduct fat found in casein residue	2.18	
Actual albumenoids	—	1.20
Sugar, determined by method	8.19	
Deduct albumenoid found in sugar	0.78	
Actual sugar	—	7.41
Ash	—	0.21
Total solids, by summation		13.62
Total solids, by direct evaporation		13.63

Determination of the Albumenoids by Precipitation with Alcohol.—20 c.c. of dilute acetic acid are added to weak

acid reaction, then four volumes of strong alcohol, the mixture well stirred, allowed to settle during an hour, and filtered upon a weighed filter. The precipitate is washed six or eight times with cold 60 per cent alcohol, then with ether, dried at 120° to 125° C., and weighed. The alcoholic filtrate is evaporated to small volume, the resultant precipitate transferred by means of 60 per cent alcohol to a weighed filter, washed repeatedly with the same alcohol, and finally with ether. These filtrates are again evaporated to a small volume, the precipitate obtained dissolved in water, an aqueous solution of tannic acid added, the precipitate so obtained transferred to a weighed filter, washed first with water, then with alcohol and ether, dried at 120°, and weighed. The three precipitates together contain all the albumenoids. They must be ignited, and the amounts of ash deducted. This method gives too low results when the addition of tannic acid is omitted. The trial of this method, as performed on sample, Laboratory No. 1133, yielded the following results:—

	Per cent.
Albumenoids in first precipitate	0.66
„ second precipitate	0.55
„ third precipitate	0.42

Total albumenoids so determined .. 1.63

The analysis of these albumenoids yielded—

Fat	0.00
Milk-sugar	0.43

Deducting this amount of milk-sugar, we have—

Total albumenoids as found	1.63
Deducting milk-sugar	0.43

Albumenoids actually present 1.20

Distilling off the alcohol and ether from the first and second precipitates, and determining the milk-sugar in the collected filtrates from the albumenoids, I obtained—

	Per cent.
Fat	4.80
Milk-sugar	6.98

These results make it evident—what, indeed, was feared during the whole course of the analysis by this method—that notwithstanding the great expenditure of time in washing these precipitates, the washing was incomplete, and some milk-sugar was left behind. This supposition is confirmed by the fact, that upon adding the milk-sugar contained in the albumenoid precipitates to that contained in the filtrates, the sum is the correct percentage of sugar.

Determination of the Albumen and Peptone by Precipitation with Magnesium Sulphate.—The assumption upon which this method is founded is that when crystallised magnesium sulphate is added to milk to the point of complete saturation the casein is completely precipitated, whilst the albumen and peptone are not. In the execution of the method, 40 c.c. of a saturated solution of magnesium sulphate are added to 10 grms. of milk, and afterwards crystals of the same salt are added in slight excess of the maximum quantity which can be made to enter into solution. After standing several hours, with frequent stirring, the precipitate is transferred to a beaker, and washed six or eight times with a saturated solution of magnesium sulphate. The collected filtrates are then diluted with water, a drop or two of acetic acid added, heated to boiling for a few minutes, filtered through a weighed filter, the precipitate washed first with water and afterward with alcohol, dried along with the filter at 120° to 125°, weighed, and ignited. By subtracting the weight of ash from that of the precipitate the amount of albumen is determined.

In the filtrate the peptone can be precipitated by means of tannic acid, or by phospho-tungstic and sulphuric acids. I failed entirely in an attempt to perform an analysis

* "Handb. der Physiolog. Chem. Anal." Berlin, 1883, p. 492. Hoppe-Seyler.

* "Handb. der Physiol. Chem. Anal." p. 492. Hoppe-Seyler.

by this method. Owing to the great density of a saturated solution of magnesium sulphate the casein did not precipitate, but formed a layer on the surface of the liquid, and so slow was the operation of filtration that I did not succeed in completely washing the casein during the course of several days.

Haidlen's Method, as Modified by Christenn. *Total Solids.*—Instead of drying the milk at 110° with one-fifth of its weight of powdered gypsum, as proposed by Haidlen, Trommer proposed the use of pulverised marble, and Christenn employed powdered glass, the drying being conducted at 95° to 100° instead of 110°. Christenn found that the hygroscopic nature of the gypsum and its solubility in alcohol gave rise to errors, the latter property raising the percentage of milk-sugar and diminishing the percentage of albumenoids.*

Other Constituents.—To 10 grms. of milk add 10 c.c. ether and 20 c.c. alcohol, mix thoroughly, collect the precipitated albumenoids on a weighed filter, and wash with a mixture of ether and alcohol (1:2) until the filtrate runs through clear. The precipitate, dried at 95° to 100°, gives the weight of albumenoids and insoluble salts. By ignition the weight of the latter is obtained, and the difference gives that of the albumenoids. The weight of evaporated filtrates gives the combined weight of the fat, milk-sugar, and soluble salts. The loss of weight after extraction with ether gives the fat. The soluble salts and sugar are ignited, the residue treated with hot water, the solution evaporated to dryness, and ignited. The weight of this ignited portion gives the soluble salts, and the milk-sugar is found by difference.

NOTE. In the trial of this method I did not wash the precipitate of albumenoids and insoluble salts on the filter, but by decanting. The precipitate was shaken up six or eight times with the mixture of alcohol and ether, and the latter then pipetted off through a weighed filter. Finally, the albumenoids were thrown on the filter and washed exhaustively with the same mixture. The method of decantation is more rapid and thorough, but even with its aid and with the use in all of 250 c.c. of the mixed solvent, the washing of the albumenoids was incomplete, as shown by the following results of an analysis performed upon sample, Laboratory No. 1133.

Analysis according to the Haidlen-Christenn method:—

	Per cent.
Fat	2.90
Albumenoids	2.19
Sugar	8.23
Ash	0.21
Total solids	13.53

These various educts of the Haidlen-Christenn method were analysed and separated into their individual constituents. The albumenoids were exhausted with ether, and the fat determined in the ethereal solution. The residue was then exhausted with water, and the sugar determined in the aqueous extract. In the final residue, containing according to Haidlen the sugar, the nitrogen was determined directly, and multiplied by 6.25 to obtain the percentage of albumenoids. The nature of the errors inherent in the method is strikingly shown when the corrected results obtained in this manner are compared with those stated in the table above:—(See next column.)

This loss of 1.26 per cent represents fat, which I did not succeed in perfectly exhausting from the sugar residue after evaporation to constant weight, although the treatment with ether was performed very many times.

Meigs's Method.† *Total Solids and Ash.*—Pipette off 5 c.c. of milk into a platinum dish and weigh. Evaporate to dryness on a water-bath to constant weight. Incinerate, beat over a blast-lamp, and weigh the ash.

	Per cent.	Per cent.
Fat, extracted from the albumenoids ..	0.76	
Fat, extracted from sugar residue ..	2.90	
Fat, total as thus found	—	3.66
Albumenoids, determined by method ..	2.19	
Deducting fat in albumenoids	0.76	
Deducting sugar in albumenoids	0.16

Sugar in albumenoids	0.16	
Sugar in final residue	7.10	
Actual sugar	—	7.26
Ash	—	0.21
Total solids, as found by summation ..	12.30	
Total solids, as found by evaporation ..	13.56	
Loss	—	1.26

Fat.—Weigh off 10 c.c. in another dish, and wash with the aid of 20 c.c. of water into a tall 100 c.c. stoppered cylindrical graduate. Add 20 c.c. ether, stopper, shake for five minutes, then add 20 c.c. alcohol, and shake five minutes more.

Allow the cylinder to stand until the ether has risen to the top, pipette off, add 5 c.c. ether, shake, allow to separate, pipette off, and repeat this operation five times. Evaporate off the ether in a weighed dish; the increase in weight is fat.

Casein and Sugar.—The remaining contents of the graduate, after the ethereal solution of fat has been removed, are washed into a platinum dish and evaporated to dryness on a water-bath. The residue is treated with boiling-water, and allowed to stand. The undissolved casein precipitates, the solution of sugar is poured off. This latter is again evaporated to dryness, and the same process of settling and decantation repeated. This must be done four or five times, until it is found that when boiling-water is poured upon the dry sugar it dissolves completely, no flocculi of casein being seen in suspension. The casein residue is then, after being dried, treated once or twice with boiling-water to extract sugar. This sugar is added to the main portion. Both casein and sugar are then evaporated over the water-bath to constant weight, incinerated over a blast-lamp, and the losses in weight give the amounts of casein and sugar respectively.

Experimental Trial of Method. *Total Solids.*—In the weighing out of milk it must be poured directly into the dish in which it is weighed. If a pipette be used, the milk leaves minute particles upon its walls, and the alteration in composition thus produced is the greater, the more extensive the wetted surfaces of the measuring vessel.

Evaporation to dryness on a water-bath to constant weight is tedious, usually requiring three hours, and is neither so accurate nor so expeditious as the method of coagulation with alcohol.

Thus with sample No. 1133:—

To 5.1195 grms. milk add 3 c.c. alcohol, evaporated to dryness on water-bath, an operation requiring one half-hour, and then to constant weight in air-bath at 105°, requiring with intervals for weighing one hour longer.

Loss of weight 0.699 grm. or 13.56 per cent.

Compare with this the results obtained by direct evaporation without coagulation.

Evaporated 5.059 grms. of same milk for three hours on water-bath.

Loss of weight, 0.6985 grm. or 13.81 per cent.

Dried the same for two hours longer in air-bath at 105°. The weight decreased to 13.59 per cent.

Dried the same for two hours longer at 103°. The weight decreased to 13.56 per cent. In other words, at the expiration of seven hours, I had obtained the same constant weight as I had found by the method of coagulation at the expiration of one and one-half hours.

The explanation of the difficulty of evaporating milk without addition of any kind is evident, the casein coagu-

* The addition of gypsum, marble, glass, sand, &c., is unnecessary and a source of error.

† Philadelphia Medical News, June, 1884.

lated by heat forming a skin upon the surface of the milk which renders any further evaporation very difficult. Alcohol, on the other hand, divides the milk into fine coagula, which readily permit the escape of moisture.

Fat.—When water is present, ether will extract not only fat, but substances soluble in water. This was probably the case in the present instance, and experiment confirmed the conjecture. After distilling off the impure ether, drying the fat to constant weight at 105° and weighing, the fat thus obtained was re-dissolved in absolute ether. In every trial a residue was left behind. This residue dissolved readily in water. It proved to be milk-sugar, and its percentage was determined and added to that found elsewhere.

Casein and Sugar.—The method has two objections. The albumenoids of milk, and more especially of woman's milk, are partly soluble in boiling water, and cannot be perfectly separated from milk-sugar by its use. In the second place, the finely-divided albumenoids left after evaporation to dryness and treatment with boiling water cannot be accurately separated by the crude method of settling and decantation. As a result, in case the albumenoids are washed in this manner so completely that they do not contain any milk-sugar, their amount will be much too low, whilst that of the sugar will be correspondingly too high. The percentage of albumenoids in the milk-sugar was determined by direct determination of contained nitrogen in the following test analyses.

An attempt was made to separate the albumenoids by decantation through a weighed filter, but the process was extremely tedious, the albumenoids so coagulated quickly gumming up the filter-paper.

The results obtained were as follows, several analyses being made of the same sample, No. 1133.

	Percent.
Fat, originally obtained	4.77
Fat, after re-dissolving in absolute ether	4.66
Containing by direct determination, milk-sugar	0.10
Fat as originally obtained	4.82
Fat, after re-dissolving in absolute ether	4.48

1st Trial.

Albumenoids in residue	0.79
Albumenoids in milk sugar	0.63

Total albumenoids 1.42

2nd Trial.

Albumenoids on weighed filter	0.36
Albumenoids in milk-sugar	0.71

Total albumenoids 1.07

3rd Trial.

Sugar as originally determined	8.30
Add sugar contained in fat	0.34

Deduct albumenoids contained in milk-sugar 8.64

Actual milk sugar 7.92

Summary of Analyses,

	Per cent. (1)	Per cent. (2)
Ash (not with blast)	0.21	0.21
Fat	4.77	4.82
Albumenoids	0.79	0.36
Sugar	8.01	8.30
	13.78	13.69

The results obtained by Meigs's method will always differ from those by Hoppe-Seyler's, Haidlen's, and Christenn's methods, and from Ritthausen's method, by

giving necessarily a lower percentage of ash, a higher percentage of fat, a lower amount of albumenoids, and a larger percentage of milk-sugar. These differences are inevitable, and depend upon errors inherent in the method.

Gerber-Ritthausen's Method.—After using for a considerable length of time the methods of milk analysis in common use, the author was led by a comparison of the results obtained thereby with those found by Ritthausen's method to abandon the other methods and adopt Ritthausen's. The latter, as modified by Gerber, has now been in constant use in his laboratory for more than two years, and hundreds of analyses have been performed in accordance with it. The author regards it as the only method known at the present time which is precise and rigidly accurate. Moreover, it is so rapid and, when familiar, so easy of execution, that its employment soon becomes a source of pleasure and satisfaction.

Details of Method. Total Solids.—Weigh off 5 grms. of milked in a tared covered platinum capsule. Coagulate with absolute alcohol (about 3 c.c. are used), and evaporate to dryness on water-bath. Transfer to drying-oven, and keep at 105° C. until constant weight is attained.

Ash.—Ignite the residue first over a small flame, and finally at a dull red-heat. Cover the dish, cool in the desiccator, and weigh.

Albumenoids.—Dissolve 63.5 grms. pure sulphate of copper in a litre of water. Prepare also a potash solution containing 50 grms. caustic potash in 1 litre.

Weigh out 10 grms. of milk in a covered beaker glass, and dilute with 100 c.c. water. Add 2.5 to 3 c.c. of the copper solution. Then run in sufficient potash to exactly neutralise the excess of sulphate, which will require about 1.25 to 1.5 c.c. of the potash. The coagulated albumenoids settle immediately, leaving the liquid clear. In testing the reaction, the stirring-rod, which has been washed and withdrawn from the solution as soon as the potash has been stirred in, is dipped into the clear supernatant liquid. A drop of this liquid should turn neutral test-paper neither blue nor red. Care should be exercised not to allow the stirring-rod to bring up particles of the coagulum, since these interfere with the reaction. The clear liquid is then decanted through a filter-paper, previously dried at 110°, and weighed in a weighing-flask. The precipitate is then stirred up with 100 c.c. water, allowed to settle, the supernatant liquid again decanted through the filter, and, finally, the precipitate is washed upon it. The beaker is thoroughly cleansed with a rubber washer, and all these filtrates, amounting to about 240 c.c., are finally made up to exactly 250 c.c. for the determination of milk-sugar.

The filter-paper containing the precipitate is then opened out upon a large watch-glass, and, after drying to a certain point, is divided up into small particles by a platinum spatula, and this comminution is repeated from time to time until finally the whole mass becomes a fine powder.

Fat.—The filter-paper containing the precipitate is gathered up and placed loosely in a proper funnel. The beaker-glass used for the precipitation is washed out with ether to dissolve any traces of fat adhering to it, and these ethereal washings are poured through the funnel and allowed to run into a small weighed flask, with which the funnel is connected by a ground-glass joint. The funnel is then connected with a return cooler, the flask carefully heated by a water-bath, and the filter-paper is made to swim in the ether condensed in the funnel for about an hour, when the extraction of fat will be complete. The ether is distilled off, the flask dried at a temperature of 105°, cooled in a desiccator, and weighed. Its increment in weight gives the amount of fat.

Albumenoids.—The residue in the filter is dried at 110°, and weighed in the weighing-flask until constant weight is attained. It is then ignited in a platinum crucible, and the weight of ash deducted. The loss of weight is the amount of albumenoids.

Milk-Sugar.—This is determined in the filtrate by

Fehling's solution. The figures thus obtained are identical with those found by evaporation of the filtrate to dryness, igniting, and subtracting ash.

In case the above method is carefully followed, the sum of the several constituents as separately determined will not differ by an appreciable quantity from the amount of solid matter as determined directly by evaporation. Thus, it will be seen from the table, giving the results of 62 separate analyses of human milk (excluding Laboratory No. 1063 as being manifestly affected by some accidental error), the maximum difference is 0.21 per cent.

The average error, as determined by ordinary arithmetical methods, is 0.001 per cent. The probable error of any individual analysis, as determined by the method of least squares, is a difference of 0.0008 per cent in the sum of the several constituents as found by addition, and the sum as determined by direct evaporation.

This close agreement does not itself prove the accuracy of the methods employed. But, in connection with the fact that an analysis of the fat showed no trace of albumenoids or sugar, that an analysis of the albumenoids revealed no sugar or fat, and that an analysis of the sugar showed no albumenoids or fat, it does afford such proof.

The only serious objection to the method is that, in the precipitation of the albumenoids by Ritthausen's solution, hydrated basic sulphate of copper is precipitated at the same time, and that this hydrate does not lose its water at the temperature at which drying of the albuminates is effected. Hence, the weight obtained would be in excess of the true amount. This objection is not borne out by the results of analyses of the precipitated cupric albuminate, since I have failed to detect in it the presence of more than traces of hydrated basic sulphate.

(To be continued.)

NOTE ON THE CONSTITUTION OF THE β -AZO-COMPOUNDS.

By RAPHAEL MELDOLA, F.G.S., F.I.C., &c.

In a paper published in the March number of the *Journal of the Chemical Society* (*Trans.*, p. 106), I pointed out that the azo-compounds resulting from the action of diazo-nitraniline (para and meta) upon β -naphthylamine gave nitroso-derivatives by the action of nitrous acid, and from this circumstance I suggested that these bodies might be regarded as azimido compounds of the formula:—

instead of ortho-azo bodies of the formula—

I promised to extend my experiments in this direction, and for some months past have been engaged during the intervals permitted by other investigations in studying the various reactions of the bodies in question, with the object of proving or disproving the formula suggested. The crucial test of this formula is obviously the preparation of an alkyl derivative and subsequent reduction. Thus, by methylating or acetylating we should have, according to the old formula, a dimethyl or acetyl derivative—

Whereas an azimido body might furnish a diacetyl derivative or a dimethyl derivative of the formula—

The reduction-products of these bodies might be expected to be respectively—

and para- or meta-phenylene diamine. The formation of a diacetyl derivative would thus furnish strong evidence in favour of the new formula, and this evidence would be further strengthened if the reduction-product of the diacetyl derivative gave a dinitroso compound by the action of nitrous acid—

although it is doubtful whether such a body would not be too unstable for isolation. The dinitroso-derivative of the reduction-product of the dimethyl derivative (new formula) might be more stable:—

Dimethyl-diamido-naphthalene of the formula—

would possibly diazotise by the action of nitrous acid.

My experiments are as yet in too incomplete a state to pronounce decisively in favour of either formula, and I should not have put forward these purely speculative statements had it not been for the appearance of a paper by Rob. Henriques in the number of the *Berichte* just received (p. 2668). The author of this paper has made the interesting discovery that ethyl- β -naphthyl-nitrosamine acts upon aniline, toluidine, &c., in the sense of the equation—

The diazo-amido body becomes immediately transformed into the isomeric benzene-azo-ethyl-naphthylamine—

Speculating as to the reason why only β -naphthylamine derivatives lend themselves to this reaction and not diphenyl-nitrosamine, the author suggests that the hypothetical diazo-amido compound transforms itself so readily into the isomeric compound because the substitution takes place in neighbouring (ortho) positions.

Another explanation is furnished by the formula suggested by me in the paper above referred to, and the author proposes to test these views by ethylating the pro-

duct of the action of ethyl- β -naphthyl-nitrosamine and then reducing. According to the older view a base of the formula—

would be obtained, and in accordance with the new formula this base should have the constitution—

As regards this last suggestion, it will thus be seen that our respective lines of research threaten to come into collision, and without in any way wishing to chuck Herr Henriques's important investigation, I will only intimate my intention of continuing the experiments herein projected, and hope shortly to be able to offer some definite results for the consideration of my chemical colleagues.

I should like to take the present opportunity of stating that the diamido-azo bases of the general formula—

described in a former paper (*Chem. Soc. Jour.*, 1883, *Trans.*, p. 433), are also undergoing investigation. For these bases, which are isomeric with the Chrysoidines, I propose the name "Flavoidines."

Atlas Works, Hackney Wick,
November 27, 1884.

NOTES ON THE KOETTSTORFER METHOD FOR THE EXAMINATION OF BUTTER FOR FOREIGN FATS.

By RUSSELL W. MOORE.

WHILE testing butters according to the methods of Hehner,* Reichert,† and Koettstorfer,‡ it occurred to the writer that an examination of vegetable oils by the last two of these methods might furnish some interesting results. The object in view was to ascertain whether it is possible to mix butter or oleomargarine with an oil in such a manner that detection would be impossible by any one of the above methods.

In every case the analysis was conducted as directed in the papers referred to.

The following oils were examined in duplicate by the Koettstorfer process; singly, by the Reichert:—

	M.grm. KOH.	C.c. 1-10th Nor. NaOH.
Olive oil	185.2	0.2
Cotton seed oil ..	191.2	0.3
Peanut oil	196.6	0.4
Palm oil	196.3	0.8
Oil beune.. .. .	192.4	0.6
Oil sweet almonds..	187.9	0.3
Poppy oil.. .. .	192.8	0.5
Rapeseed oil	183.0	0.3
Linseed oil	195.2	0.2
Cocoa butter	199.8	1.6
Cocoanut oil	250.3	3.7
" " washed	246.2	2.7

It will readily be seen that none of the above oils could be mixed with butter without fear of detection by both processes, with the notable exception of cocoanut oil.

The cocoanut oil used was a refined article of evidently superior quality. Exposed to the air for more than a

week it did not turn rancid nor did its characteristic odour become perceptibly stronger.

Koettstorfer fixes the limits of the number of m.grms. of caustic potash requisite to saponify a grm. of real butter as between 221.5 and 232.4. Cocoanut oil, it will be seen, exceeds by a considerable amount the highest of these limits.

After the first results were obtained it was suggested that soluble free fatty acids might be present to render the result high. Accordingly about 20 grms. of the oil were thoroughly washed with boiling water to the amount of six litres. An examination then furnished slightly lower results by the Koettstorfer process, while the figures obtained by the Reichert process were reduced in a much greater proportion. It is then possible to mix an oleomargarine with cocoanut oil so as to bring the results within Koettstorfer's limits. In proof of this the following mixtures were made and results obtained, the object being to approach nearly the limits of Koettstorfer:—

Cocoanut Oil.	Oleomargarine.	M.g. KOH per grm.
49.3 p.c.	50.7	220.0
70.2 p.c.	29.8	234.9
Washed Oil.		
53.1 p.c.	46.9	223.6
75.9 p.c.	24.1	234.9

The oleomargarine used required 193.5 m.g. KOH per grm.

It is improbable also that these mixtures could be detected by the Hehner process, since cocoanut oil yielded 86.43 per cent of insoluble fatty acids.

The Reichert process would with such a mixture be sure to show the adulteration, for the number of cubic centimetres of 1-10th normal NaOH would be under one-third the amount requisite for a genuine butter.

In Dietzsch's "Nahrungsmittel," 4th Edition, p. 212, mention is made of cocoanut oil as an adulterant of "Schmalzbutter," and in the *Analyst*, vol. vii., p. 93, a case is reported of its use to adulterate lard. In this latter case the Koettstorfer process would serve as a test, since lard requires for saponification but 195.5 m.g. KOH per grm., and an addition of only 10 per cent of the oil would raise the figures to 201.

If a process should ever be devised to render cocoanut oil completely inodorous (and it should be extensively used as an adulterant of butter), it will be seen that the Koettstorfer process would be utterly worthless as a test, and the Hehner of scarcely greater value. Thus entire reliance would have to be placed on the method of Reichert.

John C. Green School of Science,
Princeton, N.J., U.S.A.

A NEW METHOD FOR THE DETECTION OF IODINE, BROMINE, AND CHLORINE.

By EDWARD HART.

If nitrates, chlorates, bromates, or iodates are present it is necessary to fuse the substance with a little sodium carbonate and charcoal to reduce them. If the haloids are united with silver it is best to fuse with sodium carbonate and extract with water, although with iodine and bromine this is not absolutely necessary (see Exp. No. 8 below).

The substance is placed in the flask shown in the figure with some water and a few drops of solution of ferric sulphate. In the bulbs are poured a few drops of dilute starch paste. The bulbs are kept cold by immersing in water in a beaker. The contents of the flask are then boiled, and if iodine is present the starch is coloured blue. This test is extremely delicate. If iodine is found the cork with the bulb tube is removed and the solution

boiled until on testing again in the same way no more iodine is found. If much iodine is present it is necessary to add more ferric sulphate solution. The bulb tube is now cleaned, charged with a few drops of water and a drop or two of chloroform, and a very small crystal of potassium permanganate added to the solution in the flask. The contents of the flask are boiled again, and if bromine is present the chloroform becomes red. The tube is now removed and more potassium permanganate and ferric sulphate added little by little, boiling between each addition until the bromine has all been driven off. A few drops of alcohol are added to the contents of the flask to decolourise any excess of permanganate, and after filtration chlorine is tested for in the filtrate with silver nitrate.

Mixtures were given to three qualitative students, neither of whom had used the test, with the result given in the Table above.

As in testing No 3 only about 1-10th of the substance given out was used for testing it is evident that an ordinary qualitative student can by this method detect the bromine in 0'0001 grm. KBr, and a very much smaller amount of KI can easily be found. It is also evident from 9, 11, and 12 that the presence of a large amount of bromine decreases the delicacy of the test for iodine.

The solution of ferric sulphate is made as follows:—Copperas is dissolved in water, oxidised with nitric acid, the solution precipitated with ammonia, and the precipitate washed by decantation and finally brought on a filter. 50 c.c. of dilute sulphuric acid (1 acid to 1 water) is then saturated with the still moist precipitate and to the solution 50 c.c. of the same sulphuric acid is added.

Nov., 1884.

Fluoric Apatites.—A. Ditte.—In the fluoric apatites, as well as in those containing chlorine, bromine, or iodine, arsenic and vanadic acids may be substituted for phosphoric acid, giving analogous compounds.—*Compt. Rend.*

ON THE SEPARATION OF ARSENIC FROM TIN AND ANTIMONY.

By F. HUFSCHMIDT.

THE author was induced by Prof. Classen to use along with Bunsen's process that recommended by E. Fischer, which consists in forming volatile arsenic trichloride by means of ferrous chloride and distilling it off.

The substance to be analysed, consisting of arsenic and antimony sulphides, was therefore first oxidised with ordinary nitric acid, a little fuming nitric acid being afterwards added, and was then distilled with 20 per cent hydrochloric acid (sp. gr. 1'1), exactly as directed by Fischer. The author did not, however, succeed in separating the arsenic by a thrice repeated distillation. On the contrary, even in the tenth distillate, traces of arsenic could be detected by means of hydrogen sulphide. The behaviour of a solution prepared by oxidising arsenious acid with chlorine in an alkaline solution was similar. On distillation with 20 per cent of hydrochloric acid, arsenic was detected in the seventh distillate by means of hydrogen sulphide. On the contrary, a solution of arsenious anhydride in hydrochloric acid, distilled as above, gave the result indicated by Fischer. On employing 0'1 grm. arsenious anhydride the third distillate was completely free from arsenic. On repeating the distillation of the arsenious acid oxidised by means of nitric acid or chlorine with hydrochloric acid containing 40 per cent actual HCl, it was found practicable under otherwise similar circumstances to separate the arsenic perfectly after the fourth or fifth distillation. Here it appeared, however, that not all the arsenic was condensed in the receiver, so that it had to be connected with an additional apparatus for condensation.

At the suggestion of Professor Classen it was next attempted to distil off the arsenic in a current of hydrochloric acid gas. The experiment was completely successful, the arsenic being entirely removed in a single distillation. The arsenical liquid was made up to 250 c.c. with the strongest hydrochloric acid. It was then completely saturated with hydrochloric acid gas and was then distilled in a plentiful current of the same gas. The volatility of the arsenic chloride was found to be so great that it had been almost entirely expelled before the first drops of the distillate had reached the receiver. After about 50 c.c. of the liquid had passed over, on continuing the operation, arsenic could no longer be detected in further portions of the distillate by means of hydrogen sulphide.

This method is in one sense more difficult than that of Fischer, since, in consequence of the excessive volatility of arsenious chloride, a receiver is not sufficient for condensation. The author has, therefore, modified Fischer's apparatus by connecting with the receiver a Wolff's bottle of about 900 c.c. capacity, containing 300 to 400 c.c. either of water or of potassa-lye of sp. gr. 1'1 to 1'2. To prevent an obstruction in the delivery-tube leading into the potassa-lye in consequence of the formation of potassium chloride, a glass tube, 28 c.m. in length and

its internal diameter, was arranged so as to dip 10 to 15 m.m. into the liquid. As the contents of the Wolff's bottle become strongly heated in the course of the operation suitable refrigeration is necessary. The author has satisfied himself by direct experiments that the last traces of arsenious chloride remain in the Wolff's bottle whether filled with water or with potassa-lye, and whether more or less arsenic is originally present. In all cases where large quantities of arsenious chloride have to be driven off the use of potassa-lye is preferable, as the distillate is otherwise more or less turbid. The author has further ascertained by especial experiments that when solutions of antimony and tin in hydrochloric acid are distilled as above in a current of hydrochloric gas, not the slightest traces of these metals can be detected in the distillate.—*Berichte der Deutsch. Chem. Gesell.*

THE DETECTION OF CYANOGEN.

By A. VOGEL.

THE reaction of picric acid with hydrocyanic acid is quite distinct even when the latter is diluted 30,000 times, and, as compared with the reaction of the formation of Prussian blue, it has the advantage of giving an immediate, or at least very early, decision, whilst the other method, in case of very dilute liquids, may require days. As an aqueous solution of picric acid, if heated with alkaline lye, takes a rather deeper colour; it is recommended to use for this reaction picric acid which has been already heated with soda- or potassa-lye.

The picric acid reaction effects the detection of hydrocyanic acid in tobacco-smoke very easily. The smoke is passed through soda-lye, which is then boiled with neutralised picric acid, when the deep red-colour at once appears. The author succeeded in demonstrating the presence of cyanogen compounds in coal-gas; he passed 6 litres of gas through strong soda-lye, and then treated it with neutralised picric acid, applying heat. A deep blood-red colour at once appeared.—*Bavarian Academy of Sciences, and Chemiker Zeitung.*

THE LATE HENRY WATTS, B.A., F.R.S., F.C.S.

Mr having become known to some of the friends of the late Mr. Henry Watts, whose death occurred very suddenly on the 30th of last June, that his widow and family are in very straitened circumstances, an informal meeting was held at the Royal Institution on Tuesday, the 11th of November. Those present resolved to form themselves into a committee, with power to add to their number, in order to collect a fund for the benefit of Mrs. Watts and those of her children who are not of an age to provide for their own support. Dr. Atkinson consented to act as Secretary, and Dr. Perkin, President of the Chemical Society, as Treasurer.

The following gentlemen constitute the Provisional Committee:—Sir F. A. Abel, H. E. Armstrong, Edmund Atkinson, William Crookes, Warren De La Rue, James Dewar, G. C. Foster, J. H. Gladstone, A. G. V. Harcourt, Hugo Müller, E. C. Nicholson, William Odling, W. H. Perkin, W. Chandler Roberts, Sir H. E. Roscoe, W. J. Russell, W. A. Tilden, W. A. Williamson, P. J. Worsley.

Mr. Watts's public labours for the advancement of Chemical Science may be said to have begun with the translation of Gmelin's "Handbook of Chemistry," the admirable English edition of which was prepared and edited for the Cavendish Society by him. This work occupies eighteen large octavo volumes, of which the first appeared in 1849, and the last in 1871. A work scarcely, if at all, inferior to this in magnitude, and one which has perhaps been of even greater service to English chemists,

both scientific and industrial, is Watts's great "Dictionary of Chemistry," which appeared from 1863 to 1881, in eight volumes, containing altogether nearly 9700 pages. Mr. Watts also edited and largely added to the second volume of the late Professor Graham's "Elements of Chemistry," published in 1858; he prepared several editions of Fownes's well-known "Manual of Chemistry," which he almost entirely re-wrote and made into virtually a new work; and in conjunction with Mr. Ronalds and Dr. Richardson he prepared for Messrs. Baillière an elaborate treatise on Chemical Technology. Up to the time of his death, and for about thirty years previously, Mr. Watts was Editor of the *Journal of the Chemical Society*, and in this capacity, as well as in that of Librarian to the Chemical Society, he became personally known to and gained the friendship of very many among the Fellows of the Society.

But although Mr. Watts's life was one of unremitting labour, the money return for his work was barely sufficient to enable him to provide for the daily wants of a delicate wife and a numerous family. It was not possible for him to provide for their future needs. But if he could not leave behind him pecuniary resources, he accumulated esteem and affection among all who knew him, which, it is confidently hoped, will prove a valuable legacy for those who were dependent on him. The following facts will show that there is great need of whatever practical proof of their regard for him and appreciation of his labours Mr. Watts's friends, and English chemists generally, may be willing to make.

For many years Mrs. Watts has been in ill-health, so that she cannot do anything for her own support and that of her family. Her only income is about £100 a year, and of her ten children only two are in a position to afford her help. They hope to contribute between them £150 a year. One son is a permanent invalid, and the four youngest children have still to be educated. A considerable expenditure is therefore unavoidable for a good many years to come, if the children are to have a fair chance of a start in life.

Subscriptions will be received and acknowledged by the Secretary, Dr. Edmund Atkinson, Portesbury Hill, Camberley, Surrey, or by the Treasurer, Dr. W. H. Perkin, The Chestnuts, Sudbury, Harrow.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

General Monthly Meeting, Monday, December 1, 1884.

The Hon. Sir WILLIAM R. GROVE, D.C.L., F.R.S.,
Vice-President, in the Chair.

THE following Lecture Arrangements were announced:—

Professor Tyndall, D.C.L., F.R.S.—Six Lectures (adapted to a Juvenile Auditory) on "The Sources of Electricity: Friction-electricity, Volta-electricity, Pyro-electricity, Thermo-electricity, Magneto-electricity;" on Dec. 27 (Saturday), Dec. 30, 1884; Jan. 1, 3, 6, 8, 1885.

Professor Henry N. Moseley, M.A., F.R.S.—Five Lectures on "Corals and other Colonial Organisms;" on Tuesdays, Jan. 13, 20, 27, Feb. 3, 10.

Professor Arthur Gamgee, M.D., F.R.S.—Four Lectures on "Digestion" (the subject to be continued after Easter); on Tuesdays, March 3, 10, 17, 24.

Professor Dewar, M.A., F.R.S.—Eleven lectures on "The New Chemistry;" on Thursdays, Jan. 15, 22, 29, Feb. 5, 12, 19, 26, March 5, 12, 19, 26.

Charles Waldstein, Ph.D., Heidelberg, Hon. M.A. Cantab.—Three Lectures on "Greek Sculpture from Pheidias to the Roman Era;" on Saturdays, Jan. 17, 24, 31.

George Johnstone Stoney, F.R.S.—Three Lectures on "The Scale on which Nature Works, and the Character of some of her Operations;" on Saturdays, Feb. 7, 14, 21.
Carl Armbruster.—Five Lectures on "The Life, Theory, and Work of Richard Wagner" (with Illustrations, Vocal and Instrumental); on Saturdays, Feb. 28, March 7, 14, 21, 28.

UNIVERSITY COLLEGE, LONDON,

CHEMICAL AND PHYSICAL SOCIETY.

Thursday, November 20.

C. E. CASSAL, F.I.C., F.C.S., President, in the Chair.

DR. MORLEY distributed specimens of hydroxylamine hydrochlorate prepared by the method recently described by Dr. E. Divers (*Journ. Chem. Soc.*, 1883.)

Mr. M. CHURCH gave a short note "On the Relative Merits of the various Qualitative Tests for Nickel and Cobalt."

Dr. J. F. EWAN (Hygienic Laboratory) exhibited a collection of the various salts obtained in the extraction of cobalt and nickel from the manganiferous ores of New Caledonia. These ores, containing the metals in the form of oxides, are extensively distributed over the island, and are also to be found on the continent of Australia. The amount of nickel and cobalt in various samples ranges from 1 up to 10 per cent. The process employed for obtaining the metals is that patented by M. Herrenschmidt, and is now being worked at Sydney, New South Wales.

SAMUEL RIDEAL, Hon. Sec.

NOTICES OF BOOKS.

Chemiker-Kalender (Chemist's Calendar), for 1885. By Dr. RUDOLF BIEDERMANN. Berlin, 1885: Julius Springer.

This excellent pocket-book, to which we have on several previous occasions drawn attention, and which has doubtless become well known and appreciated among our chemists, again makes its appearance for the coming year. The contents are much the same as in former editions, as well as the arrangement, a few extra tables having been added. The division of the calendar into two parts is still maintained, one containing tables relating to purely chemical matters, such as analytical factors, solubilities, specific gravities, short descriptions of the commoner analytical methods, and a lengthy mineralogical table; the other part contains tables that will be especially useful to the physicist, bearing on barometry, thermometry, thermochemistry, expansion, electricity, magnetism, and such like. All the published data issued since the last edition of this work have been employed in correcting several of the tables, whilst the new matter that has been added relates to diffusion, capillarity, and galvanic batteries.

The division of such a handy pocket-book as the present one into two separate parts possibly has its advantages, but we think it would be just as useful and might perhaps be rendered more convenient if the two parts were bound together.

Second Annual Report of the Board of Control of the New York Agricultural Experiment Station for the Year 1883. With the Report of the Director and Officers. Albany: Weed, Parsons, and Co., 1884.

In this Report, which is somewhat late in appearing, little matter of chemical value is contained; such as it is consisting wholly of analytical results—no special chemical investigation bearing on agriculture being recorded.

As regards the determination of nitrogen in fodder plants and such like materials, Dr. Babcock, the chemist of the Station, records a few comparative experiments made with the view to testing Kjeldahl's recently-described process for such determinations against the ordinary soda-lime method, and comes to the conclusion that the process is accurate and economical of time and gas, not to mention combustion-tubing.

In the botanical and horticultural reports a mass of heterogeneous data is given, from which the agriculturist may glean some interesting facts, perhaps more curious than of practical value; facts such as Darwin alone might have fully appreciated in compiling a work on botany to plead his theory.

In this, as well as in other countries, agricultural experimentation of a purely empirical character is yearly increasing, with its accompanying literature in the shape of reports. Such work as is undertaken in many cases appears to be utterly purposeless, or at most to support some pet theory, and consequently renders the squeezing out of the essence (if there be any) from these lengthy reports a most laborious process,—one, certainly, that few persons will be found inclined to undertake. If any real good is to be done by agricultural investigation it seems to us that the fewer words employed in describing the procedures the better, and that to each published investigation or report the conclusions that have been arrived at: as the result of the experiments should be appended. By this means, although the theory or aim that started the investigation may not be grasped, the facts that were obtained will be made capable of apprehension.

CORRESPONDENCE.

COCOA-NUT OIL.

To the Editor of the Chemical News.

SIR,—I notice that cocoa-nut oil has been examined by the Koettstorfer process by E. Valenta (*Wagner Jahresberichte*, 1883, p. 1152), and A. H. Allen (*Ibid.*, p. 1157), but hope that my results, as given in the article dated Nov. 14, will be of interest as confirming and extending those obtained in the paper referred to.—I am, &c.,

RUSSELL W. MOORE.

John C. Green School of Science,
Princeton, N.J., U.S.A.

ATOMIC WEIGHT OF CERIUM.

To the Editor of the Chemical News.

SIR,—In the *CHEMICAL NEWS*, vol. 1, p. 251, there is a paper by Mr. Henry Robinson containing an account of a re-determination of the atomic weight of cerium. As there seems to be some doubt about the colour of ceric oxide, obtained by igniting the oxalate in air (*CHEMICAL NEWS*, vol. xlix., p. 282), it would be interesting to know whether the material employed by Mr. Robinson for his atomic weight determinations gave a yellow or a white oxide.—I am, &c.,

SAMARIUM.

Formation of Anhydrides of Monobasic and Bibasic Acids.—R. Anschütz.—Many bibasic acids, if heated, give off water and pass into anhydrides, whilst most monobasic carbon acids distil unchanged. The author has especially studied the action of acetyl chloride upon the hydrates of certain bibasic acids. In the present paper he combines the results of previous experimentation on the formation of anhydrides by the action of acid chlorides upon hydrated acids.—*Liebig's Annalen*.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—A degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 19. November 10, 1884.

Penetration of the Light of Day into the Water of the Lake of Geneva.—H. Fol and E. Sarasin.—The light penetrates into the water of the Lake of Geneva to a depth of 170 metres, and probably beyond. At this depth the strength of the light in the day is about equal to that which we perceive in a clear moonless night. At 120 metres the light is still tolerably strong. In September, in cloudy weather, the light penetrated more deeply and more abundantly into the water than in August under a clear sky.

A General Enunciation of the Laws of Chemical Equilibrium.—H. Le Chatelier.

The Polymorphism of Silicium Phosphate.—P. Hautefeuille and J. Margottet.—Silica dissolves abundantly in trihydrated phosphoric acid. To demonstrate this property it is merely requisite to throw into phosphoric acid, heated to above 120°, hydrated silica as obtained on decomposing silicium fluoride with water. Ignited silica does not dissolve more rapidly than in hydrofluoric acid. In chemical analyses great care must be taken not to heat silica in contact with phosphoric acid above 100°. Silicium phosphate, SiO_2PO_5 , crystallises spontaneously in four crystallographic forms, mutually incompatible, and constituting four distinct chemical species: hexagonal crystals are formed below 300°, lamellæ resembling tridymite about 360°, regular octahedra between 700° and 800°, and clinorhombic prisms between 800° and 1000°. This polymorphism cannot result from the grouping of identical crystalline elements, for the hexagonal crystals are attacked by water, whilst the octahedral and prismatic crystals resist its action.

The Action of Primary Alcoholic Iodides upon Silver Fulminate.—G. Calmels.—The author has succeeded in methylating silver fulminate. He finds that this body consists of two dissymmetric portions, each containing silver. He views the fulminates as metallic isocyanides or carbilamines joined by nitrogen to a diatomic residue of metallic nitromethane.

Hydrate of Neutral Aluminium Sulphate.—P. Marguerite Delacharlonny.—The author gives instructions for the preparation of this salt which, if kept from contact with the air, contains 27 mols. water, but losses it off on free exposure.

Saponification of simple Aromatic Ethers by Neutral Bodies.—A. Colson.—On examining the action of water the author finds that the limit of saponification is reached more rapidly than with the fatty ethers. As regards the simple ethers derived from the xylenic glycols, the limit is the same for the three isomers, and probably for all the homologous ethers. The rapidity of saponification alone distinguishes the three isomers from each other. Alcohols attack the ethers of the aromatic series with rapidity at 100°, and very sensibly even at common temperatures. The alcohols ROH reacting upon the aromatic bromides give complex reactions, due, probably, to their dissymmetric constitution. They behave like true mixed bases, exchanging sometimes the group OH and sometimes the group RO.

Researches on Saccharogeny in the Beet-root.—Aimé Girard.—The author traces the origin of betose in the plant and its emigration towards the root.

The Peptonic Fermentation.—V. Marciano.—The name peptonic fermentation has been given to the transformation of albumenoids into peptones by the vital

action of microbia. The author added a few drops of the juice of the *Agave* to minced meat, covered with water and placed in a flask, which was then placed in a stove at 35° to 40°. An active fermentation set in, with liberation of inodorous gases: thirty-six hours afterwards the fibrine had disappeared, leaving a liquid charged with peptone, which, when dried in the stove, represented 20 per cent of the weight of the meat employed. The author proved by further experiments that this action is due to a figured ferment. Among the products of the reaction are lactic acid and a trace of alcohol. The author suggests that this process may be applied for exporting meat in a far more nutritive and economical form than the extracts of meat.

No. 20, November 17, 1884.

Experimental Demonstration of the Electromotive Force from the Contact of Iron and Copper at Elevated Temperatures.—F. F. Le Roux.—At the temperature of 1000° a current proceeding from the copper to the iron heats the point of junction, but refrigerates it at ordinary temperatures.

On the Rain-Waters of the City of Algiers.—M. Chairy.—The author has sought for ammoniacal salts in rain-water. In two cases he has found little or no ammonium nitrate, but has easily ascertained the presence of nitrite, even when operating upon so small a quantity as half a litre. Iodine has never been discovered. Hydrogen peroxide has been repeatedly sought for by Schœne's method, but with a negative result.

On Combustible Compounds of Carbon existing in the Atmosphere.—A. Muntz and E. Aubin.—The authors show that hydrogen carbides are poured into the atmosphere from a variety of sources. They prove that such gases, even when in minimum quantities, are decomposed by electric discharges with formation of carbonic acid.

On Arsenic Trifluoride.—H. Moissan.—If this compound is heated in presence of silica there is no deposit of arsenic, this body being entirely converted into arsenious acid.

Reaction of Ferric Oxide at High Temperatures upon certain Sulphates.—M. Scheurer-Kestner.—If a mixture of 2 parts calcium sulphate and 1 part ferric oxide is ignited to strong redness, all the sulphur of the mixture is expelled. There remains a melted mass, soluble even in weak acids, and insoluble ferric oxide. The result is similar with other diatomic metals. The sulphur is given off at first in the state of sulphuric anhydride, but afterwards as sulphurous acid and oxygen.

On the Ammoniacal Ferment.—A. Ladureau.—By ammoniacal ferment the author means that which transforms urea into ammonium carbonate. It exists in considerable quantities in the soil, in the atmosphere, in the waters on the surface of the earth, in rain, and in many underground waters. It acts as well in a barometric vacuum as at the normal pressure or even under a pressure of 3 atmospheres. It decomposes urea in presence of air, of oxygen, nitrogen, hydrogen, carbonic oxide, and nitrogen monoxide. With the exception of chloroform, which delays its action, anæsthetics have no effect upon it. Antiseptics do not interfere with its action, except when used in very large quantities.

The Presence of Amylase in Leaves.—L. Brassa.—The author finds amylase constantly present in all the leaves which he has examined, and in several seeds.

Justus Liebig's Annalen der Chemie,
Vol. 225, Part 1.

Communications from the Chemical Institute of Marburg.—These consist of a memoir by Th. Zincke and A. Breuer, on a Hydrocarbon, $\text{C}_{16}\text{H}_{12}$, from Styrolene

Alcohol; a paper, by Th. Zincke and A. Hedebrand, on the Action of the Quinones upon the Amido-phenols; and an Account of the Carbonic Ethers of Bivalent Alcohols and Phenols, by M. Wallach.

Communications from the Principal Chemical Laboratory of the University of Tübingen.—These include an illustrated memoir, by Lothar Meyer and Karl Seubert, on Gas-analysis at greatly-reduced pressure, and a paper by Lothar Meyer on the Calculation of Gas-analyses.

The Substitution of an Atom of Oxygen for Two Atoms of Chlorine in Chlorides, by means of Oxalic Acid.—R. Anschütz.—By means of dehydrated oxalic acid the author obtains the corresponding aldehyds from the chlorides of the monobasic and bibasic carbon acids; the aromatic aldehyds from the aromatic aldehyd chlorides and the aromatic acid chlorides; and the corresponding anhydrides from the aromatic ortho-acid chlorides.

Cosmos les Mondes.

No. 10, November 15, 1884.

The Liquefaction of Gases.—Dr. D. Tommasi.—The author has come upon the following passage in the *Antologia di G. P. Viessieux* (vol. xxvii., A.D. 1827):—"Perkins has submitted water and other liquids to powerful pressure, employing a bronze cylinder in which worked a steel piston. The cylinder was 34 inches in length; its internal diameter is 1½ and its external diameter 13½ inches. The greatest pressure exerted by means of this apparatus was 2000 atmospheres. Compressed air in contact with mercury began to be liquefied at 500 atmospheres; at 1000 atmospheres the mercury filled two-thirds of the space previously occupied by the air, and small liquid drops began to appear. At 1200 atmospheres there was seen over the mercury a transparent liquid occupying 1-2000 of the space previously taken up by air. Ethylen began to be liquefied at 40 atmospheres, and at 1200 it was entirely reduced to a liquid." Dr. Tommasi raises the question whether the air operated on by Perkins was absolutely dry?

MISCELLANEOUS

The Recognition of Atropine.—Dr. O. Schweissinger.—Some time ago A. W. Gerrard published a memoir on the behaviour of atropine with mercuric chloride. Unlike all other alkaloids it gives a red precipitate, whilst most other alkaloids give a white precipitate, codeine and morphine a pale yellow, and strychnine and caffeine none. Schweissinger has repeated Gerard's experiments. He finds that arbutine, condurangine, and sparteine give no precipitates, cocaine a white and scoparine a yellow precipitate. The behaviour of hyoscyamine and homatropine is especially interesting. If 1 m.g. of hyoscyamine (as Gerrard proposes) was covered with 2 c.c. of the reagent (5 per cent mercuric chloride dissolved in alcohol at 50 per cent) the red precipitate did not appear. If the hyoscyamine was only moistened with 1 or 2 drops of the solution and gently heated, the red precipitate appeared exactly as with atropine, and was not affected by the further addition of the mercuric solution. Homatropine gives no red precipitate, but a yellowish white one in very strong solutions.—*Chemiker Zeitung*.

NOTES AND QUERIES.

* Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Copper Matte.—A correspondent in the United States wishes to know of some responsible buyers of copper matte, carrying gold and silver.

Calcined Magnesia.—As a constant reader of your journal I should be glad if you could inform me of the best method to manufacture "calcined magnesia" from the original stone. Also the description of plant needed for the manufacture.—N. C. WRIGHTSON.

To Replace Coal-Gas.—Being so unfavourably situated as to be unable to have the advantages resulting from the use of coal-gas, I would be much obliged to any of our readers if they could inform me how to construct a furnace suitable for heating, say, 1 to 5 grms. of iron to the melting-point by means of petroleum, or any other cheap liquid fuel, with or without bellows power.—T. CHARLTON.

MEETINGS FOR THE WEEK

MONDAY, Dec. 8th.—Medical, 8.30.
— Society of Arts, 8. (Cantor Lectures.) "The Use of Coal-Gas," by Harold B. Dixon, M.A.
— London Institution, 5.
TUESDAY, 9th.—Institution of Civil Engineers, 8.
— Royal Medical and Chirurgical, 8.30.
— Photographic, 8.
WEDNESDAY, 10th.—Society of Arts, 8. "The Preparation of Butterine," by Anton Jurgens.
— Microscopical, 8.
THURSDAY, 11th.—Royal, 4.30.
— Society of Arts, 8. (Howard Lectures.) "The Conversion of Heat into Useful Work," by W. Anderson, M.Inst. C.E.
— Royal Society Club, 6.30.
— Mathematical, 8.
— London Institution, 5 and 7.
FRIDAY, 12th.—Astronomical, 8.
— Quekett Microscopical Club, 8.
SATURDAY, 13th.—Physical, 3. "On the Effect of an Electrical Current on the Thinning of a Liquid Film," by Prof. A. W. Reinold, F.R.S., and Prof. A. W. Rücker, F.R.S. "On a Theory of the Molecular Architecture of Solids, illustrated by a Wire Vibrating Torsionally," by Herbert Tomlinson.

TO CORRESPONDENTS.

T. Charlton.—Apply to the Secretary, stating your wish, and he will send you a balloting paper and directions for filling it up.

C. A. S.—(1) L. Meyer's and Mendelejeff's discoveries and theories are to be found fully described in our back volumes. (2) The library of the Chemical Society contains all the foreign and English scientific journals. Access to it is easy for any young chemist.

Now ready, 8vo., pp. 520, price 10s. 6d.

A FIFTH thoroughly REVISED EDITION, embodying the Act of 1883 and all Reported Decisions to date.

BICHROMATE OF SODA.

Potter and Higgin's Patent

A complete substitute for Bichro-
mate of Potash in Dyeing,
Calico Printing, Colour Making,
and all other manufactures
where Chromic Acid is a neces-
sary element.

*It contains as much Chromic Acid as
Bichromate of Potash.*

*It is cheaper than Bichromate of Potash.
It is more soluble than Bichromate of
Potash.*

It is of uniform strength and purity.

VOL. L. No. 1307.

ON JAPANESE CAMPHOR OIL.

By H. OISHI.

Laurus Camphora, or Kusu-no-Ki, grows in Japan mainly in those provinces in the islands Shikoku and Kiushiu, which have the southern sea coast. It also grows in Kishiu.

The amount of camphor varies according to the age of the tree. That of a hundred years old is pretty rich in camphor.

In order to extract this such a kind of the tree is selected, and its trunk, stems, &c., are cut into small pieces and introduced into a wooden tub, *a*, having a false bottom. This tub stands over an iron pan containing water, which is heated by a furnace, *c*, below, as represented in the figure. The steam arising from the pan passes into the tub, where it meets with the cut pieces of the wood, and carries the vapours of camphor and oil together into a condenser, *a*, by means of a bamboo pipe. Here all the camphor and oil, together with steam, are condensed, while the uncondensed portion of steam escapes into the air through a pipe attached to the corner of the condenser. The latter is made of a wooden trough which is surrounded by another one, *b*, filled with cold water. In order to expose a large surface to perfect condensation of the vapours, the condensing trough is fitted internally with a number of vertical partitions which are open at alternate ends, so that the vapours may travel along the partitions in the trough from one end to the other.

The continual supply of water is made by a pipe from which it flows into a wooden trough, *c*, placed just over the condenser. From the upper trough the water flows into the lower one, *b*, thus keeping the condenser cool all the time.

One operation requires about 20 hours. After that time the contents of the tube is withdrawn, dried, and used as fuel. A new charge is then introduced from the top of the tub, after which it is well closed and the distillation is again commenced.

To supply the water into the pan, it is better introduced from the top of the tub, before the charge is taken out; by this means the water in passing down through a heated layer of the wood becomes itself heated, and thus shortens the time of heating in the pan.

As the distillation begins, a semi-solid mixture of the camphor and oil generally accumulates between the partitions in the trough, floating above the condensed water. The camphor and oil thus accumulated in the trough are taken out after several charges, usually 5 to 10 days. The quantity of the yield varies greatly in different seasons. The solid camphor is obtained much more in winter than in summer, while the amount of the oil is just reverse. In summer time, from one charge consisting of 120 kilos. of the wood, 2.4 kilos. of the camphor are obtained in one day, while in winter from the same amount, 3 kilos. of solid camphor can be obtained in the same time.

In summer, from the semi-solid mixture obtained during 10 days, 18.04 litres of the oil are obtained, while in winter only 5 to 7 litres are obtained.

The oil, which contains in solution a considerable quantity of camphor, was formerly regarded as useless, but three years ago a method was devised which consists in distilling the oil and cooling the distillate. The arrangement of the apparatus is as shown in the figure.

The crude oil is introduced into iron kettles, *a*, *a'*. Each of them is provided with a stopper having two holes; one is for inserting the delivery tube, and the other is for introducing the crude oil during the operation. The vapour passing through spiral tubes made of brass, and kept cool by water, is condensed and the oil is received

into suitable vessels, which, when full, are taken away and cooled by surrounding with a fresh quantity of cold water. By this means the camphor separates out as a semi-solid mass, and in order to separate the solid camphor from the oil, the liquid is filtered or squeezed out through a cloth bag. The oil thus separated still contains a certain quantity of solid camphor. In order to remove this it is again mixed with a fresh quantity of the oil and distilled as before. In this way 173 kilos. of the crude oil yields 36 to 45 kilos. of solid camphor; thereby the volume of the original oil becomes about a half. The purified oil, or that which is freed from the camphor, is used as a lighting material by the lower people of the province.

The purified camphor oil is a colourless liquid and burns with a bright smoky flame; the general properties resemble very much those of the solid camphor. Crude oil has specific gravity 0.959 and the purified oil has 0.895 at 15° C. By oxidation in the air, or by nitric acid, or by oxygen, a change in the composition occurs, and it produces ordinary camphor together with certain higher oxyhydrocarbons, and the oil gradually becomes yellow. The oil dissolves many resins, such as gum-mastic, gum eleui, colophonium, &c.; it dissolves asphaltum, sulphur, and many other things.

Reactions with acids:—

Hydrochloric acid separates the oil into two layers, the upper one being transparent, the lower one is turbid. Nitric acid separates the oil also into two layers, the upper being yellow and the lower being colourless, but on heating it becomes a reddish liquid, which after some time again separates into two layers, but the oil suffers oxidation. When sulphuric acid is added, the oil is dehydrated, leaving a liquid smelling like terpene; when added in a large quantity, the oil is charred.

When chlorine is passed slowly into the oil, it is absorbed with elevation of temperature and evolution of hydrochloric acid fumes; the oil is thus changed into a yellow liquid. When excess of chlorine is passed, the oil becomes viscous. This semi-solid substance does not smell like camphor oil. With bromine the same reactions are produced, and when excess of bromine is added a red amorphous substance is formed. The oil dissolves a large quantity of iodine, and when heated becomes dark red. This dark red liquid when cooled below 0° C. becomes a semi-solid mass.

The specific rotatory power of the oil was examined by Sohli's saccharimeter and was found to be 68.96°, while the calculated value for $[\alpha]_D$ is 68.29°.

To separate the oils of different boiling-points, the original camphor oil was subjected to fractional distillation. The following is the result of distillation, using 200 c.c. of the oil.

Temp. of Distil.	Vols.
35 to 150° C.	12.0 c.c.
150 to 155	5.5
155 to 160	3.6
160 to 162	9.0
162 to 164	7.3
164 to 166	6.0
166 to 168	6.9
168 to 170	10.0
170 to 172	13.6
172 to 174	14.5
174 to 176	21.8
176 to 178	12.7
178 to 180	12.7
180 to 182	9.0
182 to 184	11.8
184 to 186	5.0
186 to 188	4.0
188 to 190	3.6
190 to 198	4.5
Residue	25.0
Total	188.5
Loss	1.5

All the distillates afford nearly the same reactions with the reagents.

The analysis of the distillate between 180° to 185° gave following result :—

C	78.87
H	10.73
O	10.40 by difference.

The composition thus nearly agrees with that of ordinary camphor.

After repeated distillations he gave the following analysis of the fraction between (178 to 180)° :—

$$C = 86.95 \text{ and } H = 12.28.$$

Thus it is a hydrocarbon.

(Exponent 3 means that the distillation was done three times). The vapour density of the hydrocarbon was found to be 5.7; its molecular weight is therefore 164.4. We have then the necessary data to ascertain its molecular formula :—

$$\frac{164.4 \times 12.28}{100} = 20.18 = H_{20}$$

$$\frac{164.4 \times 86.95}{190} = 11.91 = C_{12}$$

1. When colophonium, liquid balsam, gum elemi, or gum mastic is respectively melted in a porcelain dish and mixed with camphor oil, stirring all the time, each of them completely dissolves, and, when cooled, a heavy liquid is obtained, which may be used as a varnish. In applying this as a varnish it should be slightly warmed. This varnish, when spread over foreign paper and slightly warmed makes the paper very transparent. Japanese paper soaked in the same also becomes very bright and transparent.

2. When a little turpentine oil is mixed with the resin solution in the oil, the varnish dries much more quickly and assumes a brighter surface. The turpentine oil should be added after the resin is dissolved in the oil.

After various trials the following mixture was found to be the best :—

Camphor oil	10 grms.
Turpentine oil.. .. .	3'3 "
Resin	8'0 "

3. When mixed with linseed oil the same result as above is obtained, but this varnish does not dry so quickly as the second one, so that the varnished object requires slight warming in order to dry it completely.

4. Since the camphor oil dissolves dragon's blood, gamboge, the varnish may be coloured red or yellow. Little

FIG. 1.

One charge consists of 32 grammes = 120 kilos.
Boiler, 3 shaku in diameter. Wooden tub, 2.8 shaku in lower diameter and 1.5 in the upper, and 4 shaku in height.

The formula is therefore $C_{12}H_{20}$; thus it is a hydrocarbon of the terebene series, having the general formula C_nH_{2n-4} .

The appended table will show clearly the nature of different distillates and resemblance of the oil to the ordinary camphor.

From these experiments it appears that the camphor oil is a complicated mixture consisting of hydrocarbons of terpene series, oxy-hydrocarbon isomeric with camphor, and other oxidised hydrocarbons.

The distinguishing property of the camphor oil, that it dissolves many resins and mixes with drying oils, finds its new application as solvent for varnish. He tried in various ways with different resins and drying oils, and obtained rather a satisfactory result.

alcoholic solution of aniline-red, purple, and blue were respectively mixed with the resin solution and coated on paper, and on drying in sunshine the first two colours disappeared, but the last remained as a fine blue.

5. When camphor oil is added to melted asphaltum, stirring all the time, a good varnish is obtained, which, when coated upon metallic surface and dried, produces very fine bright surface just like Japanese urushi. The best proportion is 22 grms. of oil to 5 grms. of the asphaltum.

6. The mixture of camphor oil with linseed oil or rapeseed oil produces a kind of varnish, which when coated upon paper makes it water-proof. The best water-proof paper is obtained by using the solution of aluminium palmitate in camphor oil.

FIG. 2.

First, the paper was coated with a thin solution of the palmitate; this, after being dried, is again coated with more concentrated solution and dried; when the third coating is done the paper becomes stronger, and capable of resisting the action of water for more than thirty-five hours.

Soot has somewhat an extensive application, being used for making inks, paintings, and colouring walls, &c. The soot obtained from the camphor oil is one of the best qualities, and is used for making the best kind of our solid ink. It is therefore important to see how much soot can be obtained from a certain definite quantity of the oil, and whether it can be got profitably or not. The first method consisted simply in burning the oil and putting a cold metallic plate over the flame and collecting the soot deposited: by this means 7.5 grms. were obtained from 100 c.c. of the oil. When presenting this black to a certain dealer, the author was informed that the soot under question is next to the best quality, and that its price may be 35 cents per 375 grms.: the quantity of the oil required to produce it is 5 litres, calculated from the experimental result, and the price of 5 litres of the oil is 27.8 cents.

In the second experiment the oil was burnt in the same way, but within a metallic cylinder, whose bottom has many holes for admission of air. From 100 c.c. of the oil 13 grms. were obtained; therefore, only 3 litres of the oil are necessary to obtain 375 grms.

Three litres of the oil cost 16.7 cents, and produce 375 grms., costing 35 cents; thus there is an excess of 18 cents over the cost of the oil required. From this it may be said that the soot can be profitably prepared from the camphor oil.

The following is the report on the amount of annual production in Tosa:—

10th Year of Meiji (1877).

Amount of camphor produced .. 504,000 kins.
The total cost.. .. 65,520 yens.

11th Year of Meiji (1878).

Amount of camphor produced .. 519,000 kins.
The total cost.. .. 72,660 yens.

12th Year of Meiji (1879).

Amount of camphor produced .. 292,890 kins.
The total cost.. .. 74,481 yens.

13th Year of Meiji (1880).

Amount of camphor produced .. 192,837 kins.
The total cost.. .. 58,302 yens.

NOTE ON THE ESTIMATION OF ANTIMONY.

By GEORGE T. DOUGHERTY,

Chemist and Assayer Chicago Smelting and Refining Company.

In smelting-works like ours, the chemist is frequently called upon in the course of his work to determine antimony in ores, hard leads, antimony slags, and other products or by-products of the smelting and refining process. Great accuracy in the assay of this metal is attainable only by resort to a complete chemical analysis, which, as all of us know, takes quite a long time. The management usually cares for quick and approximately correct returns on antimony.

The method that will best answer these desiderata for the present is to be done half in the fire, and afterward completed with wet or chemical agents. Where the substance tested is an oxide, we may reduce the metals together into a button by means of charcoal or red argol. If there is any sulphur present, it would be better to dispense with the common method of reduction with argol and iron wire, but instead, to decompose with a mixture of equal parts of potassium cyanide and sodium carbonate. The button of lead and antimony thus produced will be clean and free from lumps of iron matte, which are often very difficult to remove by hammering without losing particles of the brittle alloy.

If assayed for lead and antimony, the button may be weighed, and after hammering thin or cutting into small pieces, put into a small porcelain dish; nitric acid (diluted with its volume of water) is poured over it, and is allowed to boil down with no replenishing of acid until very shallow, when the alloy will have been completely decomposed. All the lead goes into solution, while the antimony is converted into a white precipitate, which, after diluting the solution, may be filtered, dried, ignited, and weighed as antimony tetroxide (Sb_2O_4). The difference between the weight of the button and that of antimony in that button gives the amount of lead. If the button has been too impure, the lead may be determined in the filtrate from the antimonious acid as a sulphate. Ten grms. is a most convenient quantity to work on in assaying for those metals by this method.

It has been no easy matter to many of us before in attempting to cut up such alloy in solution quickly. One of the standard works on assaying, which is high in authority, and has always enjoyed deference of opinion among men of our profession, directs the use of "concentrated" nitric acid for dissolving. I have repeatedly tried with it; but it always has a very slow action on buttons of a similar composition, even when boiling, and taxes our patience heavily; for it takes not hours but good days to finish its prescribed work. With weaker acid (half acid and half water) the button can be separated completely within thirty or forty-five minutes.—*Engineering and Mining Journal*.

National Association of Science and Art Teachers.

—At the first meeting of the new Executive Council of this Association held in Manchester on Saturday, November 29th, Dr. H. C. Sorby, F.R.S., in the chair, Sir Henry E. Roscoe, F.R.S., &c., was elected President. Steps were taken to largely extend the Association, and it was decided to hold the next meeting of the Council in Birmingham, early in February.

NOTE ON THE ESTIMATION OF IRON BY POTASSIC PERMANGANATE IN PRESENCE OF FREE HYDRIC CHLORIDE AND CHLORIDES.

By JOHN J. HOOD, D.Sc., Assoc. Royal School of Mines.

THE estimation of iron by means of permanganate in solutions containing free hydric chloride is well known to be unreliable, owing to the action of this acid on the permanganate, and partly to the objectionable yellow colour acquired by the solution masking the final point in the titration.

In the course of some preliminary experiments on the rate of oxidation of ferrous chloride in presence of other chlorides towards a classification of chemical substances on a dynamical basis depending on their retardation effects, it was necessary to determine accurately the permanganate equivalent of the iron in such solutions to within 0.03 c.c. in 10 c.c. of the permanganate. It was found that in attempting to apply a correction for the error introduced by a constant amount of hydric chloride the presence of many soluble chlorides likewise produces an appreciable error in such estimations. In attempting to get over the difficulty a simple device was hit upon, one possibly employed by others, by means of which the estimation of iron in solutions containing hydric chloride or chlorides may be made as reliable as is the case when hydric sulphate is the acid employed and no chlorides in solution; at least in solution of such strength as indicated below, which, however, are somewhat more dilute than are usually employed. The device consisted in the addition of a few c.c. of a strong solution of magnesian sulphate,—from 1 to 2 grms. according to the amount of hydric chloride or other chloride present—to the iron solution before titration. By this means, probably ferric sulphate and not chloride being formed, the solution scarcely acquires any more perceptible colour than when ferrous sulphate is titrated, and the final point in the titration is well shown by the pure pink colour of the solution.

In the following results magnesian sulphate was employed, although a few comparative experiments made with ammoniac sulphate gave equally good results. Other soluble sulphates, however, might also be found equally efficient, but magnesian sulphate was selected owing to its great solubility, low molecular weight, and great retarding effect on the oxidation experiments referred to.

The solution contained 0.7 gm. iron as chloride in 250 c.c.; of this 10 c.c. were employed for each determination, equal to 0.028 gm. Fe.

The burette used was one of 10 c.c. capacity, on which 0.02 c.c. could be read. The results, although given in cubic centimetres, are only approximately so, being in reality expressed in the unit employed in calibrating the instrument.

By means of a solution of ferrous sulphate and one of potassic bichromate it was found that 10 c.c. of the above ferrous chloride solution should require 9.41 c.c. of the permanganate employed, and the following results were obtained under the different conditions:—

	C.c. KMnO_4 .
10 c.c. FeCl_2 solution—	
+0.1 gm. free HCl	required 9.54
+0.2 gm. free HCl	9.55
+0.3 gm. free HCl	9.55
+0.5 gm. free HCl	9.57
+1 gm. free HCl	9.65
+2 grms. MgSO_4	9.48
+1 gm. MgSO_4	9.43
+1 gm. MgSO_4	9.44
+1 gm. MgSO_4	9.43
+1 gm. MgSO_4	9.46

In presence of chlorides similar results were obtained.

Two solutions were made, each containing 0.7 gm. of the same iron wire, in one case dissolved in hydric sulphate and in the other in 3 grms. hydric chloride. 10 c.c.

of the ferrous sulphate required of the permanganate 9.29 c.c., whilst 10 c.c. of the chloride solution gave the following numbers:—

10 c.c. FeCl ₂ sol.	required	C.c. KMnO ₄ .
Ditto, +1 grm. MgSO ₄		9.31
Ditto, +0.5 grm. AmCl		9.62
Ditto, " " " " +1 grm. MgSO ₄		9.33
Ditto, +0.5 grm. MgCl ₂		9.45
Ditto, " " " " +1 grm. MgSO ₄		9.34
Ditto, +0.5 grm. BaCl ₂		9.47
Ditto, " " " " +1 grm. MgSO ₄		9.31
Ditto, +0.5 grm. ZnCl ₂		9.51
Ditto, " " " " +1 grm. MgSO ₄		9.34
Ditto, +0.5 grm. CaCl ₂		9.46
Ditto, " " " " +1 MgSO ₄		9.33

When baric chloride was employed the precipitate formed by the addition of the sulphate seemed to carry down some of the iron, and unless a little care was taken the results were liable to be slightly too low.

A few experiments were made by varying the amount of chloride up to 1 grm. (with 0.28 grm. Fe). Of the salts tried ammoniac chloride produced the greatest discrepancy, increasing with the amount of salt added, the depth of yellow colour of the solution also increasing. The addition of magnesian sulphate prevented almost wholly the formation of this colour, and gave practically the normal reading for the permanganate.

THE ESTIMATION OF ALKALIES IN SILICATES.*

By THOMAS M. CHATARD.

WALTER HEMPEL proposed (*Fres. Zachr.*, 1881, p. 496) bismuth subnitrate as a means of decomposing silicates containing alkalies, and recommended the use of 20 parts of this salt (= 10 parts of bismuth oxide) to one part of the silicate. In the *Berichte d. D. Chem. Gesellsch.*, 1881, there is an abstract of his paper, in which is proposed the use of bismuth oxide directly.

This process has been in use in this laboratory for the past six months, and, with some modifications, has given great satisfaction. Bismuth oxide has been used instead of the subnitrate, and experience has shown that, instead of 10 parts, as stated above, two parts of oxide to one part of the mineral are ample in every case in which we have employed the method.

The oxide and mineral, both finely powdered, must be thoroughly mixed, and then heated in a platinum crucible; applying at first a gentle heat and gradually increasing to full redness, which is kept up ten to fifteen minutes. In the case of an acid silicate, complete fusion may result, while the more basic the silicate the less fusible the mixture will be. Complete decomposition has been obtained when the resulting mass was so slightly sintered together as to fall on gentle pressure into powder, none of which adhere to the crucible. It has therefore been found advantageous, in dealing with acid silicates, to add to the mixture a quantity of calcium carbonate, in weight equal to that of the mineral. This device prevents the fusion which might hinder the after treatment with acid.

After the mass has been thoroughly heated to bright redness it is allowed to cool, placed in a dish, and hydrochloric acid somewhat diluted poured over it. On heating over the water-bath the mass should go into solution rapidly, leaving no residue of undecomposed mineral, which is easily distinguishable from floating flakes of silica.

If complete analysis is required, evaporate to dryness and separate the silica, as in a soda fusion, afterwards removing the bismuth by sulphuretted hydrogen. If only alkalies are to be determined, add ammonia and ammo-

nium carbonate, filter, and separate magnesia from the alkalies by any of the usual methods.

The results of this process have been very satisfactory. Out of a large number of analyses the following duplicate has been selected as being sufficient to show the accuracy of the work. It may be remarked that in the case of this margarite (a very basic silicate) the mass was but slightly sintered together.

Margarite.—Gainesville, Ga.

1.0300 grms. gave 0.0440 alkali chlorides = 0.0233 Na₂O = 2.26 per cent.

1.0243 grms. gave 0.0435 alkali chlorides = 0.0231 Na₂O = 2.25 per cent.

THE OCCURRENCE OF AMMONIA, NITROUS ACID, AND NITRIC ACID IN POTABLE WATERS.

By M. GREINERT.

THE natural formation of nitrites and nitrates is explained by a more or less complete oxidation of the ammoniacal compounds formed by the decomposition of animal matter. The case that ammonia or ammoniacal salts are present, unaccompanied by more highly oxidised compounds, is frequent. Occasionally there are found along with ammoniacal compounds, nitrates without the slightest trace of nitrites. In some cases nitrous acid is detected, whilst it is impossible to establish the presence of ammonia and nitric acid. The examination of 126 waters containing nitrogenous compounds gave the following result:—Ammonia alone, 21; nitrous acid alone, 6; nitric acid alone, 35; nitrous and nitric acid, 15; nitrous acid and ammonia, 13; nitric acid and ammonia, 17; nitrous and nitric acids with ammonia, 19. Hence it appears that nitric acid alone was the most frequent impurity in the wells under examination and in the third rank nitric and nitrous acids along with ammonia. Nitric acid with ammonia was more common than nitrous acid with ammonia. Nitrous acid alone was the rarest. The theory of the gradual conversion of ammonia into nitric acid is well known. But it does not explain why nitrous acid alone should be present, for the natural assumption is that those ammoniacal strata of water which come in contact with the atmosphere begin to take up oxygen and gradually transfer it to the lower strata. Ammonia should therefore always be detected along with nitrous acid, which in certain cases did not hold good. The theory, further, does not explain the striking phenomenon that ammoniacal compounds may be present along with nitrates, but without the slightest trace of a nitrite. —*Chemiker Zeitung and Pharm. Zeitung.*

COULOMB'S EXPERIMENTS.

A TEXT-BOOK CORRECTION.

By JOSEPH M. STOCKS.

MANY books state that in Coulomb's experiments with his torsion balance—the results of which experiments are given as proving that magnetic repulsions vary inversely as the square of the distance—"he found that the moveable disc at the top had to be turned 35° in order to move the needle 1°; that is, the earth's magnetic action was equal to a torsion of the wire corresponding to 35°." But there is evidently only a torsion corresponding to 34°; because the top disc has only moved 35°, and the needle has followed it 1°, so that 35° - 1° = 34°, the true angle of torsion.

"The torsion being proportional to the angle of torsion"

* From the *Bulletin of the United States Geological Survey*, No. 9.

the action of the earth corresponds to a torsion of 34° (and not 35°) for each 1° the needle moves away from the meridian.

This correction reduces the experimental error of Coulomb's experiment by 75 per cent, or rather by 125 per cent, because when, "by inserting a magnet, he repelled the needle through 24° ," the repulsive force (R) between the two, being balanced by the torsion of the wire, aided by the earth's action—

$$R = 24^\circ + (24 \times 34^\circ) = 816,$$

and not, as is usually given,

$$24^\circ + (24 \times 35^\circ) = 864.$$

When, turning the upper disc eight times round, he brought the needle back to 12° , where the repulsive force is balanced by the torsion (produced by the needle turning the bottom end of the wire 12° in one direction, and the upper end of the wire being turned eight times round in the opposite direction), aided by the earth's action, from which—

$$R = 12^\circ + (8 \times 360^\circ) + (12 \times 34) = 3300,$$

and not, as generally given,

$$12^\circ + (8 \times 360^\circ) + (12 \times 35^\circ) = 3312$$

$$4 \times 864 = 3456$$

$$3312$$

$$\text{Error } 144$$

$$3300$$

$$4 \times 816 = 3264$$

$$\text{Error after correction } 36$$

THE

COMPOSITION AND METHODS OF ANALYSIS OF HUMAN MILK.*

By Prof. ALBERT R. LEEDS, Ph.D.

(Continued from p. 267).

History of Samples Analysed.

THE mother's diet in every instance was simple, but abundant and nutritious. Only normal milks were analysed, such as came from healthy women; these presented, when submitted to the microscope, a normal appearance.

The physical history of mothers and infants is given in the original memoir, in Table I. (here omitted).

COMPARISON OF FINAL RESULTS WITH PREVIOUS ANALYSES.

Analyses of Eighty Samples of Woman's Milk.

	Reaction uniformly alkaline.		
	Average.	Minimum.	Maximum.
I. Specific gravity..	1.0313	1.0260	1.0353
II. Albumenoids ..	1.995	0.85	4.86
III. Sugar ..	6.936	5.40	7.92
IV. Fat ..	4.131	2.11	6.89
V. Solids not fat ..	9.137	6.57	12.09
VI. Ash ..	0.201	0.13	0.37
VII. Total solids (by addition of constituents)	13.268	10.92	16.79
VIII. Total solids (directly by evaporation) ..	13.267	10.91	16.66
IX. Difference between VII. and VIII. ..	0.001	0.00	0.21
X. Water..	86.732	83.21	89.08

The most interesting comparison which can be made is that with the results given by König (*Chemie der Mensch.*

Nahrungs und Genussmittel), which are deduced from the analyses of 190 samples. These analyses, it should be remembered, were performed according to the most diverse methods, errors in opposite directions operating to mutually compensate one another.

Analyses of samples of woman's milk (König) :—

	Average.	Maximum.	Minimum.
Albumenoids ..	1.94	0.57	4.25
Sugar ..	6.04	4.11	7.80
Fat ..	3.90	1.71	7.60
Ash ..	0.49	0.14	1.78(?)
Water ..	87.09	83.69	90.90

As might be anticipated, the extremes are wider apart than in my own analyses, but the general mean of all, with the exception of the ash, is tolerably concordant.

Omitting particular reference to the results of Fernois and Becquerel and earlier investigations, I will quote further only the results of Gerber (mean of six analyses), Christenn and Marchand (*Beilstein's Handb. der Organ. Chem.*, 2081).

	Gerber.	Christenn.	Marchand
Albumenoids ..	1.8	1.9	1.7
Sugar ..	5.4	6.0	7.1
Fat ..	5.3	4.3	3.7
Solids not fat ..	7.2	8.2	9.0
Ash ..	0.4	0.3	0.2
Total solids by evaporation..	10.9	12.8	12.7
Water ..	89.1	87.2	87.3

Bidert (*loc. cit.*) found the albumenoids to vary, in the samples which he analysed, between 1.5—2.4 per cent; fat, between 3.8 to 4.4 per cent. His mean for albumenoids is 1.95; my own is 1.995; König's is 1.94 per cent.

Two per cent., therefore, may be regarded, without sensible error, as the average amount of albumenoids in woman's milk.

The more extended series of eighty analyses confirm, however, the statements made in my earlier paper (that on Infant Foods), the albumenoids being the most variable constituent of woman's milk, the fat the next most variable, and the sugar the least. Nor have I any reason to alter the interpretation therein given of the physiological significance of the greater and less variability of the individual constituents.

Relations between the Physical History of the Milk and its Composition.

The only relations which I shall attempt to discuss here are those appertaining to the—

- 1st. Colour, taste, consistency, and specific gravity.
- 2nd. Age of the mother.
- 3rd. Period of lactation, and interval since nursing.
- 4th. Nationality.
- 5th. Physical constitution of the mother.

I. *Colour, Taste, &c.*—Whether bluish-white, chalky-white, whitish, yellowish-white, or yellow, the colour is no indication of the composition. For example, the milk of a German brunette, taken one hour after previous nursing and during the tenth day of lactation, was chalky-white in colour, whilst it contained 6.89 per cent of fat. This was the largest percentage of fat in any sample. On the other hand, though many of the yellow samples were rich in fat, other yellow samples were very poor. Thus, No. 8 was yellow (the milk being drawn during the fourth day of lactation, and four and one-half hours after nursing), while it contained only 2.31 per cent of fat.

Taste.—Although the amount of sugar in woman's milk is large, being nearly 7 per cent or 2 per cent more than in cow's milk, it is rarely sweet to the taste. Usually, it has a more less saline, somewhat disagreeable animal flavour.

Consistency.—Although the amount of solids in woman's milk is decidedly greater than in cow's milk, its consistency is much thinner and more watery.

* Read by invitation, before the College of Physicians of Philadelphia, May 7th, 1884, and reprinted by permission from advance-sheets of its Transactions.

Specific Gravity.—The average is somewhat greater than in cow's milk, though the entire range of variation is not very different. Thus, in the 80 samples examined, the average specific gravity is 1.0313, the minimum 1.026, the maximum 1.0353. Conrad obtained in 130 observations for the two last figures 1.025, and 1.039. In 147 samples

the first lustrum is 2.18 per cent, while it is only 1.92 per cent for the second, and 2.10 for the third. The difference is still more striking in regard to sugar. In the first lustrum the sugar is 7.17 per cent, falling to 6.91 in the second lustrum, and in the third only 6.77 per cent. This falling off is notable, not only in the percentages, but in the

of normal cow's milk L. Jenke found 1.0245 for the minimum, 1.034 for the maximum, and 1.0297 for the mean.

II. Age of Mother.—The milk of women under the age of 20 is richer in each and every constituent than that of older women. The general average of albumenoids for

number of samples which exceed the average. Thus, in the first lustrum, 83 per cent of the whole number of samples exceed the general average in sugar, while in the second lustrum only 60 per cent exceed. A similar diminution is observable in the fat and total solids,

(To be continued).

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, Thursday, December 4, 1884.

Dr. W. H. PERKIN, F.R.S., President, in the Chair.

THE following certificates were read for the first time:—W. L. Clarke, J. N. Collie, A. E. Dixon, G. Embrey, G. S. Jones, F. Rindskopf, H. White.

Mr. S. U. PICKERING then read a paper "*On Calorimetric Determinations of Magnesium Sulphate.*" The heat of dissolution of monohydrated magnesium sulphate is given by Graham as 13,200 cal., by Favre as 10,986, and by Thomsen as 13,300. None give any details of the preparation or analyses of the salt which they used. The author found it impossible to determine the sulphur by means of barium chloride with the requisite accuracy; the sulphur trioxide was found to be 1 to 1.5 per cent too high. The only reliable method for ascertaining the composition of any magnesium sulphate is a determination of the water. When the hepta-hydrated salt is heated to 100° to 130° it retains about $1\frac{1}{2}$ H₂O. This excess of one-ninth H₂O may be expelled by heating to 150° to 160°, but if this temperature be exceeded, some anhydrous salt will be formed. As a mean result the author finds that $\text{MgSO}_4 \cdot \text{H}_2\text{O} + 420\text{H}_2\text{O}$ evolves 12131 cal. Favre's salt probably contained $1\frac{1}{2}$ H₂O: Thomsen's specimen, on the other hand, may have contained some anhydrous salt. The anhydrous salt, $\text{MgSO}_4 + 420\text{H}_2\text{O}$ evolves 20765 cal.

Mr. HOWARD confirmed the statement of Mr. Pickering as to the very great difficulty of determining the sulphuric acid in magnesium sulphate by precipitation with barium chloride.

Dr. JAPP then read a paper "*On Condensation Compounds of Benzil with Ethyl Alcohol.*" by Miss M. E. OWENS and F. R. JAPP. In preparing benzylic acid by heating benzil with alcoholic potash Jena observed the formation of a neutral compound fusing at 200°, to which he gave the formula $\text{C}_{14}\text{H}_{12}\text{O}_2$. Limpricht and Schwanert obtained the same body by heating benzoin and alcoholic potash with access of air, and concluded that it was a derivative of benzoin and had the formula $\text{C}_{30}\text{H}_{26}\text{O}_4$. The authors of the present paper, by the protracted action of very dilute alcoholic potash upon benzil in the cold, have prepared this substance in large quantity, the yield being 60 per cent. The analyses lead to the formula $\text{C}_{30}\text{H}_{24}\text{O}_4$. Its formation may be represented—

10 grms. of caustic potash were dissolved in 2500 c.c. of alcohol, and 200 grms. of benzil in fine powder added. The whole was well shaken, and allowed to stand for about a fortnight, with occasional shaking. The new body gradually separates out as a crystalline powder. The substance after purification fused at 200° to 201°. It crystallises from alcohol with a molecule of alcohol of crystallisation, which seems to have been overlooked by Limpricht and Schwanert. When crystallised from benzene it also contains benzene of crystallisation. When heated with acetic acid a compound of the condensation product with acetic acid is obtained, but no true acetyl derivative could be prepared either by the action of acetic anhydride or acetyl chloride. A second condensation product was found in the mother-liquors, fusing at 232°, and having the formula $\text{C}_{46}\text{H}_{34}\text{O}_4$. The authors have also examined the action of dilute alcoholic potash on benzoin, and promise an account of it in a future paper.

THE SECRETARY then read a "*Note on the Solubility of certain Salts in Fused Nitrate of Soda.*" by F. B. GUTHRIE. The author has experimented with the sulphates, chromates, and carbonates of barium, strontium, calcium, and lead. The salts are added in small quantities to the fused nitrate of soda with stirring. The whole was allowed to

cool, and after partial solidification the remaining liquid was poured out and analysed. The chief results obtained are solubility of barium sulphate, 2.6 per cent; barium chromate, 0.205; barium carbonate, 0.916. The strontium salts taken in the same order gave 1.845, 2.133, and 0.69; calcium salts, 1.477, 0.547, 0.294; lead salts, 6.82, 0.245. Lead carbonate decomposed at the temperature of fusing nitrate of soda.

The following paper was also read by the SECRETARY:—"*On certain Derivatives of Isodinaphthyl.*" by A. STAUB and WATSON SMITH. In a former paper it was suggested that "by gentle oxidation of the dinaphthyls the corresponding isomeric naphthoic acids may be obtained." The authors, however, find that isodinaphthyl is not amenable to gentle oxidation. Strong nitric acid in the cold gives a nitro-body; dilute nitric acid in sealed tubes forms phthalic acid; potassium permanganate also gave phthalic acid. Chromic acid in glacial acetic acid, however, produced isodinaphthyl quinone, $\text{C}_{20}\text{H}_{10}\text{O}_4$, a yellow amorphous powder, melting with decomposition at 250° to 260°. By the action of strong nitric acid on isodinaphthyl a tetra-nitro body, $\text{C}_{20}\text{H}_{10}(\text{NO}_2)_4$, was obtained as an amorphous brownish yellow powder, melting with decomposition at about 150°. By the action of zinc-dust a tetramido body was formed. In conclusion, the authors give a list of the compounds of this remarkably stable dinaphthyl which have been obtained.

The Society then adjourned to December 18, when a ballot for the election of Fellows will be held.

UNIVERSITY COLLEGE, LONDON,
CHEMICAL AND PHYSICAL SOCIETY.

Thursday, December 4, 1884.

C. E. CASSAL, F.I.C., F.C.S., President, in the Chair.

THE Annual Address was delivered by Prof. T. G. BONNEY M.A., D.Sc., F.R.S., on "*Serpentine Rock and its Origin.*" The lecture was illustrated by Wright and Newton's new oxy-hydrogen microscope.

After the lecture a Conversazione took place in connection with University College Society. Exhibitions of scientific apparatus and chemical compounds were shown in the Library and Chemical and Physical Laboratories. During the evening demonstrations were given by Mr. Rose Innes, B.Sc., on "Radiant Matter;" by Mr. C. A. Schunck, on "Absorption Spectra;" and by Mr. E. E. Graves, F.C.S., on "Ozone."

The meeting was well attended.

SAMUEL RIDEAL, Hon. Sec.

OBITUARY.

THE LATE PROFESSOR KOLBE.

ON the evening of Tuesday, November 25th, this distinguished chemist came suddenly to his end. He had experienced no premonitory symptoms, and had, on the day of his death, been at work in his laboratory up to 5 p.m. He then went to a meeting, from which he returned about 8 p.m. and fell dead at the door of his house. An autopsy showed that fatty degeneration of the heart had been in progress for some time.

Adolf Wilhelm Hermann Kolbe was born in 1818 at Elliehhausen near Göttingen. He was educated at the Gymnasium and afterwards at the University of that town, where he studied chemistry under Wöhler from 1836 to 1842. During the three following years he was Bunsen's assistant at Marburg, and in 1846 he was co-assistant in

conjunction with Frankland in the laboratory of the Museum of Economic Geology in London, which was then under the management of Dr. (now Sir Lyon) Playfair. In 1847 he became editor of the *Dictionary of Chemistry*, (*Handwörterbuch der Chemie*) published at Brunswick. In 1851 he was appointed Professor of Chemistry at Marburg, whence he was called in September, 1865, to the chemical chair of the University of Leipzig, which he filled with efficiency and honour up to his death. In 1869 he undertook the editorship of the *Journal f. Praktische Chemie*, founded by Otto Linné Erdmann. In this position he had latterly, as his colleague, Prof. E. von Meyer, by whom the Journal will doubtless be continued.

From an early date Kolbe took a meritorious part in the development of organic chemistry. His first researches appeared in *Liebig's Annalen*, and treated of the composition of the fusel oil of grain, the action of chlorine upon carbon disulphide, and the discovery of trichlor-methyl-hyposulphuric acid and methyl-hyposulphuric acid. In concert with Frankland he undertook an investigation on the conversion of cyanomethyl and cyanethyl into acetic and propionic acids. The results of these researches were communicated to the Chemical Society of London in 1847, and here we find the first enunciation of the view that the fatty acids and benzoic acid contain alcohol radicles in place of an atom of hydrogen in formic acid. Kolbe further developed this view and verified it experimentally. When Wurtz subsequently endeavoured to appropriate these discoveries Liebig emphatically upheld Kolbe's prior claim, concerning whom he said:—"His researches are all harmoniously connected, and are supported by theories which throw more light on the origin of the non-nitrogenous organic compounds than any others which organic chemistry possesses. In 1847 Kolbe proved that the compounds obtained from alcohols as cyanides of their radicles can be transformed into acids containing a proportion of carbon higher than that of the alcohol. In 1848 Kolbe, proceeding on his view that methyl is a component of acetic acid, represented the kakodyl compounds as dimethyl-arsenic derivatives. In the same year Kolbe and Frankland succeeded in isolating methyl (dimethyl), and in the following year the former chemist obtained methyl by the electrolysis of acetic acid. In 1850 he developed his views on conjugated radicles. In 1855 he showed the conversion of an acid into the corresponding aldehyd by means of the chloride and the cyanide. In 1860 he brought forward the view that certain compounds bear the same relation to carbonic acid as do others to the sulphuric. In the same year he discussed the natural connection of the organic and inorganic compounds. He regarded glycolic acid as oxy-acetic acid and glyocoll as amido-acetic acid, and interpreted rightly the composition of lactic acid and its relation to alanine. He recognised isethionic acid as oxy-ethyl-sulphonic acid and taurine as amido-ethyl-sulphonic acid. His methods of exact investigation enabled him to foresee the existence of the secondary alcohols and to apprehend the constitution of the di- and tri-carbon acids. Kolbe and Frankland must be indubitably recognised as the authors of the doctrine of the saturation-capacity of carbon—a doctrine which has been more fruitful than any other in the development of theoretical organic chemistry. He has also enlarged our knowledge of the acids of gum benzoin, of the chemical constitution of asparagine and asparagic acid; of the isomeric relations of fumaric and maleic acid, as well as of itaconic, citraconic, and mesaconic acid; of uric acid, of certain derivatives of cyanide, and the phosphorus compounds of platinum. His method for the industrial preparation of salicylic acid has rendered this substance widely available for sanitary and medical purposes.

We must not overlook another phase of Kolbe's activity. As a chemical critic he exerted a wholesome influence by exposing baseless, or at least undemonstrable, speculations. Vagueness and ambiguity of thought and expression in chemical memoirs and treatises he denounced without mercy. It need scarcely be added that by taking up this

position (see the "Cemisch-kutischen Gänge," passim in the *Journal f. Praktische Chemie*) he isolated himself to a great degree from the less sober minded chemists of the day. It must be admitted that his critical writings occasionally at least bordered upon personalities. A singular but characteristic action was his rejection of the diploma of corresponding member of the Berlin Academy of Sciences, on the plea that he was too old to correspond with the Academy on scientific subjects.

Among his separate works are his "Manual of Organic Chemistry," in three volumes, (1854—1878); volumes iii. to v. of Graham Otto's "Manual of Chemistry,"; a "Short Text-book of Inorganic Chemistry (Brunswick, 1877), of which a second edition appeared this year, and of which a good English version has been recently brought out by Dr. Humpidge (Longmans and Co., 1884) and a corresponding "Text-book of Organic Chemistry," 1883. Nor must we forget his able satire "Aus der Molecular Welt."

His papers in the *Journal f. Praktische Chemie* cannot be here specified, but we may mention that his recent researches on isatine are said to promise, if not to present, "surprising results," and will be prosecuted by his assistants.

The greater part of the facts here given are taken from an article in the *Chemiker Zeitung* (Cathen).

CORRESPONDENCE.

HEATS OF FORMATION OF ORGANIC COMPOUNDS.

To the Editor of the Chemical News.

SIR,—There appeared in the *CHEMICAL NEWS*, vol. 1, p. 15, a communication from Dr. Ramsay on the "Heats of Formation of Organic Compounds calculated indirectly," and in a later number a letter from Mr. H. F. Morley briefly criticising the above paper.

As it appears to me that, in spite of Mr. Morley's lucid explanation, many young chemists and students might still be misled by Dr. Ramsay's views, I have allowed myself to write a few words on this important subject.

In the first place, the numbers —27,820 and —27,830, both of which Dr. Ramsay calls the "heats of formation of CH_2O_2 from its elements," are not, as Mr. Morley pointed out, the heats of formation of hydric formiate from its elements; and similarly, —16,380 and +63,160 are not the heats of formation of hydric acetate from its elements. That these numbers do not represent the formation heats of those compounds from their elements is apparent on mere inspection of the method in which Dr. Ramsay proceeds in his calculations, a method which he teaches us to adopt, not in preference over the ordinary way, but as the only true method of calculation.

He quotes Berthelot's calculation on the heat of formation of dipropargyl for showing some error in that calculation, but for my own part I am not able to find there any error, unless, of course, the experimental data are inexact.

Now, for calculating the heat of formation of an organic compound, we need make no assumption whatever as to the states in which carbon or hydrogen may exist in that particular compound. Let us, for example, calculate the formation heat of hydric acetate from its elements.

We start from an initial system consisting of C_2 (amorphous carbon) + $\text{H}_4 + \text{O}_2$, and arrive at an identical final system consisting of $2\text{CO}_2 + 2\text{H}_2\text{O}$ (liquid) by two different processes.

(i) Suppose we combine together C_2 , H_4 , and O_2 to form hydric acetate; this would evolve or absorb a quantity of heat which we want to determine. Call this quantity x . Let us then burn $\text{C}_2\text{H}_4\text{O}_2$ into 2CO_2 and $2\text{H}_2\text{O}$.

This, which represents the heat of combustion of hydric acetate, is found by experiment to be 210,300.

(2) Suppose we directly burn C_2 and H_4 into $2CO_2$ and $2H_2O$. This evolves, according to Julius Thomsen's data,—

$$2(C_2O_2) = 2 \times 96,960 = 193,920$$

$$2(H_2O) = 2 \times 68,360 = 136,720$$

$$330,640$$

Now, since starting from an identical initial system, we have arrived at an identical final system, the quantity of heat evolved during the first process must be equal to that evolved during the second. That is—

$$x + 210,300 = 330,640$$

$$\text{whence } x = 120,340$$

This number then represents the heat of formation of $C_2H_4O_2$ from amorphous carbon, gaseous hydrogen, and gaseous oxygen.

It may be observed that in this calculation we need not take into account the heat of vaporisation of amorphous carbon, because in both of the above processes we start from carbon in an equally solid state, so that the same factor entering into both sides of the equation of course cancels each other.

Dr. Ramsay seems to think that the only correct way of calculating the heat of formation of an organic compound is from "gaseous carbon," but I do not see any fault in stating the heat of formation from amorphous carbon or from diamond, as is indeed usually done.

In conclusion, I may point out that the heat of vaporisation of carbon is not exactly 39,780, as Dr. Ramsay states, even if we assume that "the heat of combustion of carbon supposed to be gaseous to form CO is identical with that evolved when CO burns to CO_2 ." And for this reason. When amorphous carbon burns to carbonic acid there is no gaseous condensation, but when carbonic oxide burns to carbonic acid there is a condensation from 3 volumes to 2, a process which evolves heat. We must take this into account, and consider the heat of combustion of carbonic oxide under constant volume, which is $68,370 - 290 = 68,080$. Hence the heat of formation of carbonic oxide from amorphous carbon is $96,960 - 68,080 = 28,880$, and the heat of vaporisation of amorphous carbon is, therefore, $68,080 - 28,880 = 39,200$.—I am, &c.,

J. SAKURAI,
Professor of Chemistry,
University of Tokio, Japan.

October 22, 1884.

THE ATOMIC WEIGHT OF CERIUM.

To the Editor of the Chemical News.

SIR,—Will you allow me to state, in reply to "Samarium," that an answer to his question will be given in a future paper.—I am, &c.,

HENRY ROBINSON.

Hardwick Street, Newnham Croft,
Cambridge.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—A degrees of temperature are Cent' grade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 21, November 24, 1884.

Experiments on Cocaine Hydrochlorate.—M. Vulpian.—These experiments relate solely to the physiological action of this compound.

Certain Reactions of Carbon Disulphide, and on its Solubility in Water.—G. Chancel and F. Parmentier.—If baryta-water is added to an aqueous solution of carbon disulphide the reaction at ordinary temperatures is scarcely appreciable. If heat is applied there is quickly formed a plentiful white precipitate of barium carbonate, whilst the supernatant liquid takes a fine yellow colour. In time the whole of the carbon present passes into the state of carbonic acid. This reaction is so definite that the authors found upon it a process for the quantitative determination of small quantities of carbon disulphide. The proportion of this compound dissolved in water sinks from 2 grms. per litre at 3.4° to 1.05 at 41.0° , and becomes null at the boiling-point of carbon disulphide. These experiments lead to the remarkable result that a solution of carbon disulphide in water behaves in a manner analogous to the solutions of gases which have no action on water.

The Action of Heat on Batteries, and on the Law of Kopp and Woestyne.—G. Lippmann.—The author establishes by a mathematical investigation that the battery elements which have a constant electromotive force are those which conform to the law of Kopp and Woestyne.

Dynamo-electric Machines: Experimental Confirmation of the two Reactions during Motion on the Effective Values of the Internal Resistance and of the Inducing Magnetism.—G. Cabanellas.—Not capable of useful abstraction.

Action of Water upon Double Salts.—F. M. Raoult.—The double salts which the author has studied are those containing more than one molecule of acid, and which may be regarded as formed by union of two simple salts of the same kind. He concludes that according as the lowering of the congelation-point of a double salt dissolved in water is equal or inferior to the sum of the partial lowerings of its simple constituent salts, we may decide whether the double salt is or is not entirely split up into its two components.

Composition of the Gaseous Products of the Combustion of Pyrites.—M. Scheurer-Kestner.—The deficiency of oxygen in the gases escaping represents the quantity of that gas which has been consumed by the sulphurous acid in its conversion into sulphuric acid. In fifteen determinations the author has found sulphuric anhydride absent in two cases only. The remaining thirteen gave results varying from 0.1 to 8.5 per cent.

Development in France of the Nematodes of the Beet-root during the Season 1884.—M. Aimé Girard.—The beets have been attacked by a parasite, *Heterodora schachtii*.

The Formation of Vegetable Acids in Combination with Potassa and Lime, of Nitrogenous Matters, and Potassium Nitrate in the Vegetation of Saccharine Plants.—H. Leplay.—Soluble potassium and calcium salts of the vegetable acids are distributed in all parts of the plant. There is a partial fixation of lime in insoluble combinations in the tissues, and an accumulation of the potassium salts of vegetable acids in the leaves.

Cosmos les Mondes.

No. 10, November 15, 1884.

A Congress of scientific societies is to be held at the Sorbonne during the year next ensuing. Among the physical questions to be discussed we find:—"Researches on the Presence of Watery Vapour in the Air by Astronomical and Spectroscopic Observations," and "What is the Utility of Magnetic and Electric Observations with reference to Weather-Prediction?"

A Forerunner of Pasteur.—Athanasius Kircher, in a work published in Rome in 1658, and entitled "Scrutinium Physico-medicum Contagiosæ Luis quæ Pestis dicitur," ascribes the Plague to the action of minute germs, or "animalcules."

No. 11, November 22, 1884.

Calculation of the Electromotive Force of Batteries.
—Dr. Tommasi.—The figure for a Daniell's element obtained by means of electro-chemical equivalents is too great by 7.5 per cent, whilst that given by the method of thermic constants only exceeds the experimental result by 0.46 per cent.

No. 12, November 29, 1884.

This issue contains no chemical matter, except such as has been taken from other journals.

Moniteur Scientifique, Quesneville.

Vol. xiv., December, 1884.

On the Bark of Remijia purdieana and its Alkaloids.—O. Hesse.

On Quinine and Homoquinine.—O. Hesse.—These two papers are taken from *Liebig's Annalen*.

Review of Foreign Chemical Researches.—G. de Bechi.—This consists of a series of extracts from the *Berichte der Deutschen Chem. Gesellschaft*, comprising notes on a new method of forming anhydrides, by B. Lackowitz; on a new process for preparing nitriles, by G. Kruss; on the trimethylenic derivatives, by W. H. Perkin; the replacement of amidogen by chlorine in aromatic compounds, by T. Sandmeyer; the action of bromine aqua-regia upon organic compounds, by Brunner and Kraemer; the action of copper upon the chloro-derivatives of toluene in the chain, by M. Onufrowicz; on certain derivatives of ortho-amido-aceto-phenone, by A. Baeyer; on amido-aceto-phenone and its homologues, by P. Klingel; on thiophthalic anhydride, by Graebe and Zschokke; on the presence of diphenyl in the oil of coal-tar, by K. E. Schulze; on α - and β -methyl-naphthaline, by K. E. Schulze; the action of bibasic organic acids upon hydrazo-benzene, by E. Bandrowski; on dinitro- β -naphthol, by Graebe and Drews; on β -ethyl-naphthaline, by O. Brunel; on certain derivatives of naphthaline, by R. Flessa; on some derivatives of the naphthoic acid, by A. G. Eckstrand; the preparation of chlorine derivatives of anthracene and anthraquinone from tetra-chlorophthalic acid, by G. Kircher; on Laubenheimer's reaction, by E. Odernheimer; on the condensation-products of thiophene with the aldehyds, methylal, and benzylic alcohol.

Means Employed to render Photographic Surfaces more Sensitive for the Green, Yellow, and Red Rays.

—H. W. Vogel.—In this memoir, which is taken from the *Berichte der Deutsch. Chem. Gesell.*, the author speaks of the substances which, when added to silver bromide, render it sensitive to all rays. He finds that one and the same colouring matter acts in very different manners upon different surfaces. Paris violet used with dry silver bromide collodion is as sensitive for the orange rays as for the blue, whilst with gelatino-bromide the sensitiveness for the orange rays is scarcely 1-50th of that for the blue rays. Moist collodion is still less favourable. Eosine behaves in an opposite manner; if a solution containing 1-400th of this colour is added to gelatino-bromide in the proportion of 2 per cent, the yellow of the spectrum has one-third of the sensibility of the blue. With dry collodion the yellow and the blue are equally sensitive to light, and moist collodion containing eosine is 8 to 10 times more sensitive for the yellow than for the blue.

Industrial Review and Patents.—A summary of English and German chemical patents along with a few technological notes.

Industrial Society of Mulhouse.—Meeting of October 8th, 1884.—M. Goppelsröder sent in two memoirs on the formation of oxy-cellulose and on that of persulpho-cyanogen by the electrolytic process. In the former paper he shows that if cotton is soaked in a solution of potassium or sodium nitrate, chloride, or chlorate, whether acid,

neutral, or alkaline, placed upon 8 or 16 folds of moist tissue resting on a sheet of platinum which serves as the negative electrode, whilst there is placed above another sheet of platinum forming the positive electrode, and the current is passed, the cloth is converted into oxy-cellulose in the parts touched by the positive electrode. In discharging Turkey reds or vat blues by the electrolytic process the cloth is weakened in the discharged parts by the formation of oxycellulose. In the second memoir the author describes the formation of persulpho-cyanogen by the electrolysis of a boiling solution of potassium sulpho-cyanide. He shows that this body may be simultaneously formed and fixed electrolytically upon cloth, either white, or dyed a Turkey-red or a vat blue.

A. Scheurer described the power of the alkaline hypobromates of discharging indigo blues. Upon this colouring matter they act much more energetically than the corresponding hypo-chlorates. With certain other colours e.g. that of raw cotton, this is not the case.

Certain Reactions of Silver Cyanide.—C. L. Bloxam.—From the *CHEMICAL NEWS*.

Detection and Determination of Picric Acid.—G. Christel.—From the *CHEMICAL NEWS* and the *Zeitsch. für Anal. Chemie*.

The Pungent Principles of Plants.—Dr. Thresh.—From the *Pharmaceutical Journal*.

Lectures on Fermentation.—Professor W.N. Hartley.—From the *Journal of the Society of Arts*.

Bulletin de la Société Chimique de Paris.

Vol. xlii., No. 8.

This issue contains no original memoirs.

Nos. 9 and 10.

Apparatus for the Rapid Determination of Oxygenated Water.—M. Martignon.—The author's method cannot be described intelligibly without the accompanying figures.

Justus Liebig's Annalen der Chemie,

Vol. 225, Part 2.

On the Carbon Acids of Synthetic Pyridic Bases.

—R. Michael.—The author considers that the natural alkaloids may be regarded as complicated pyridine-derivatives. In this paper he examines collidine-dicarbon-etheric acid with its salts, collidine-dicarbon ether hydrochloric acid, collidine-monocarbonic ether, collidine-monocarbonic acid, collidine carbon hydrochloric acid, the oxidation-products of collidine-monocarbonic acid, such as lutidine-dicarbonic acid and its salts, picoline-tricarbonic acid, and pyridine-tetracarboxylic acid.

Communications from the Principal Chemical Laboratory of the University of Tübingen.—These consist of an inaugural dissertation by R. Brix on the exchange of the halogens between organic and inorganic compounds, a paper on the same subject by B. Köhnlein, and a memoir on inorganic chlorides as transferers of chlorine by A. G. Page.

Bark of Remijia Purdieana and its Alkaloids.

—O. Hesse.—As the alkaloids present in this bark the author enumerates and describes cinchonine; cinchonamine with its salts, its behaviour with acetic anhydride, with nitric acid, with methyl-iodide and with ethyl-iodide; conusconine, its salts, its behaviour with methyl-iodide and the two series of derivatives thus obtained; chairamine and its salts; conchairamine, its salts and its behaviour with methyl-iodide; chairamine and conchairamine.

Physico-Chemical Notes.—Eilhard Wiedemann.—A reply to the criticisms of Schiff on the author's method of determining the change of volume in bodies during fusion.

MEETINGS FOR THE WEEK

- SATURDAY, 13th.—Physical, 3. "On the Effect of an Electrical Current on the Thinning of a Liquid Film," by Prof. A. W. Reinold, F.R.S., and Prof. A. W. Rücker, F.R.S. "On a Theory of the Molecular Architecture of Solids, illustrated by a Wire Vibrating Torsionally," by Herbert Tomlinson.
- MONDAY, Dec. 15th.—Medical, 8.30.
Society of Arts, 8. (Cantor Lectures.) "The Use of Coal-Gas," by Harold B. Dixon, M.A.
London Institution, 5.
- TUESDAY, 16th.—Institution of Civil Engineers, 8.
Pathological, 8.30.
- WEDNESDAY, 17th.—Society of Arts, 8. "The Present and Prospective Sources of the Timber Supplies of Great Britain," by P. L. Simmonds.
Geological, 8.
- THURSDAY, 18th.—Royal, 4.30.
Chemical, 8. Ballot for the Election of Fellows.
Philosophical Club, 6.30.

MANCHESTER CORPORATION GAS-WORKS.

MANAGER.

The Gas Committee are prepared to receive applications for the Appointment of a Manager for their New Station at Bradford Road, at a Salary of £500 per annum. Preference will be given to a gentleman possessing a practical knowledge of the working of Regenerative Furnaces.

The successful candidate will be required to devote the whole of his time to the duties of his office.

Applications, stating age and experience, and enclosing copies of recent testimonials, to be forwarded to the office of the Superintendent of the Gas Department, on or before 12 o'clock noon on Monday, the 22nd December instant, addressed to the Chairman of the Gas Committee, and endorsed "Application for Appointment of Station Manager."

Canvassing will disqualify.

Town Hall, Manchester,
3rd December, 1884.

By Order, JOS. HERON,
Town Clerk.

BAILEY'S HYDRAULIC MOTORS.

BAILEY'S WATER MOTORS.

Silver Medal, Manchester, 1879; Blackburn, 1881.

WHAT THEY ARE DOING:—

- The Water Motor blows Blacksmiths' Fires at Penmaenmawr.
The 2-horse Water Motor daily works Waggon up an incline at Edge Hill Collieries, Bolton, with success.
The *Brighton Guardian* is regularly printed by these Motors, giving the highest satisfaction.
The Lifts are in Hotels and Warehouses of Manchester, Dublin, Liverpool, Lancaster, &c.
The "Thirlmere" drives a Grindstone at Bristol.
The 4-horse Water-Motor is at work Cutting Timber, by circular saw, 5 inches thick.
A 20-horse Water Motor, pumping for H. Vivian, Esq., M.P.
A 12-horse Water Motor, pumping at the Mine of G. N. Newdegate, Esq., M.P.

TESTIMONIALS.

- June 22, 1881.—From H. H. Vivian, Esq., M.P.—"I have just heard that the Water Motor sent out last year is doing well."
Lord Salisbury's Clerk of Works writes:—"I am much pleased with the Water Motor, for it is most compact and useful."
From Messrs. Seed Brothers, Leather Merchants, Halifax:—"The Water Motor is doing its work well and quietly, and bids fair to answer our highest expectations."
From Lever Edge Coal Company, Bolton:—"The Water Engine you have supplied does its work well."

Prices and full particulars on application to—
W. H. BAILEY & Co., Albion Works, Salford, Manchester.
Hydraulic Engineers, Pump Makers, Gauge Makers, also Makers of all kinds of High-class Steam Fittings; Brass Founders to Her Majesty's Government Departments, Woolwich Arsenal, Indian State Railways, Trinity Board, &c.

E. J. DAVEY

(Printer of THE CHEMICAL NEWS).

Estimates forwarded for all descriptions of
Scientific, Technical, and General Printing.

BOY COURT, LUDGATE HILL, LONDON, E.C.

ESTABLISHED 1879.

ROBERT DAGLISH & CO., ENGINEERS, BOILER AND BRIDGE MAKERS, MILLWRIGHTS, BRASS AND IRON FOUNDERS.

Manufacturers of every description of Condensing, or High-pressure Blowing, Pumping, Rolling, Winding, and Patent Steam-engines of any required power, for Irrigating, Draining, Mining, Rolling Mills or Water Works purposes, and Manufacturers of every description of Chemical, Colliery, Copper Ore, Gold Mining, Glass, and Rock-sal Machinery.

- Black-ash Revolving Furnaces of the Most Approved Type.
- Bessemer Steel-Rail Plant.
- Compressing-Engines for Collieries, Iron Works, and Weldon's Patent Bleaching-Powder Process.
- Caustic, Chlorate, Decomposing, Nitre Nitro-Glycerine, Iodine Potash, Sulphur, Acid, and Oxalic Pans.
- Gas Producers Patent for Heating and other Purposes.
- Pyrites Burners for Irish, Norwegian, and Spanish Ores of Improved Construction.
- Patent Rousing Machinery for Brewers.
- Retorts, Acid, Gas, Iodine, Nitric, Nitre Nitro-Glycerine and Vitriol Refining.
- Steam Superheaters improved or Oil Tar and Resin Refining.
- Steam Sulphur Melter.
- Stills for Oil, Resin, and Tar.
- Wheels, Bevel Mitre, and Spur Moulded on the Shortest Notice by Patent Machinery.
- Makers of Alizarine Plant, Jones and Walsh's Patent Sulphate of Soda Furnace, Kynaston's Patent Alum Plant, Macdon's Patent Carbonating Furnace, and Farnell and Simpson's Patent Causticiser, Improved Revolving Copper Calcining Furnaces.

Lists sent on Application.

Photographs, Plans, and other information supplied on receipt of Order.

51 HELEN'S ENGINE, BOILER, AND BRIDGE WORKS
AND FOUNDRY,
LANCASHIRE

BICHROMATE OF SODA.

Potter and Higgin's Patent

A complete substitute for Bichromate of Potash in Dyeing, Calico Printing, Colour Making, and all other manufactures where Chromic Acid is a necessary element.

It contains as much Chromic Acid as Bichromate of Potash.

It is cheaper than Bichromate of Potash.

It is more soluble than Bichromate of Potash.

It is of uniform strength and purity.

SOLE MAKERS—

E. P. POTTER & CO.,
LITTLE LEVER, NEAR BOLTON.

Vol. L. No. 1308.

THE ABSORPTION-SPECTRA OF THE ALKALOIDS.*

By W. N. HARTLEY, F.R.S.,

Professor of Chemistry, Royal College of Science, Dublin.

WHILE studying the molecular constitution of various organic substances by means of their action on the ultra-violet rays in the manner described in the *Philosophical Transactions*, vol. 170, 1879, it was considered of importance to ascertain whether absolute physical measurements could not be substituted for the uncertain chemical reactions and variable physiological tests at present employed as a means of detecting the alkaloids in medical examinations. About forty alkaloids and derivatives therefrom have been examined, authentic specimens having been procured from the chemists by whom they were prepared. Solutions were carefully made of the same strength in most cases, only diastinic solvents, most generally alcohol, being employed. The cells with quartz sides for holding the solutions were of various thicknesses, ranging from 1 m.m. to 20 m.m. The electrodes employed to give a well-defined spectrum consisted, one of an alloy of tin with 20 per cent cadmium, the other of lead with cadmium in the same proportion. Spectra are thus obtained with lines of the same intensity, numerous and evenly distributed throughout a spectrum extending from wave-length 4414.5 to 2145.8. The prominent lines of cadmium are distinguished by their extension across the spectrum from pole to pole, while those of lead are on one side only and those of tin on the other. As a weaker continuous spectrum fills the intervals between the lines, there is no difficulty in obtaining accurate measurements. To secure well-defined spectra the photographs were taken with the solutions placed in front of the slit upon which the rays from the sparks were concentrated by a quartz lens of 2 inches diameter and 3 inches focal length. The spectra were measured by means of an ivory scale applied to the surface of the photographs; this had bevelled edges and was divided thereon into hundredths of an inch. The linear measurements are termed scale numbers and are arbitrary, but they were reduced to wave-lengths by the use of an interpolation curve. The oscillation frequencies were also read off on a second curve, whenever it was considered desirable to record them. The wave lengths were taken from those published in the *Philosophical Transactions*, p. 63, 1884, but for use in recording these measurements the fractions of a tenth-meter were disregarded. The total number of lines employed, including two or three air lines, was seventy.

The absorption curves which have been drawn differ from those figured in my previous communications, owing to the use of wave-length numbers, and the curves being made continuous, and so avoiding the necessity for shading; but very careful descriptions of the spectra are furnished in addition, so that no detail may be omitted. Nearly all the samples of alkaloids examined were obtained from Messrs. T. and H. Smith and Co., of Edinburgh, Mr. David Howard, of the firm of Howard and Sons, of Stratford, and Dr. C. R. A. Wright, F.R.S. The bodies may be divided into two groups, those which exhibit spectra with absorption-bands and those with continuous spectra.

Alkaloids and Derivatives exhibiting Absorption-bands in their Spectra.

Aconitine	Tetracetyl morphine
Pseudoaconitine	Diacetyl codeine
Japaconitine	Quinine
Morphine	Quinine sulphate
Narcotine	Cinchonine sulphate
Codeine	Quinidine sulphate
Thebaine	Cinchonidine sulphate
Papaverine	Veratrine
Oxynarcotine	Piperine
Apomorphine hydrochloride	Brucine
Cotarnine hydrobromide	Strychnine

Alkaloids yielding Continuous Spectra.

Narceine	Hyoscyamine
Aconitine (foreign)	Digitaline
Cevadine	Picrotoxine
Atropine	Nicotine
Solanine	Caffeine

The conclusions to be drawn from this investigation are the following:—

1. The absorption-spectra offer a ready and valuable means of ascertaining the purity of preparations of the alkaloids, and practically of establishing their identity.

The quantity of some of the alkaloids present in a solution may be estimated by means of the absorption-curves.

The different character of the various specimens known as aconitines may be recognised: thus the comparatively harmless base may be distinguished from those of great physiological activity by its transmission of a continuous spectrum, while the three specimens of physiologically active aconitines are distinguished from one another by their characteristic absorption curves.

That the three active aconitine bases are substances each with a different chemical constitution, is a conclusion confirmed by optical examination.

The purity of quinine and absence of any admixture of cinchonine can be readily determined by reason of the latter substance being much less diastinic than the former; but for the same reason quinine cannot be estimated in presence of cinchonine. Drugs of such potency as aconitine, morphine, quinine, strychnine, &c., which ought to be prescribed only when of absolute purity, should have their exact nature and degree of purity guaranteed by an examination of their absorption-spectra.

2. In comparing the spectra of substances of similar constitution it is observed that such as are derived from bases by the substitution of an alkyl radical for hydroxyl, the curve is not altered in character, but may vary in length when equal weights are examined. This is explained by the absorption-band being dependent upon the compactness of structure of the carbon and nitrogen nucleus of the molecule, and because equal weights are not molecular weights. Examples are afforded by morphine and codeine (methyl-morphine), diacetyl-codeine, and tetracetyl-morphine.

3. Bases which contain oxidised radicals, as hydroxyl, carboxyl, or methoxyl, diminish in diastinic quality in proportion to the amount of oxygen they contain. Examples are papaverine, narceine, narcotine, and oxynarcotine. The apo-derivatives are less diastinic than the parent bases in a degree which indicates that the molecular weights have been nearly doubled. Examples are apomorphia and pseudo-aconitine.

4. Bodies with the pyridine and quinoline nucleus exhibit absorption-bands extending between wave-lengths 350 and 280, those with a benzene nucleus generally from 290 to 260, or rays even more refrangible; while the aconitines and opium bases, likewise strychnine, give evidence of a benzene nucleus, the cinchona bases, with piperine and brucine, appear to contain a nucleus of pyridine or quinoline.

* Abstract of a Paper read before the Royal Society, Dec. 17, 1884.

CHEMICAL PHENOMENA OF THE
RESPIRATION OF PLANTS.

(SECOND NOTE)

By Dr. T. L. PHIPSON, F.C.S., &c.

IN two previous communications to this journal I have studied the production of oxygen gas by *unicellular algae*, and in the latter, which appeared a short time ago (CHEMICAL NEWS, vol. 1, p. 37), the influence of *temperature* was merely referred to in a note, as I intended to treat of it more particularly in the present communication.

It is generally supposed that it is sufficient to expose the green parts of a plant to *light* to cause it to breathe, and that the so-called *actinic rays* which cause the combination of hydrogen and chlorine, and act upon the photographic plate, are the chief agents which bring about the evolution of oxygen gas by plant cells. I have found that *temperature* is also a most important agent, and that without a certain degree of heat no evolution of gas takes place.

It was Cloez and Gratiolet, however, who first drew attention to the fact that some water weeds only gave off oxygen gas when the thermometer stood at a certain height, but these observers did not compare the intensity of light on days of different temperatures as I have done.

On a day in November when the temperature was 38° F., the intensity of the daylight, measured photometrically, was about equal to what it was on a day of the previous September when the thermometer stood at 70° F.; yet on the first-named day the evolution of oxygen was *nil*, and on the latter very abundant. On the 14th January, the temperature outside my window being 45° F., little or no gas was evolved, in spite of the bright sunshine; but when the flask containing the plants was removed to the inside, where the thermometer stood at 50° F., some evolution of gas was apparent in about an hour.

I find that from 60° to 90° F. the respiration of unicellular algae is extremely active in sunlight, and it appears evident that this process is intimately connected with the *circulation*.

The circulation in plants, as in animals, is much dependent upon temperature. A leaf of *Anacharis alsinastrium*, in which circulation is active, when pulled from the stalk exhibits a very feeble movement; the shock has the effect of checking, or altogether arresting, the movement of the green granules. But when I warm the glass slide to about 80° or 85° F., the circulation becomes as active as before.

It appears, therefore, that in plants, as in animals, the function of *respiration* is closely connected with *circulation*, and that *temperature* has quite as much to do with it as *light*.*

It was shown in my former note on this subject that the presence of *carbonic acid* alone was not sufficient to produce the evolution of oxygen gas by plants exposed to sunlight; that something else was required in the water in which they vegetate; for water which has been boiled for five minutes, then cooled and supplied with the requisite quantity of carbonic acid, gave no oxygen. It was pointed out that *peroxide of hydrogen* was the substance destroyed by boiling the water; and I hope soon to be able to publish some further observations on this important point.

In the meantime I wish to add a few words with regard to the supposed production of oxygen gas by infusoria, by the *Chlamidomonas pulvisculus*, *Euglena viridis*, &c., alluded to in the writings of Ch. Morren and of Justus von Liebig.

I have often observed that towards the end of May stagnant waters may be seen covered with a thin dark

green film of oleaginous aspect, from which oxygen gas is given off most abundantly. On examining the composition of this film I find that it is formed, not of infusoria, but of *zoospores* in rapid motion. The motion continues for a few hours, after which the spores become fixed, and germination proceeds. There are certainly some minute infusoria also carried up to the surface of the water with these zoospores of the algae, but they are easily distinguished by their *sarcodæ* and by a notable difference in their movements. The sarcodæ is seen to contract, whilst the membrane of the zoospore does not; the latter is solely moved by vibratile cilia, whilst the infusoria move by cilia and by the contraction of the sarcodæ. I am convinced that it is these zoospores (in which vegetation is extremely active, and which evolve oxygen in abundance) that have been mistaken for infusoria in the old observations alluded to, and that we have no evidence whatever that any infusoria, whether green or not, evolves oxygen gas in the sunlight.

Another point may be referred to here. It has been often thought that the *stomata* of leaves are essentially organs of respiration; but it is evident that they are by no means essential; for most of my observations have been made with unicellular algae, in which these little organs do not exist.

A more important point is connected with the nature of *chlorophyll*. Some authors look upon chlorophyll as being intimately connected with the evolution of oxygen by plants in daylight. Several works state that the green parts only of plants act in this way. But not only do the cells of *Protococcus Pluvialis*, which are not brilliant green, but brownish or yellowish, emit oxygen like those of *P. palustris*, which have a dark emerald colour, but a curious observation which I have made seems to show that the production of chlorophyll depends on the evolution of oxygen, and not the evolution of oxygen on the chlorophyll.

Wishing to neutralise the carbonic acid in the water in which the unicellular algae grew, I added a minute quantity of hydrate of soda, and found that in twenty-four hours the protococcus cells were bleached—the soda appears to have dissolved their chlorophyll—but were not killed. After being thoroughly washed in three waters for a day each time the plant was again exposed to sunlight. In about four hours oxygen began to be given off rather abundantly, and next day green specks began to be visible everywhere. It is natural to conclude that chlorophyll is formed under the influence of light, since we all know that plants placed in the dark are more or less bleached; but this experiment appears to show that the function of respiration in plants is independent of the chlorophyll; in other words, that the *chlorophyll* is formed by the process of *respiration*.

It has also been asserted by a German chemist that certain *organic acids* could replace carbonic acid in the respiration of plants. I have found, with regard to *tartaric*, *citric*, and *oxalic acids*, that this is not the case when these acids are introduced in place of their equivalent of CO₂ into the water surrounding the unicellular algae.

When these organic acids are employed in exceedingly minute quantity they may set free a little CO₂ from the carbonates naturally present in the spring-water, and so give rise to a minute quantity of oxygen gas, which may thus appear to be derived from the organic acids. If, on the other hand, these organic acids are used in larger quantity they act as antiseptics, and put a stop to the functions of the plant altogether.

I conclude from this that the *organic acids* cannot replace CO₂ in the process of respiration; if they could do so it would be impossible that plants could contain any free acids.

As shown in my first note, it is probable that the *ternary compounds* in the plant cell are formed as the evolution of oxygen takes place. Hence the influence of both *light* and a certain *temperature* is necessary for the production of these compounds; and not only organic acids cannot

* It thus becomes evident that in making *actinometric observations* the apparatus used must account for *temperature* as well as for *light* (and probably for *moisture*) if the observations are to yield perfectly accurate results.

replace CO_2 in this process, but it is evident they must be formed from this CO_2 , also that *sugar* is in its turn formed from them. I find that in grapes grown out of doors the production of sugar occurs first in the periphery, and gradually extends inwards as autumn advances, whilst the organic acids disappear. These remain to the last in the pulp around the seeds, where they act as antiseptics, until the moment arrives for the seed to fall and germinate. At this moment only is the greater portion of organic acid replaced around the seed by sugar.

A GENERAL ENUNCIATION OF THE LAWS OF CHEMICAL EQUILIBRIUM.

By H. L^e CHATELIER.

Every system in a state of stable chemical equilibrium if submitted to the influence of an external cause which tends to modify either its temperature or its condensation, whether in its totality or only in some of its parts, must experience internal changes which, if they are produced alone, bring about a change of temperature or of condensation of a sign contrary to that resulting from the external cause. These modifications are generally progressive and partial. They are sudden and complete when they can be produced without any changing the individual condensation of the different homogeneous parts which constitute the system in equilibrium whilst nevertheless changing the condensation of the entire system. They are null when their production cannot bring on changes analogous to that due to the external cause. Lastly, if these modifications are possible they are not necessary. In the cases where they are not produced and where the system remains unaltered, the equilibrium becomes unstable, and can then only experience modifications tending to approximate it to conditions of stability.

As examples the author gives the following:—

1. Heating the totality of a system involves endothermic modifications such as fusion and volatilisation of all the bodies; polymerisation of C_2N_2 &c.; reversible dimorphic transformations of AgCl , NH_4O , NO_3 ; dissociation of CO_2 , CaO , CO_2 , Bi_2O_3 ; reversible endothermic combination of CS_2 and very probably of NO_2 ; endothermic solution of most salts; endothermic crystallisation of such salts as sodium sulphate well known to decrease in solubility with the temperature.

2. The partial heating of a system involves changes all tending to cool the heated part, such as the propagation of heat by conduction, the production of thermo-electric currents, the changes of concentration by diffusion, the transfer of metals from one point to another of a plate immersed in a solution of one of its salts.

3. The increase of condensation of the totality of a system kept at a constant temperature brings on modifications which tend to diminish the condensation of the system, such as the fusion of ice, the solidification of paraffin, the dimorphic modification of AgI , the combination of the dissociated products of CO_2 .

4. The increased condensation of a part of a system involves modifications tending to diminish the condensation of the part affected, such as the condensation of watery vapour, the combination of $\text{CaO} + \text{CO}_2$ at a red heat, the diffusion of solutions unequally concentrated, the transfer of metal on a plate plunged into a solution of one of its salts of variable concentration, reduction of the melting-point of an alloy or a mixture of metals during its progressive solidification.

5. Modifications of equilibrium are generally progressive: e.g., in the dissociation of carbonic acid, and generally in all systems whose elements are not simply juxtaposed, but some of which form homogeneous mixtures among themselves.

6. Modifications of equilibrium are total when they may

be produced without altering the condensation of each of the parts of the system, whilst still altering the condensation of its totality.

Such is the condensation of watery vapour, the fusion of ice, the dimorphic transformation of AgI , the dissociation of calcium carbonate, of solid copper oxide, the solution of salts. These systems on an infinitely small change of condensation in one of their parts pass from one extreme limit of their state of equilibrium to the extreme opposite limit.

7. The modifications of equilibrium are null when they cannot produce an effect analogous to that due to the external cause. Dissociation is independent of pressure for mixtures which combine without change of volume, e.g. hydriodic acid. The limit of equilibria is independent of the temperature when their transformations do not evolve heat, which is the case with etherification.

8. All these modifications of equilibria are merely possible and are not necessarily produced as is shown by superfusion, superheating, supersaturation, the sudden refrigeration of dissociated carbonic acid. The instable systems thus obtained can only be modified so as to approach the conditions of stable equilibrium. The transformation of these instable equilibria is generally effected with a liberation of heat, in conformity with the principle of maximum work, because, as M. van 't'Hoff remarks, the ordinary temperature differs little from the absolute zero, for which the stable equilibrium corresponds to the liberation of the totality of heat contained in bodies.—*Comptes Rendus*.

THE COMPOSITION AND METHODS OF ANALYSIS OF HUMAN MILK.*

By Prof. ALBERT R. LEEDS, Ph.D.

(Continued from p. 281).

THIS research affords no adequate data as to the rate of decrease beyond the age of thirty years. The only complete analysis bearing upon this point is that of the milk of a dark-haired, black-eyed swarthy Pole, of gross habit and enormous breast development, who, at the age of thirty-three years, had been the mother of nine children. Two ounces were drawn from the right breast only, five hours after previous nursing. It was low in specific gravity, and yellow in colour. It contained—

Albumenoids	2'24
Sugar	6'25
Fat	2'76
Solids not fat	8'84
Ash	0'35
Total solids	11'45

III. *Period of Lactation, &c.*—If we divide this period into four intervals, the first extending from the beginning of lactation to the eleventh day after; the second from the eleventh to the thirty-first day; the third from the thirty-first to the ninety-first day; the fourth from the ninety-first day to the tenth month of lactation, we shall note the following changes:—

Albumenoids are greatest in the first intervals, being 2'32 per cent. In the second they exceed the general average, being 2'09 per cent. In the third interval they fall as much below the average as in the first they exceeded it, remaining at a low figure during the rest of lactation.

Sugar is least immediately after parturition and much below the average, whilst it is above and nearly constant during the three remaining periods.

* Read by invitation, before the College of Physicians of Philadelphia, May 7th, 1884, and reprinted by permission from advance-sheets of its Transactions.

TABLE III.—MILK OF WOMEN FROM 15 TO 20 YEARS OF AGE. (FIRST LUSTRUM.)

A = No. of cases above or below the general average.

B = Averages for A.

C = Averages for women from 15 to 20 years of age.

D = General averages for all years.

No. of sample.	Albuminoids.		Milk sugar.		Fat.		Solids not fat.		Ash.		Total solids.

Fat, like the albumenoids, is much in excess of the general average immediately after parturition, being 4.93 per cent. After the eleventh day it falls, being only 3.97 per cent.

The saline constituents are nearly constant during all stages of lactation, although slightly in excess during the first ten days.

The sum of solids not including fat does not vary greatly. Its amount in the first interval is 9.15 per cent, the general average being 9.14.

Interval since Nursing.—Nearly all the samples were drawn two hours after nursing, but certain ones, more especially Nos. 18, 32, 33, 39 were drawn immediately. In fat, albumenoids, salts, and total solids, they were in excess of the general average.

(To be continued).

ON NITROGEN IN ARTIFICIAL MANURES.

By J. OSTERSETZER.

THE fertilising property of nitrogen in manures varies with the source it has been obtained from. Some years ago Peruvian guano occupied the foremost position as a source of nitrogen. Essentially an organic substance, more than one-half of the nitrogen contained in Peruvian guano appears in the state of ammonium sulphate, phosphate, and oxalate, whilst the remainder presents itself in the form of guanin, uric acid, &c. At the present moment the most important sources of nitrogen, both as to quality and quantity, are sodium nitrate of the Chili saltpetre, and ammonium sulphate, chiefly manufactured from gas-liquor. Next we find a great number of organic substances containing nitrogen in combination with the other elementary constituents of organic matter. The molecular relation of nitrogen to carbon, hydrogen, oxygen, and sometimes sul-

phur, differs in various organic substances, hence their different properties of assimilation when applied as fertilisers. Practical results have established a scale, so to speak, according to which nitrogen from various sources may be classified as to its specific value.

Viewing this subject from a theoretical stand-point, I have selected four organic substances to represent the great number of nitrogenous organic combinations, used as manures either as such, or as additions to artificial fertilisers, and endeavoured to ascertain the relative properties of nitrogen from different sources. I have taken as a basis, first, the degree of solubility of nitrogen in water, citric acid, sulphuric acid, and ammonium citrate, an intermediate reagent adopted in determining the so-called retrograde phosphates in manures, and secondly, the dissociation of nitrogen by subjecting the organic substances to the process of destructive distillation.

I. Solubility.

The substances selected for determining the degree of solubility were Peruvian guano, dried blood, bone meal, and wool waste. A weighed quantity of the substance of a known percentage of nitrogen I first treated with water at boiling-point, filtered, washed and dried the insoluble residue, separated the same from the filter, and made a determination of nitrogen with soda-lime in the usual way. The difference of this result and the nitrogen originally contained in the substance showed the amount of nitrogen soluble in water. New weighed portions of the organic substances were treated with a large excess of an ammoniacal solution of ammonium citrate in the cold for 12 hours, and with rectified sulphuric acid of the sp. gr. 1.85, and a concentrated solution of citric acid at boiling heat; then diluted and the insoluble residues collected on filters, carefully washed until the last traces of either alkaline or acid reaction of the filtrate disappeared, the residues treated in the same manner as before by ultimately making a determination

TABLE I.

SUBSTANCE.	Containing Nitrogen in 100 parts.	N soluble in Water.	N soluble in Ammonium Citrate.	N soluble in Citric Acid.	N soluble in Sulphuric Acid.	N left insol. in Sulphuric Acid.	Per cent of the N soluble in Water.	Per cent of the N soluble in Ammo. Citrate.	Per cent of the N soluble in Citric Acid.	Per cent of the N soluble in Sulphuric Acid.	Per cent of the N left insoluble in Sulphuric Acid.
Peruvian guano	5.88	3.78	1.10	0.27	0.58	0.15	64.27	18.71	4.59	9.88	2.55
Dried blood (at 100° C.).	15.91	2.35	2.32	3.98	6.46	0.80	14.77	14.59	25.00	40.55	5.09

Wool waste	9.12	0.00	0.00	5.60	2.23	1.29	—	—	61.41	24.44	14.15

TABLE II.

SUBSTANCE.	Containing N in 100 pts.	Nitrogen formed in the shape of H_3N .	N yielded as N_2 &c.	N left in the Char.	Per cent of the N formed as H_3N .	Per cent of the N yielded as N_2 &c.	Per cent of the N left in the Char.
Peruvian guano	5.88	4.90	0.84	0.14	83.33	14.27	2.40
Dried blood (dried at 100° C.).	15.91	7.57	6.24	2.10	47.58	39.23	13.19
Bone meal	3.50	1.68	1.47	0.35	48.00	42.00	10.00
Wool waste	9.12	4.90	2.82	1.40	53.73	30.92	15.35

of nitrogen in the insoluble residues. The difference of nitrogen soluble in water and that soluble in ammonium citrate showed the amount of soluble nitrogen due to ammonium citrate. Again the nitrogen soluble in ammonium citrate deducted from the total nitrogen soluble in citric acid indicated the percentage of nitrogen due to the action of the latter reagent, whilst the addition of the three results subtracted from the total nitrogen made soluble by sulphuric acid showed the amount of nitrogen rendered soluble by sulphuric acid only. I have obtained the results given in Table I:—

The same substances were next subjected to—

II. Destructive Distillation.

A weighed quantity of the organic substance was heated in a combustion-tube, a portion of the nitrogen evolved in the shape of H_3N , which was estimated in the usual way by titration. The char left in the tube, carefully collected, and the amount of nitrogen determined, the difference or loss of nitrogen was due to the nitrogen leaving the organic substance as nitrogen gas or nitrogen oxides. I give the results in Table II.

With the exception of dried blood, an analogy appears to be existing between the nitrogen left untouched by sulphuric acid and the nitrogen left in the char.

These results also plainly show that sulphuric acid is capable of rendering a very large percentage of the nitrogen in organic substances in a soluble state, thus presenting the nitrogen to the plants in a most perfect form of division.

Goulding's Manure Works,
North Wall, Dublin.
December 2, 1884.

A NEW DEVICE FOR OBTAINING HYDROGEN SULPHIDE.

By HARRY N. DRAPER, F.C.S.

WERE it not that the occurrence in the laboratory cases in which a quite small quantity of hydrogen sulphide is required is so frequent, I should with reluctance propose to add to the already long list of apparatus for its production.

Water saturated with the gas is often very useful, but the solution does not keep well, and in the smallest and best arranged contrivances in which iron sulphide is employed the escape of gas continued after the acid has been withdrawn from its contact. The plan which I ven-

ture to suggest avoids all escape of gas except when the apparatus is in actual use, and then if the hydrogen sulphide is doing useful work there is no escape into the surrounding air.

The simplest form of construction is that shown in the engraving, where A is a two-necked bottle containing ammonium sulphide and B another such bottle filled to a somewhat greater height with sulphuric acid diluted with four volumes of water. Through the tube *a* a gentle current of air is forced either by water pressure or by a small hand blower.*

No free ammonia passes through B (as may be easily demonstrated by adding a few drops of phenol-phthalein solution to the water of the wash-bottle), and remarkably enough there is no deposition of sulphur in the acid liquid, which remains perfectly clear.

The arrangement has its weak point. The gas produced is not of course pure, but is largely mixed with air. I venture to think nevertheless that, as it has supplied a want to myself, it may do so to others.

The interception of a glass or vulcanite stopcock at C will prevent any possibility of the diffusion of ammonium sulphide into B when the apparatus is at rest.

I have not yet tried the experiment of forcing the vapour from fuming hydrochloric acid into a solution of sodium sulphide, but it seems very probable that this modification of the original idea would give a good result.

Dublin, December 4, 1884.

* Where the local coal gas pressure is sufficient (which is not the case in Dublin) this would afford quite the most convenient means of producing a continuous current.

THE DETERMINATION OF MOISTURE IN FODDER.

By F. E. FURRY.

THOSE who have had occasion to analyse crude fodders, as grass, clover, corn-stalks, ensilage, and the like, know how much depends on an accurate determination of the total moisture, and at the same time how many difficulties present themselves in an attempt to handle a fair average sample, which must necessarily be quite large.

After considerable unsatisfactory experience with porcelain and platinum evaporating dishes, which were not only cumbersome to weigh but invariably left the sample unequally dried unless exposed to heat for a long time, a very simple apparatus was tried which has since been used exclusively.

The annexed figure will be understood without much explanation.

A is a cylinder of light tin 18 c.m. in length by 7 c.m. in diameter, provided at both ends with wire gauze disks, one of which is removable. The end of the cylinder provided with the stationary disk is tapered to a tube having a diameter of 1 c.m. B is the "chimney." During the process of drying, A is to be placed in the drying oven

heated to the desired temperature, and B, fitting on it as shown in the cut, is to project into cooler air, above. A strong draft is thus established. Any moisture contained between the gauze disks of A will be carried upward into B, where some will escape into the air, and some will be condensed on the walls and escape by the small exit tube at the side into a dish of sulphuric acid provided for the purpose. This latter tube has a diameter of 0.5 c.m.

In practice the part A is thoroughly cleaned, dried, and weighed. The substance to be treated is then put in it, the bottom disk replaced, and the whole weighed again. A comparatively short time is required for complete desiccation. When a cold substance held over the chimney does not deposit moisture, the chimney is removed, and the part A cooled and again weighed. With a little experience not more than one more weight is necessary. If any volatile substance, as ammonia, is likely to be given off, which it is desired to estimate, the chimney is replaced by an Erlenmeyer flask containing a standard solution for its retention and measurement. This arrangement is also employed when natural manures and the like are under examination in order to prevent the escape of unpleasant and injurious odours into the working room. In either case the flask is necessarily connected with suction.

The removable disk may be "wired" if necessary to prevent bending. Any good tin-smith will construct the whole affair in a few minutes for seventy-five cents.

Cornell Univ. Chem. Laboratory,
Ithaca, N.Y., Nov. 21, 1884.

PROCEEDINGS OF SOCIETIES.

PHYSICAL SOCIETY.

December 13th, 1884.

Prof. GUTHRIE, President, in the Chair.

THE following communications were read :—

"On the Effect of an Electrical Current on the Rate of Thinning of a Liquid Film," by Profs. A. W. REINOLD, F.R.S., and A. W. RÜCKER, F.R.S., read by Prof. REINOLD. In 1877 the authors communicated to the Royal Society an account of some experiments upon the electrical resistance of liquid films. The results then obtained showed that there was some disturbing influence present, and the authors now find this to be the action of the current upon the film itself. The films experimented upon were, as in the original experiments, cylindrical and vertical, formed upon two co-axial platinum rings, which are the electrodes by which an electric current can enter and leave the film. The mode of formation of these films, and the precautions necessary to keep them from gaining or losing moisture by condensation or evaporation, have been already described before the Royal Society (*Phil. Trans.*, 1881, Pt. II.). When such a film just formed is left to itself it shows a set of colours of different orders arranged in horizontal bands. As it thins under the action of gravity these bands gradually broaden out and descend. A black band soon appears at the top, which likewise extends downwards. If a current is now passed downwards through the film the motion of the colour bands is accelerated, showing that the effect of the current is to assist gravity in thinning the film; the black band, however, becomes in part or entirely white. This upon examination is found to be due to the following action:—The film is not directly dependent upon the upper ring, but is attached to it by a comparatively thick mass of liquid. The action of the current is to transfer liquid in its own direction, thus, like gravity, thinning the film. The mass of liquid, however, on which the film hangs by this same action is forced down into the black portion, which consequently becomes white. If the current be passed upwards the reverse effects occur; the downward motion of the bands is retarded, or, with a strong current, reversed. The explanation is precisely the same as before; the liquid is transferred along the film in the direction of the positive current. It sometimes collects in the form of pendent drops attached to the upper ring; these increase in size, and stream down the sides of the film. Prof. Reinold then formed a plane film between two horizontal wires. The film was illuminated by the lime-light, and its image projected upon a screen. The motion of the bands of colour in the direction of the current produced by 50 Grove's cells was clearly shown.

In a discussion which followed upon the transference of matter with the current,

Prof. AYRTON described some experiments recently made by Prof. Perry and himself, which showed that certain metals were carried through mercury in the direction of the current.

Mr. BOYS remarked upon the apparent inertia of the film. The current seemed to require time to develop its action, no motion of the colour-rings being visible for some seconds after making the current.

Dr. STONE exhibited a Tuning-fork Interruptor Commutator. This is an instrument for reversing an electric

current through a circuit a given number of times per second. From the free end of a spring, kept vibrating in unison with an electrically-maintained fork by an electromagnet in the circuit of the fork acting upon an iron armature attached to the spring, project two small aluminium plates, side by side, but insulated by ebonite from the spring and from each other. These are connected by fine wires, which do not interfere with the vibration of the spring, to screws upon the base of the instrument to which the poles of a battery are joined. The motion of each plate is arrested upwards and downwards by aluminium stops, so that there are four such stops arranged at the corners of a rectangle. They are connected in pairs, diagonally, and each pair is in communication with one end of the external circuit. Thus, when the spring is up the current flows to the aluminium plates, and is transmitted through the circuit in one direction; when the spring is down it flows by the lower stops in the opposite direction. The electromotive force is thus reversed in the circuit twice as many times as the fork vibrates per second.

Mr. LEWIS WRIGHT exhibited his New Oxy-hydrogen Lantern Microscope. Details of this instrument will shortly be published. Geological, medical, and biological specimens were exhibited upon the screen with great distinctness, the definition being singularly perfect under the highest powers.

NOTICES OF BOOKS.

Diaries for 1885. London: Letts, Son, and Co., Lim.

THE enormous demand that now exists for diaries and other time-saving publications is fully shown by the multitude and variety of these books that are produced annually by the firm of Messrs. Letts and Co. For the incoming year the useful publications manufactured by this firm maintain their high standard combined with remarkable cheapness, ranging as they do in price from a few pence to a couple of guineas.

Some of the largest sized diaries, with one day to the page, although their intended place of usefulness is the counting-house, would form excellent note-books for the laboratory table, as each day's experimental work could be therein inserted.

The professional diaries are sure to find an extensive field on account of the useful and appropriate information they contain; the Medical Diary, for instance, is ruled for obstetric engagements, vaccination, nurses' addresses, thermometric fluctuations, &c. The same, in fact, applies to most of Messrs. Letts's Diaries, there being a large number of them, varying in size and price, for the Army and Navy, the Clergy, Farmers, Travellers, &c., each containing information of the kind most likely to be required by the different professions.

The Housekeeper's Account Book and the Household Expenses Book are good in design and workmanship as well as moderate in price. To the same domestic class of diaries belong the Game Book for Sportsmen, the Stable Expenses Book, the Farm Expenses Book, and the Improved Rent-Book. A good supply of the latter might be sent over to Ireland.

Townson and Mercer's Catalogue of Chemical and Physical Apparatus and Chemicals.

THIS enterprising firm have now issued a third and greatly enlarged illustrated catalogue. On examination it will be found exceedingly complete, including a number of recently-introduced instruments, such as Scheibler's calimeter, Stead's and Elliott's apparatus for the analysis of furnace and chimney gases, Rammelsberg's and Geissler's burettes, Bunte's gas burettes for furnace gases,

Schwarz's and Staedel's nitrogen apparatus, a good assortment of filter-pumps and presses, Le Bel Henninger's and Glyusky's tubes for fractional distillation, Victor Meyer's vapour-density apparatus, &c.

We may also notice sets of apparatus for certain especial purposes, such as the beer-set, the wine-set, apparatus for determining sulphur in spent oxide, the apparatus used by the Metropolitan gas referees for testing the purity of coal-gas, MacIvor's and Sacker's apparatus for testing lubricating oils, and Schützenberger's apparatus for determining dissolved oxygen in water.

The physical department includes apparatus for pneumatic, hydrostatic, thermic (under which head barometers are, rather curiously, included), optical, acoustical, and electrical experiments.

It appears that Messrs. Townson and Mercer are the sole British agents for Becker's chemical balances, and that they supply Schleicher and Schüll's chemically pure filter-paper, and Fletcher's chemical gas-appliances.

Arithmetical Physics. Acoustics, Light, and Heat (Part I. A.) Magnetism and Electricity (Part II. A.). By C. J. WOODWARD, B.Sc. London: Simpkin, Marshall, and Co., Birmingham: Cornish Bros.

THE first part of this little work contains a very novel and interesting feature; the author formally and boldly comes forward as an apologist for the examination system of education, which he thinks ought not to be regarded as "cram." Now, for examinationism thus to stand on the defensive is already a great point gained. "*Qui s'excuse s'accuse.*" But let us examine Mr. Woodward's argument. He writes:—"I do not admit for a moment that this work is a 'cram-book.' My aim has been to make it strictly educational, by fixing clearly in the minds of students the first principles of Physics. Students who have a clear perception of these first principles will undoubtedly pass beet at an examination, but because they pass are we to say that of necessity they are crammed? To have an examination in view does not detract from the attainment of knowledge or impair the reasoning power of a student. The very object of an examination is to sift from those who understood the principles of the subject others who have but a superficial knowledge." Mr. Woodward then proceeds to quote one J. G. Fitch, who in certain "*Lectures on Teaching*" said:—"Every examiner who knows his business can easily discern the difference between the knowledge which is genuine and has been well digested, and that which is superficial and is specially got up to deceive him. Dishonestly prepared men undoubtedly come up for examination, but they do not pass (?), and the blame of the transaction rests with those who send them up, not with the examinations themselves."

Perhaps Mr. Woodward and Mr. Fitch have never met with the famous and truthful dictum of Professor Huxley that "in these days we study not to know, but to pass, and the consequence is that we pass, and don't know." Here is an admission on the part of one who has had most extensive opportunities of observing that "passing" is not a function of knowledge. This our own experience corroborates. We meet with men who have passed this or that examination with honour, but yet have merely a talking acquaintance with Science. We may further ask the author, if "dishonestly prepared men do not pass," how it comes that "coaches," "grinders," &c., who make it their business to study the idiosyncrasies of examiners, and can even predict many of the very questions which will be put, continue to exist and do really get their men passed? If "to have an examination in view does not detract from the attainment of knowledge or impair the reasoning power of a student," what can be the origin of the saying, not uncommon among University tutors, that "Mr. So-and-so might do well if he did not think?"

But it will be fairer to go to the fundamental principles of the matter. A man, in studying any physical or

natural science, must, as it seems to us, have one of three legitimate ends in view. He must aim at the cultivation of certain of his own faculties, or he must wish to prepare himself for extending the present sum of human knowledge, or for applying such knowledge to practical ends. Whichever of these three be his object, he must above all things master the art of acute and accurate observation, and of tracing phenomena to their causes. Without he acquires these powers his word knowledge of "principles" will profit him nothing. But where is the examiner bold enough to assert that he can gauge the suggestiveness, the extent of mental resources, of a student, or his power of detecting and appreciating unrecorded, mis-recorded, and anomalous phenomena? Hence these powers, though far higher than the mere receptivity which enables a youth to absorb and reproduce the knowledge of others, count for nothing in an examination. As a natural consequence of the present system, teachers who have to pass their pupils rarely, if ever, attempt to train them to become original observers. It may even be said that the examinational system is a main cause why England is so much less fruitful in scientific research than is, *e.g.*, Germany.

Concerning the decided examinational character of these works, we need merely say that in Part I. A., whilst the lessons and exercises occupy 37 pages, 46 are devoted to the questions given by the Science and Art Department from 1874 to 1884; those set in the "Matriculation Examinations" of the University of London from 1864 to 1881 with the answers. In Part II. A the lessons and exercises fill up 27 pages, whilst the questions given at the Science and Art Department Examinations 1874 to 1884, and at the Oxford and Cambridge Local Examinations 1874 to 1883, with their answers, cover 25. Leaving one side, however, the dominant examinational character of these works, they will be useful manuals for students who have already studied experimentally the phenomena here discussed.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 22, December 1, 1884.

Observations on the Claim of Priority made by M. Leplay, relating to the Formation of Potassium Nitrate in Vegetation.—MM. Berthelot and André.—The authors are acquainted with the researches of M. Leplay on the formation of sugar, but are surprised that he claims a priority as regards the nitrates. After having re-read his eight memoirs they find that there is nothing in common between his researches and theirs, either as regards the facts or the conclusions.

The Fluoric Apatites.—A. Ditte.—The author has prepared and studied the fluor-arsenates and fluoro-vanadates.

Action of the Induction-Spark upon Phosphorus Trifluoride.—H. Moissan.—If the apparatus and the material are perfectly dry phosphorus is deposited on the interior of the tube, and there is a formation of gaseous phosphorus pentafluoride. If a trace of moisture is present phosphorus is still deposited on the glass, but the gas contains a gradually increasing proportion of silicon fluoride, and the internal surface of the tube is completely roughened. The transformation of phosphorus fluoride into silicon fluoride by the passage of the spark is never complete, as an equilibrium seems to be reached. The gaseous mixture resulting from the decomposition of

phosphorus fluoride not perfectly dry, if brought in contact with a solution of potassium iodide, displaces the iodine, and gives an intense violet colouration with starch-paste. But if we make the same experiment with phosphorus fluoride, perfectly dry and partially decomposed by the induction-spark, there is no colouration.

Hydro-ferrocyanic Acid and its Derivatives.—A. Etard and G. Bémont.—The authors propose to represent ferrocyanogen by a hexagonal formula.

The Action of Phosphorus Perchloride upon the Aromatic Ethers.—A. Colson.—On heating paraxylene mono-ethylene with two and a-half times its weight of phosphorus perchloride there are given off hydrochloric acid, phosphorus protochloride and oxychloride, and ethyl chloride, whilst from the residual liquid is obtained terephthalic aldehyd in fine colourless crystals.

The Determination of Odoriferous Essential Oils.—A. Levallois.—If an aqueous or alcoholic solution of bromine is poured into water or alcohol holding in solution traces of essential oil, there comes a moment when, in spite of stirring, the liquid takes a yellow colouration, due to an excess of bromine, which is the more easily detected as the liquid previously is quite colourless. At the same time the specific odour of the oil in question has disappeared, though it is still distinctly perceptible when a few drops of the bromine reagent have still to be added. A third indication of the end of the reaction (at least in case of an aqueous solution) is the sudden appearance of an insoluble, whitish, resinous body, which lines the sides of the vessel after stirring. The quantities of bromine required are proportional to the quantity of essential oil present in solution. But it is necessary to make a correction of two-tenths or three-tenths c.c. for the quantity of bromine required to produce a perceptible colouration in the volume of liquid employed, when it is 20 or 30 c.c. It is necessary to concentrate the essences in a small bulk.

Biedermann's Central-Blatt für Agrikultur-Chemie,
Vol. xiii., Part 5.

Underground Water and the Moisture of the Soil.—Fr. Hofmann.—The author contends that, in order to understand the distribution of moisture in the soil, we must distinguish three strata which differ in their power of receiving and giving up water. The upper layer, or "evaporation zone," depends on the weather, and is exposed to the greatest fluctuations in its proportion of moisture. After persistent drought it may take up the entire rain of six or even twelve months, so that not a drop passes into the lower strata. This zone is the more important in a sanitary point of view as it is exposed to contamination from above, to the direct invasion of pathogenous fungi, and to both the highest and the lowest temperatures. The middle stratum, which the author terms the "transit-zone," has a tolerably constant proportion of water, depending on the size of the soil capillaries. Evaporation has no influence upon this region, and an influx from above modifies its proportion of moisture only in as far as the water which penetrates in traverses the capillaries more or less rapidly according to their size. According to the thickness of this stratum its quantity of water may be very considerable, equal to the downfall of several years. The lowest stratum is called the zone of the capillary ground-water level. It begins at the surface of the subterranean waters, and its moisture depends on the nature of the capillary intervals. The author concludes that all impurities, organic or inorganic, placed upon the surface remain in the upper zone and cannot be washed down into the subsoil waters, even by heavy rains.

Formation of Saline Deposits, with particular reference to that of Stassfurt.—Dr. E. Pfeiffer.—A geological study.

Researches on the Influence of Different Depths of Sowing upon the Germination of Cultivated Plants.—Prof. E. Wollny.—The author concludes that the deeper seeds and tubers are planted, the later and the more irregular will be the appearance of the young plants upon the surface of the soil. At a certain depth the number of plants which come up is greatest; if the seed is set either deeper or shallower, the number of plants decreases. Shallow sowing, within certain limits, is most advantageous, both as to the number of plants obtained and their equal and rapid development. The most suitable depth depends on the kind of plant, on the nature of the soil, and on the weather. The smaller the seeds or tubers, the less favourable the weather, and the more compact the soil, the more essential is shallow sowing.

Manuring Beets with Chili Saltpetre.—Fr. Müller.—Chili saltpetre is said to give better results than the same value of ammoniacal salt.

The Manufacture of Bone-Dust.—Prof. J. König.—The author shows that when bones, previous to grinding, are freed from fat by treatment with benzol, they are purified from ingredients which have no agricultural value.

Manurial Experiment with Barley.—H. Wäterling.—An exclusive use of phosphoric acid gave a worse result than the absence of manure; the same was the case with nitrate of soda alone. The two in conjunction gave an increase both in the gross and the nett yield.

Journal für Praktische Chemie.
New Series, Vol. xxx., Part 3.

Action of Chlorocyan upon Ortho- and Para-amidophenol.—Dr. J. Berlinerblau.—An extensive paper which does not admit of useful abridgment.

Action of Chloro-carbonic Ether upon Nitrogenous Organic Compounds.—E. von Meyer.—The author has examined the behaviour of chloro-carbonic acid with cyanethine, the composition of carboxethyl-cyanethine; the behaviour of the latter body with ammonia and with aniline; the composition of carbanilido-cyanethine: the "oxy-base" obtained from cyanethine and chloro-carbonic ether; and the action of chloro-carbonic ether upon certain amides.

Simple and Productive Method of obtaining Anthranilic Acid.—H. Kolbe.—In a preliminary communication on isatine the author has briefly described isatic acid as an oxidation product of isatine. If this acid is heated with strong hydrochloric acid on the water-bath it is resolved into carbonic acid and anthranilic acid, which latter, on evaporating to dryness, remains in chemical combination with the hydrochloric acid as a white crystalline mass. Its aqueous solution precipitated with ammonia and mixed with acetic acid gives a copious precipitate of anthranilic acid. It may be obtained chemically pure by treatment with animal charcoal and recrystallisation.

Decomposition of Benzo-nitrile by Fuming Sulphuric Acid.—A. Pinner.—A reply to a paper by F. Gumpert in a former part of this journal.

Oxychlorides and Analogous Metallic Compounds.—G. André.—The author describes the oxychlorides of calcium, barium, strontium, magnesium; the oxychlorides of zinc; the chlor-zinc-ammonium compounds and the corresponding bromides; the double salts of lead chloride and bromide; and the lead and mercury oxychlorides and oxybromides.

On Perseite.—A. Muntz and V. Marcano.—Perseite is a form of sugar occurring in the fruits of *Laurus perseæ*. Perseite is an isomer of mannite, but is distinguished by its melting-point and by its lower rotatory power after the addition of borax. Dulcitol, which has the same composition and the same melting-point as perseite, in a boracic solution has no action upon polarised light.

Phosphorus Terfluoride.—H. Moissan.—*Comptes Rendus*.

Permeability of Silver for Oxygen.—L. Troost.—From the *Comptes Rendus*, as are also the three succeeding papers:—

Compounds of Gold Chloride with Phosphorus Chlorides.—L. Lindet.

Constitution of Certain Simple Cyanogen Compounds.—G. Calmels.

Phthalic Alcohol and Accessory Compounds.—A. Colson.

— — —
Justus Liebig's Annalen der Chemie,
Vol. 225, Part 3.

Communications from the Chemical Laboratory of the University of Jena.—These consist of "Researches on the Affinities of Carbon," by A. Geuther, and a memoir on "Certain Derivatives of Aldehyd and Æthyliden and on the Magnitude of the Carbon-Monoxide Affinities of Carbon," by Dr. R. Rübenkamp. The results of these two papers may be summarised as follows:—No mixed acetates exist, but in their stead there always occur the two simple ones. The mixed oxygen ethers of ethyldien alcohol can be obtained. For the latter it is indifferent into what series the oxygen-residues enter, as identical compounds are always formed. Hence it follows that the two "carbon monoxide affinities" are not different from each other, but respectively equal.

Oleum Cynæ, a Contribution to the Knowledge of the Terpenes.—O. Wallach and W. Brass.—The authors have obtained from the crude oil a compound $C_{10}H_{18}O$, isomeric with borneol, and of the boiling-point 176° to 177° , sp. gr. 0.92207 at 16° , and the vapour density 5.1168. Cynol is optically inactive. Its behaviour has been examined with the hydracids of the halogens, with the halogens themselves. From cynol the authors have obtained cynene, a hydrocarbon $C_{10}H_{16}$.

Constituents of Certain Ethereal Oils.—O. Wallach.—The author shows that the chief constituent of cajeput oil (cajeputene) is identical with the cynene mentioned in the last paper, and that it is closely related to, though not identical with, the hesperidene present in the essential oils of the Aurantiaceæ.

Communications from the Chemical Institute of the University of Halle.—These consist of a paper by Bernhard Prieb on the Action of Benzaldehyd on Nitromethan and Nitro-ethane, and a memoir by G. Baumert on the Lupinidine of *Lupinus luteus*.

On Dinitrotoluol.—W. Stadel.—The author confirms by further experiments his opinion on the constitution of dinitrotoluol as given in *Annalen*, 217, p. 205.

The Laboratory and the Teachings of J. B. Dumas.—F. Le Blanc.—An extract from *Le Génie Civil*.

Casting Porcelain.—Ch. Lauth.—A long account of the process known as "casting" porcelain, illustrated with two figures.

Degeneration of Brewer's Yeast.—H. Bungeener.—The author describes a degeneration of yeast not due to the presence of foreign *Saccharomyces*, of *Mycoderma aceti*, or of the bacterium of lactic fermentation, and brought about by the abnormal composition of the worts in which it vegetates.

Preparation of Crystalline Anhydrous Zinc Acetate.—J. Peter and O. de Rochefontaine.—The authors take the

product of the desiccation at 150° of the ordinary crystalline zinc acetate and add to it 8 to 10 times its weight of an acetic acid very free from water. The mixture is kept for an hour at a gentle boil in a flask fitted with a reflux tube. A portion is dissolved, and it is poured whilst boiling upon a filter, avoiding access of air as much as possible. The liquid is received in a bottle which is stoppered and allowed to cool slowly. The sides of the bottle become lined with a crystalline deposit, which when drained and dried between blotting-paper possesses the composition of anhydrous zinc acetate. The crystals do not lose weight in the stove or in a vacuum, and do not absorb water on exposure to the air.

Phenic Acids of Commerce.—Charles Casthelaz.—The author endeavours to give a definition of the terms "crude carbolic," 60 per cent, and liquid carbolic at 100, at 95, and 50 per cent.

MISCELLANEOUS

New Work on the Wool Fibre.—We learn with pleasure that Messrs. Palmer and Howe, of Manchester, are about shortly to publish a monograph on the structure of the wool-fibre, from the pen of Dr. F. H. Bowman, F.L.S., &c. Our readers will, doubtless, remember the treatise on cotton-fibre, by the same author, which we had the pleasure of noticing some time ago, and which has since continued to win golden opinions both from theoretical savants and from practical men. The forthcoming work, which will be copiously illustrated, discusses the wool-fibre both from a mechanical and a chemical point of view, and will, we believe, throw an important light upon the fundamental principles of the tinctorial arts.

British Association.—At the close of the British Association Meeting at Montreal, the suggestion was brought forward that, in commemoration of the meeting, and as a recognition of the hospitality with which the members of the Association had been treated in Canada, it would be a graceful act to form a fund for the purpose of founding a gold medal at the McGill University at Montreal. After consultation with the authorities at the University it was agreed that, subject to further consideration, the medal should be given annually, in the Faculty of Applied Science, in which there is at present no prize of this sort. Lord Rayleigh, the President of the Association, undertook to act as treasurer, and Mr. W. Topley and Mr. H. Trueman Wood as honorary secretaries. In answer to an appeal circulated amongst the members in Canada, and to a circular which has been issued in this country since the return of the Association, a sum amounting at present to £540 has been subscribed. Deducting the necessary expenses of printing and postage, there will remain an amount of something over £500 to provide the medal. The General Committee of the Association have agreed to provide from the funds of the Association sufficient for the purchase of a die, so that the interest resulting annually from the investment of the whole of the above amount may be available for the medal itself. The honorary secretaries will be glad to receive contribu-

tions from any members of the Association who may not yet have subscribed. These may be sent to them at the Society of Arts' House, John Street, Adelphi; or may be paid into the account of the fund, at Messrs. Hoare, 37, Fleet Street.

MEETINGS FOR THE WEEK

MONDAY, Dec. 22nd.—Medical, 8.30.

London Institution, 5.

TUESDAY, 23rd.—Institution of Civil Engineers, 8. (Anniversary).

FRIDAY, 26th.—Quekett Microscopical Club, 8.

SATURDAY, 27th.—Royal Institution, 3. "The Sources of Electricity," by Professor Tyndall.

PATENTS, DESIGNS, & TRADE MARKS ACT, 1883.

In the matter of Letters Patent granted to Charles Rumble and Frederick Sear, Chemists, both of Belmont Works, Battersea, in the County of Surrey, for an invention of "A New or Improved Process for the Separation of Glycerine from Fatty Substances," Dated 5th September, 1883, No. 4264.

NOTICE IS HEREBY GIVEN THAT the said Charles Rumble and Frederick Sear have applied under Sections 18 to 21 of the Patents, &c., Act, 1883, and Rules 48 to 56 of the Rules made thereunder, for leave to amend the Specification filed by them in pursuance of the said Letters Patent.

A copy of the Specification as proposed to be amended is open to public inspection at the Patent Office, and full details of the proposed amendment were advertised in the Official Journal of the Patent Office issued on the 5th day of December, 1884, No. 37, page 1264.

Any persons intending to oppose such application must leave particulars in writing of their objections to the proposed amendment at the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C., within one month from the date hereof.

Dated this 5th day of December, 1884,

H. READER LACK,

Comptroller General.

CARPMAEL and Co.,

24, Southampton Buildings,

London, W.C.,

CHRISTMAS LECTURES.

LECTURE HOUR THREE O'CLOCK P.M.

PROFESSOR TYNDALL, D.C.L., F.R.S., M.R.I.—Six Lectures (adapted to a Juvenile Auditory) on THE SOURCES OF ELECTRICITY: Friction-electricity, Volta-electricity, Pyro-electricity, Thermo-electricity, Magneto-electricity; on Dec. 27 (Saturday), Dec. 30, 1884; Jan. 1, 3, 6, 8, 1885. *One Guinea the Course; Children under 16, Half-a-Guinea.*

AFTERNOON LECTURES BEFORE EASTER, 1885.

LECTURE HOUR THREE O'CLOCK P.M.

PROFESSOR HENRY N. MOSLEY, M.A., F.R.S.—Five Lectures on "Colonial Animals: their Structure and Life Histories" on Tuesdays, Jan. 13, 20, 27, Feb. 3, 10. *One Guinea.*

PROFESSOR SIDNEY COLVIN, M.A.—Two Lectures on "Museums and National Education;" on Tuesdays, Feb. 17, 24. *Half-a-Guinea.*

PROFESSOR ARTHUR GAMGEE, M.D., F.R.S.—Four Lectures on "Digestion" (the subject to be continued after Easter); on Tuesdays, March 3, 10, 17, 24. *One Guinea (including Course after Easter).*

PROFESSOR DEWAR, M.A., F.R.S., M.R.I.—Eleven Lectures on "The New Chemistry;" on Thursdays, Jan. 15, 22, 29, Feb. 5, 12, 19, 26, March 5, 12, 19, 26. *One Guinea.*

CHARLES WALDSTEIN, Ph.D. Heidelberg, Hon. M.A. Cantab.—Three Lectures on "Greek Sculpture from Phedias to the Roman Era;" on Saturdays, Jan. 17, 24, 31. *Half-a-Guinea.*

GEORGE JOHNSTONE STONEY, Esq., M.A., F.R.S.—Three Lectures on "The Scale on which Nature Works, and the Character of some of Her Operations;" on Saturdays, Feb. 7, 14, 21. *Half-a-Guinea.*

CARL ARMBRUSTER, Esq.—Five Lectures on "The Life, Theory, and Work of Richard Wagner (with Illustrations, Vocal and Instrumental); on Saturdays, Feb. 28, March 7, 14, 21, 28. *One Guinea.*

Subscription (to Non-Members) to all the Courses during the Season Two Guineas. Tickets issued daily at the Institution, or sent by post on receipt of Cheque or Post-Office Order.

Members may purchase not less than Three Single Lecture Tickets, available for any Lecture, for *Half-a-Guinea*.

Now ready, 8vo., pp. 520, price 10s. 6d.

A FIFTH thoroughly REVISED EDITION, embodying the Act of 1883 and all Reported Decisions to date.

MANCHESTER CORPORATION GAS-WORKS.

MANAGER.

The Gas Committee are prepared to receive applications for the Appointment of a Manager for their New Station at Bradford Road, at a Salary of £500 per annum. Preference will be given to a gentleman possessing a practical knowledge of the working of Regenerative Furnaces.

The successful candidate will be required to devote the whole of his time to the duties of his office.

Applications, stating age and experience, and enclosing copies of recent testimonials, to be forwarded to the office of the Superintendent of the Gas Department, on or before 12 o'clock noon on Monday, the 22nd December instant, addressed to the Chairman of the Gas Committee, and endorsed "Application for Appointment of Station Manager."

Canvassing will disqualify.

Town Hall, Manchester,
3rd December, 1884.

By Order, JOS. HERON,
Town Clerk.

BICHROMATE OF SODA.

Potter and Higgin's Patent

A complete substitute for Bichromate of Potash in Dyeing, Calico Printing, Colour Making, and all other manufactures where Chromic Acid is a necessary element.

It contains as much Chromic Acid as Bichromate of Potash.

It is cheaper than Bichromate of Potash.

It is more soluble than Bichromate of Potash.

It is of uniform strength and purity.

VOL. L. No. 1309.

ON THE TESTING OF ANILINE HYDROCHLORIDE ("ANILINE SALTS.")

By ROWLAND WILLIAMS, F.C.S., &c.

THE following hints may possibly be of use to chemists who have not had much experience in the testing of aniline hydrochlorate, or, as it is usually termed in calico-printing and other works, "aniline salts." The main points for investigation are—(1), absence or presence of grit; (2), degree of acidity; and (3), purity of the aniline from which the "salts" have been prepared.

(1) *Grit*.—This is tested for by dissolving a few ounces of the "salts" (if that quantity be available) in water, and allowing the insoluble matter (if any) to settle to the bottom of the vessel. A slight trace of grit will usually be found, but this may be disregarded. If, however, a considerable amount of gritty insoluble matter be present, it must be washed with water several times by decantation, then transferred to a tared crucible, ignited, and weighed as fairly pure silica. It is very important that the "salts" should be almost absolutely free from grittiness, otherwise the "doctors" are attacked and the pieces "streaked" during the printing of aniline blacks.

(2) *Acidity*.—This estimation is made by dissolving a small quantity (say 2 grms.) of the "salts" in water, and titrating directly with standard NaHO , using either litmus or phenol-phthalein as indicator. In well-prepared "salts," the above-mentioned amount will require about 14 c.c. of normal NaHO for neutralisation of the free acid. It must be distinctly understood that, while a moderate degree of acidity is necessary for the production of a good black, an excessive amount is extremely dangerous, on account of its liability to cause injury to the cloth during the process of steaming. Consequently, in the examination of "aniline salts" this important point must always be specially attended to, as "salts" are often faulty in this respect, although satisfactory enough in others.

(3) *Purity*.—In order to ascertain the purity (or otherwise) of the aniline from which the "salts" have been manufactured, it is necessary to obtain a little of the oil in the free state. This is accomplished by decomposing an aqueous solution of the "salts" with caustic soda, treating with ether, which readily dissolves the aniline, and afterwards evaporating off the ether. A few c.c. of the resultant aniline are then heated for some time at a temperature of 180°C ., with an equal quantity of strong arsenic acid solution, and the resulting mass boiled with water. If the aniline be contaminated with toluidine, the aqueous solution is coloured crimson to a greater or lesser extent, according to the amount of impurity present, owing to the formation of rosaniline. If the aniline be pure, this colouration is, of course, not produced. It is also advisable to examine the "salts" for ammonium chloride (which I have occasionally detected in rather large amount), by heating with caustic soda in the usual way. Sulphates are also frequently present, but usually only as traces, and as they are probably due simply to a slight impurity in the hydrochloric acid employed in the manufacture of the "salts," their presence may be disregarded. A small quantity of the "salts" when ignited in a crucible should not leave more than a slight trace of residue.

In addition to the foregoing purely chemical tests, it is usual, in a print-work, to submit each fresh delivery of "salts" to a practical test by making up a small quantity

of colour in comparison with the "salts" in use, "striking off" side by side on a fent, steaming, &c., and comparing the purity and depth of shade of the aniline blacks produced.

ON JAPANESE TEA AND TOBACCO.

By J. TAKAYAMA.

THE tea-leaves are gathered in May, and quickly dried by exposure to air, and carefully sifted so as to separate dust and fragments of leaves. They are then subjected to steaming. This is done by introducing the leaves into a wooden tub, the bottom of which is formed of bamboo meshes, the tub being placed on an iron pan filled with water and heated from below. After thirty minutes, when the steam rises up, the wooden cover is taken off, and the contents are thoroughly mixed so as to steam uniformly all the leaves. This done, the tub is covered again with the lid. This process is repeated, and finally the contents are taken out and cooled. There is a tendency in leaves to adhere to the bamboo rod during mixing.

The leaves are now sufficiently softened to be rolled up between the hands by a gentle rubbing, after which the leaves are subjected to drying. This operation is a most difficult one, inasmuch as the quality of the product depends in great measure on the treatment which the leaves undergo during the operation, since it is during drying that that fine colour becomes fixed, with simultaneous production of that delicate flavour and agreeable taste which are wanting in the original leaves; so that it requires excellent workmen, whose requisite skill is only attained after a long practice.

The drying is conducted in a shallow rectangular box, the bottom of which is made of a thick paper stiffened with starch. The box is placed over a copper-wire gauze supported by iron bars, which are provided across the furnace. The furnace is simply a rectangular box coated with clay, and has the depth of 2.5 shaku.

To begin the operation, first of all a charcoal fire is made in the furnace. The rectangular box is now placed over it, the leaves are next introduced into the box, and the workman continually rubs them between the hands, alternately tossing them up and letting them fall until they are nearly dried. Thus dried the leaves are further dried by keeping for a night in the same furnace after the charcoal fire is withdrawn. In large factories numbers of these furnaces are arranged in rows, and during the drying each furnace is attended by one workman.

The tea thus dried is, before it is sent to the market, subjected to sorting and sieving. The sorting simply consists in spreading out a certain quantity of tea upon a flat table, and in removing dust, stems, and other foreign matters by picking them up, which operation is usually done by women and girls. The sorted tea is then sieved.

The sieves of different meshes are distinguished from one another by the numbers 1, 2, 3, &c., and the number of sievings as well as the sieves used vary with the quality of the tea. Thus, in the case of coarse kinds, it is passed twice or thrice through each of 1 and 2, and in the best kinds only once through 2, 3, 4, and twice through 3, which has the meshes of nearly 3 millimetres. The tea thus prepared is preserved in earthenware or metallic pots in order to preserve it from the moisture.

Black Tea.

Before intercourse with Western nations was opened this was scarcely known to us, but now at present it is manufactured, though to a very limited extent, for the purpose of exporting it to foreign countries.

The writer states the following description of the process to be due to the Report published by order of the Board for promotion of industry, agriculture, and commerce.

In preparing the black tea, the leaves from wild tea-

plants, or those which are cultivated without much care, are used, otherwise there will not be much profit.

The leaves after gathering are scattered on a straw mat, and dried by exposure to air. They are then collected and softened by tossing and clapping between the hands till they become adhesive. The leaves are then made into a number of balls, which are introduced into a large box, which is closed tightly and exposed to the sun for half-an-hour, when it is brought into the house, and allowed to lie in this state for one night. The balls are then taken out, and subjected to the rolling and drying in the same way as in the preparation of green tea. During the operation the workman turns the mass, so as to prevent it from being burnt. This process is continued until the leaves break very easily by simply pressing between the fingers, when they are considered to be perfectly dry. The tea thus produced is freed from impurities and stalks, and separated into different kinds by passing through sieves having meshes of different size.

The specimens he chemically examined are all those prepared in the celebrated tea-producing district Uji, and are supposed to be unadulterated.

The accompanying table gives the result of the analyses. On examining the table there seems to be no connection between commercial quality and chemical composition, but it is very interesting to observe how nearly the same is the amount of the constituents in all specimens; so that, in any instance, if we find some of the constituents as ash, for instance, in quantity differing from those found in the table, we may consider such specimen as being previously adulterated.

Nitrogen in the table was determined by Dumas's method.

Theine.—He estimates this most important constituent of tea by the following method:—15 grms. of powdered tea are mixed with an equal amount of magnesia, and the mixture is boiled with water, filtered, and residue washed with hot water. The filtrate being evaporated to dryness is exhausted with hot benzole, and the extract is then evaporated and the residue is weighed. By this method he found 0.189 per cent in *Nagautomo*, and 0.207 per cent in *Horin*, all brought from Uji.

Analysis of Tea Ash.

	Green Tea from Uji.		Black Tea from Settsu.	
	I.	II.	III.	IV.
Silica	8.91	6.19	5.01	4.61
Sulphuric acid ..	3.87	4.70	3.03	4.22
Phosphoric acid ..	16.62	17.02	21.87	19.77
Chlorine	1.62	1.95	1.26	1.04
Carbonic acid ..	7.82	9.45	6.23	7.02
Oxide of iron and alumina	8.21	9.06	6.35	7.96
Manganese sesquioxide ..	0.59	trace	0.98	1.30
Lime	14.57	13.17	8.33	10.42
Magnesia	6.95	6.17	6.92	7.00
Soda	2.70	4.03	5.01	2.99
Potash	27.92	28.11	35.04	33.60
	99.78	99.86	100.03	99.93

Tannin.—This is determined by a standard solution of plumbic acetate. In six specimens from Uji he found the following amounts:—Toyokumo, 16 per cent;

Toyokage, 16.25 per cent; Shimonohaua, 15.62 per cent; Nagautomo, 14.70 per cent; Toyomaye, 16.70 per cent; Hochayen, 16.12 per cent.

Gum.—Estimated by evaporating the aqueous extract of tea almost to dryness, treating the residue with methyl spirit, the extract evaporated to dryness, and the residue weighed, which, after ignition is again weighed; the loss represents the gum. By this method he found the following amounts in the same specimens as above:—Toyokumo, 17.72 per cent; Toyokage, 9.75 per cent; Shimonohaua, 12.32 per cent; Nagautomo, 10.10 per cent; Toyomaye, 9.90 per cent; Hochayen, 10.61 per cent.

Japanese Tobacco.

There are various varieties of tobacco plant, differing more or less in the form and size of the leaf, but those growing in this country are known as *Nicotiana Chinensis*, and *Nicotiana Tabacum*, bearing rose-coloured flower, and growing to the height of 3 to 5 feet. The tobacco plant is cultivated almost in every province, but the best leaves are produced in the provinces of Hizen, Hitachi, Satsuma, and Nagato.

The mode of collecting the leaves varies in different places, but generally two or three small leaves, which are situated at the upper part of the stem, are first taken off by hand, and the remaining leaves, after being exposed to the sun for 3 to 5 days, are successively taken, three or four at a time. In Awa it is just reversed; the lower leaves, which are of inferior quality, are taken off at first in June, when the leaves are slightly yellowish, and the middle leaves, which form the best sorts, are collected after 13 or 14 days. In some places a second crop is obtained from new shoots, which, if properly cultivated, yield leaves which are not inferior to those of the first gathering.

The leaves thus collected are placed on a floor covered with a straw mat, allowed to remain for one or two days, when the mat is taken off; those which have assumed the melon-yellow colour are sorted out and dried by exposure to air, while those still retaining the original colour are kept in the same condition till the required colour is developed.

The dried leaves are now packed and sent to market. According to Japanese fashion, tobacco for smoking purposes is cut into fine threads.

Malic	0.79	1.02	1.83	2.98
Citric	0.52	0.59	0.92	0.89
Pectic	1.24	5.84	7.42	2.35

The methods he used for the determination of nicotine and organic acids are as follows:—

1. *Nicotine*.—10 grms. of powdered tobacco are made alkaline by ammonia which is intended to displace nico-

tine. It is then extracted by ether, the extract evaporated to dryness, when a pasty residue of nicotine and a greenish yellow resinous body is obtained from which nicotine is determined by standard sulphuric acid.

Acetic Acid.—Tobacco powder is moistened with water and then ground with tartaric acid. The mass is exhausted with steam, which volatilises acetic acid, and which is condensed by means of Liebig's condenser. The acid is determined by means of standard alkaline solution.

3. **Oxalic, Malic, and Citric Acids.**—10 grms. of tobacco are moistened with hydric sulphate, the quantity to be used being previously calculated from the ash of the leaves. It is then exhausted with ether in a continuous distillation apparatus. The organic acids are dissolved in ether and the operation is completed when a small quantity of ether, evaporated, does not leave any residue.

In order to extract the required acids, leaving the foreign bodies in ether solution, a few drops of water are added and the whole is shaken. The aqueous solution is separated from ether solution, and the water solution is neutralised by ammonia, and a few drops of acetic acid is added. Then the oxalic acid is precipitated by a dilute solution of calcic acetate and determined.

To the filtrate a dilute solution of lead acetate is added until a permanent precipitate appears, and about 1 c.c. of the supernatant liquid is taken into a test-glass, and a drop of very dilute lead acetate solution is added; if the precipitate produced is not dissolved by addition of a few drops of acetic acid, then after 1 c.c. taken is returned to the main portion the addition of lead acetate is continued. This is repeated till a precipitate, produced by a new addition of lead acetate, is completely soluble in hydric acetate. Then it is filtered, washed with water containing a small quantity of lead acetate and acetic acid, and finally with alcohol at 36°. The washings are kept separate from the main filtrate. Citric acid is then determined from the lead oxide left after combustion of the precipitate. In the washings a small quantity of citric and malic acids are present; they are precipitated, after alcohol is expelled, by adding an excess of lead acetate, and their amounts are determined from the quantity of lead oxide, assuming the two acids to be present in equal proportions.

In the filtrate malic acid is precipitated by adding an excess of lead acetate solution, and the precipitate is treated as in case of citric acid.

4. **Pectic Acid.**—10 grms. of powdered tobacco are exhausted with alcohol at 36° containing 1/4th its volume of concentrated hydric chloride until the filtered liquid no longer contains lime. The residue is washed with alcohol so as to remove hydric chloride completely, and it is then treated with a solution containing a known quantity of ammonium oxalate, by which pectic acid is dissolved out. After two hours' digestion at 35°, it is filtered, the residue washed, the filtrate made to 1 litre, from which a known volume is measured out, and an excess of calcic acetate is added, when a white precipitate of oxalo-pectate of lime is formed, which is filtered on a weighed filter and weighed after drying at 100° C. This precipitate is then burnt, and the amount of lime formed is ascertained. The amount of pectic acid is then calculated from the following:—

$$P = (B - C \frac{A}{100})$$

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING NOVEMBER 30TH, 1884.

By WILLIAM CROOKES, F.R.S.

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford.

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To COLONEL SIR FRANCIS BOLTON, *Water Examiner,*
Metropolis Water Act, 1871.

London, December 6th, 1884.

SIR,—We submit herewith the results of our analyses of the 172 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily from November 1st to November 29th inclusive. The purity of the water, in respect of organic matter, has been determined by the Oxygen and the Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter, and the quantities of free oxygen present in the whole of the samples submitted to analysis.

Of the 172 samples, all excepting one that was recorded as "*slightly turbid*," were found to be perfectly clear, bright, and well-filtered.

The proportions of organic matter in the water supplied by the several Companies during the past month have continued low, and below the average for the season of the year, though not to so exceptional a degree as in the samples examined in the preceding month. In our report for the month of July last we called attention to the circumstance that the habitual slight monthly rise then noticed, in the always small proportion of organic matter present in the water supply of London, was "ordinarily followed by a more decided fall in August and September, to be succeeded, in its turn, by an appreciable rise in October and November." During the past month, however, the mean proportion of organic matter in the water, though above that met with in October, can scarcely be said to have manifested as yet the "appreciable rise" usually noticeable in the early winter months.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES,
WILLIAM ODLING,
C. MEYMOTT TIDY.

THE COMPOSITION AND METHODS OF ANALYSIS OF HUMAN MILK.*

be most forcibly illustrated by comparing the analysis of sample No. 40, which was obtained from a negress, with the other samples, and with the general average. Neither in colour, smell, nor other physical characteristics, nor in chemical constitution, was this one sample so markedly different from the others as to be put, as some have proposed to do with the milk of negro women, in a class by itself.

V. *Physical Constitution of the Mother.*—A comparison of the physical characteristics of the mother, whether blonde or brunette, or more minutely as to colour of eyes, hair, complexion, &c., has not shown that these differences are necessarily related to corresponding differences in the composition of the milk. But actual differences in the physical condition of the mother are intimately related. The samples obtained from women of over-robust habit were not so rich in albumenoids as those from pronouncedly anæmic women; and, generally speaking, the best milk was obtained from lean women in good physical condition.

Certain Spectroscopic Procedures.—Eug. Demarçay.—In place of the method of Lecoq de Boisbaudran the author uses the induction spark obtained from a coil with a thick and short induction wire.—*Comptes Rendus*.

THE SPECTROSCOPIC EXAMINATION OF THE VAPOURS EVOLVED ON HEATING IRON, &c., AT ATMOSPHERIC PRESSURE.

By JOHN PARRY, Ebbw Vale.

METALLURGISTS favoured with opportunities of observing the behaviour of metals whilst being heated or fused are of opinion that the fumes usually seen are due to the volatilisation of the metal itself, or of some more volatile constituent.

In casting alloys of the more fusible metals, this dissociation or volatilisation is an accepted fact, and is usually considered when adjusting the proportions of the constituents. Alloys of the more infusible metals, such as iron, manganese, nickel, cobalt, &c., have not been studied; but those who have observed the behaviour of crude iron and steel whilst being fused, or otherwise manipulated at high temperatures, have noted that, in addition to the well-known evolution of gas, fumes are given off, which has led to the inference that, as before stated, some more volatile constituent is being evolved;

and Professor Ledebur asserts that as iron is being volatilised the chemical composition of the metal may be changed, presumably within certain narrow limits. It may be that crude iron is slowly dissociated, and certainly at the high temperature of the Bessemer process iron is volatilised, and may be seen far above the mouth of the converter, forming a red cloud, quite unlike ordinary smoke or vapour.

The spectroscopic examination of the flames issuing from blast and other furnaces show only continuous spectra, with but few lines, very similar to the spectrum of the ordinary Bunsen flame, with the exception of the Bessemer flame, which gives the carbon spectrum, together with (according to some observers) that of manganese.

I have, however, found that many of the metals are volatilised at a comparatively low temperature, but give only continuous spectra when examined in the flame. The vapour requires the intense heat of the electric spark to be passed through it to ensure complete dissociation, and consequent production of the usual line spectra. (A list of metals tested is attached hereto.)

Spiegeleisen fused in a crucible evolved a fume in which I detected zinc, copper, manganese, calcium, and, with less certainty, magnesium.

Bessemer pig-iron, similarly treated, gave copper, manganese, calcium, either lead or arsenic, as well as gas burning with a flame resembling that of carbonic acid.

Bessemer pig-iron burnt in a stream of oxygen at a dull red heat gave copper, manganese, &c., as before, but more intensely; also a great number of lines which appear to be derived from iron. This spectrum requires careful study, and, when developed, may throw some light on the reactions occurring during the Bessemer blow.

Spanish iron ore reduced in a crucible with charcoal, at a heat sufficient to form a button of fused metal, evolved zinc, copper, and manganese.

It is therefore probable that matter may be evolved during the ordinary heating processes in the manufacture of iron and steel, as previously explained, but giving no visible indications of the fact, in consequence of the heat being sufficient only to volatilise without effecting dissociation.

With my present limited experience, I am of opinion that the actual quantity of matter evolved from iron, steel, &c., is very small, and not at all likely to affect the quality of the coarser kinds of iron and steel, although it may be otherwise when a material of good quality and great purity is required.

The germ of the foregoing is to be found in the recent work of spectroscopists, more especially of Mr. Lockyer, who, in his "Studies in Spectrum Analysis"—a volume abounding with suggestions which should, in my opinion, be carefully studied by those practically engaged in the iron manufacture—says, "Depend upon it, that as spectroscopy becomes the daily work of iron founders and the like, it will be found to be bristling with scientific truth which may be used in these practical applications."

Note.—Spanish iron ore evaporated to dryness with hydrochloric acid. The dried chlorides were carefully and gradually heated in the blowpipe, and copper, zinc, calcium, barium, lead, silver, and manganese lines successively detected in volatilised chlorides. At the highest obtainable heat iron lines are seen.

The impure ferric chlorides, obtained by digesting steel or iron in hydrochloric acid and evaporating to dryness, heated as above, shows—1st, copper and calcium; 2nd, manganese; next, with less certainty, chromium and magnesium. On increasing the heat the iron spectrum is vividly seen.

Steel or iron filings, mixed with ammonium chloride, and heated also, gives the foregoing series of spectra, which last longer, and may be repeated by successive additions of the chloride.

Very fine spectra of sulphur and phosphorus may be obtained by slightly heating either on a moderately hot plate of iron, placed just below the spark from the coil.

Notes on the Volatility of the Metals Heated in Crucibles. Fletcher's "Injector Blowpipe" used.

Thallium.—Very volatile. Seen in flame and spark above.

Arsenic.—Very volatile. Seen in spark only.

Copper.—Very volatile. Volatilised from most metals in flame and spark.

Cadmium.—Easily volatilised. Seen in spark only.

Zinc.—Easily volatilised. Seen in spark only.

Bismuth.—Volatilised at highest red heat. Seen in spark only.

Antimony.—Easily volatilised. Seen in spark only.

Potassium.—Easily volatilised. In flame and spark.

Sodium.—Easily volatilised. In flame and spark.

Tin.—Volatilised at highest temperature of blowpipe. Spark only.

Lead.—Volatilised at lower temperature than tin. Spark only.

Silver.—Not volatile. Copper spectrum seen. Spark only.

Gold.—Not volatile. Copper spectrum seen. Spark only.

Chromium.—Not volatile. Copper spectrum seen. Spark only.

Manganese.—Volatilised with difficulty. Spark only.

Aluminium.—Volatile. Spark only.

Selenium.—Very volatile. Spectra require further study.

Tellurium.—Very volatile. Spectra require further study.

Phosphorus.—Easily volatilised on hot plate. Good spark spectrum.

Sulphur.—Easily volatilised on hot plate. Good spark spectrum.

Notes of Experiments on the Spark Spectra of the Chlorides of the Metals and Alkalies Volatilised at Atmospheric Pressure.

The chlorides of lithium, strontium, copper, and calcium are volatile in the flame of an ordinary alcohol lamp, showing the characteristic spectral lines in the spark about one inch above the flame.

Zinc, barium, copper, and magnesium chlorides are also faintly seen. Query about arsenic? Filter-paper moistened with zinc chloride and placed in the alcoholic flame gave the line W. L. 4809.

Steel filings, mixed with ammonium chloride and heated—copper and manganese first appear, next calcium (zinc?), next iron spectra; after heating thirty minutes only, one copper and two manganese lines are seen. Iron lines nearly gone; calcium seen. Further heated thirty minutes, only calcium; traces of copper flashing out.

Spiegeleisen as above; in addition, magnesium seen; brighter spectrum throughout.

Copper chloride mixed with ammonium chloride and heated with spirit-lamp in a glass tube 20 inches long—copper distinctly seen in the spark at the top of the tube.

Impure steel chlorides, as above, heated in glass tube 4 inches long, spark at top—calcium first seen, copper, next manganese group. After heating some time, only calcium and copper were visible.

Ordinary nickel, cobalt, bismuth, tin, and antimony, show copper spectrum when heated. All metals hitherto tested evolve copper.

Query zinc in steel?

Query magnesium in spiegel? Only first line of magnesium seen on edge of nitrogen line, W. L. 5712.

Compared this line with magnesium, by clamping cross wires down on it; magnesium line distinctly seen on edge of nitrogen, W. L. 5712.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, Thursday, December 18, 1884.

Dr. RUSSELL, F.R.S., in the Chair.

THE following certificates were read for the first time:—N. F. Dutton, R. Dormer, A. G. Green, G. G. Henderson, W. A. Wrenn, A. C. Wilson, A. C. Young, H. H. Whitehead.

During the evening a ballot was held, and the following gentlemen were declared by the Scrutators, Messrs. Wilson and Cresswell, to be duly elected Fellows of the Society:—W. P. Ashe, Sir B. V. S. Brodie, Bart., W. Briggs, J. F. Ballard, M. T. Buchanan, W. G. Brown, H. M. Chapman, W. H. Eley, J. Frost, T. P. Hall, H. J. Hodges, H. Jackson, F. Johnson, J. D. Johnstone, G. F. Kendall, C. W. Low, F. M. Mercer, P. C. Porter, V. E. Perez, A. Rickard, K. B. B. Sorabji, R. R. Steele, H. Smith, E. G. Smith, G. Thorn, W. Tate, P. C. Thomas, T. Wilton, J. H. Worrall, W. C. Wise, W. H. Wood.

THE SECRETARY then read the following paper:—

"*Chemico-Physiological Investigations on the Cephalopod Liver and its Identity as a True Pancreas*," by A. B. GRIFFITHS. The author has carefully dissected out this organ from a fresh cuttle-fish. He finds that a small portion of the organ converted starch-paste into dextrose; the organ was alkaline, it emulsified oil, and rendered milk transparent. Under the microscope a small portion gave a brown deposit with iodine, and a yellow colour with nitric acid. The author obtained a glycerin extract of the organ in the usual way, and precipitated a ferment from the glycerin solution by alcohol. This ferment converted starch into dextrose, and formed from the fibrin taken from the muscular fibres of a young mouse leucin and tyrosin, the latter body giving with a neutral solution of mercuric nitrate a red precipitate, which reaction is stated by the author to be characteristic of tyrosin. The author could not detect any bile acids or glycogen, and concludes that the organ is more like a pancreas than a liver.

The Society then adjourned to Jan. 15, when a paper "On the Atomic Weight of Titanium" will be read by Prof. Thorpe.

It was announced that a lecture would be given by Dr. Frankland, probably in February, "On Chemical Changes produced by Micro-Organisms."

NOTICES OF BOOKS.

The Art of Leather Manufacture. Being a Practical Handbook in which the Operations of Tanning, Currying, and Leather Dressing are fully described, the Principles of Tanning Explained, and many Recent Processes Introduced, as also Methods for the Estimation of Tannin, and a Description of the Arts of Glue-boiling, Gut-dressing, &c. By ALEXANDER WATT. London: Crosby Lockwood and Co.

THE author is, we believe, perfectly correct in saying that hitherto no English work on the important arts in question has existed. He deserves, therefore, praise for endeavouring to supply this deficiency in our technical literature. After a historical introduction, in which reference is made to the oppressive interference of the Excise up to the year 1830, the author expounds the chemistry of the dyeing process. After describing gelatin and its behaviour with tannin, he reproduces Seguin's theory of the art, but points out many of his errors, especially his ascription of an important part to gallic acid. He points out the superiority of the leathers made on the slow process by

the older tanners as compared with the generality of the superficially-tanned quick-process leathers of the present day.

The author next proceeds to a general description of the skins of animals. Those tissues of animals which are capable of being converted into gelatin by boiling, he terms "gelatinous," instead of "gelatiginous." In the next chapter, which is devoted to an account of the various classes of hides occurring in commerce, Mr. Watt quotes from "The World of Insects," though without assenting to it, the following absurd statement:—"Indeed, tanners prefer hides that have the greatest number of bot holes, considering them the strongest and best, which indeed they are, as the gadfly never attacks any but young and healthy subjects." Common sense, independent of any special experience, must tell everyone that holes in a hide seriously diminish its value. In fact, as the author tells us, how to get rid of these holes has been an anxious subject of inquiry, no less for the tanner than for the farmer. He suggests that in the season when the gadfly makes its appearance the backs of cattle should be brushed over with some solution inimical to insects.

We come next to a chapter on tannin, its preparation and reactions. A note on the process of dialysis makes no mention of the fact that animal membranes do not allow the passage of all bodies through their tissue, but keep back some whilst transmitting others. As regards the varieties of tannin, Mr. Watt accepts the view, now generally received, that these bodies, though nearly allied, are not identical.

The table of the proportions of tannin existing in various barks, roots, extracts, &c., cannot be in all cases depended upon. The quantitative determination of tannin has only of late years been brought to an approximately trustworthy state. It would have been well, therefore, if another column had been added showing the dates of the different determinations. The figures here given are, upon the whole, lower than those to be met with elsewhere. Thus we have the tannin in myrobalans quoted as 20 per cent, and that in sumac as 16; whilst in "Spon's Encyclopædia," vol. v., pp. 1987 to 1991, they are stated as containing respectively 30 to 35 and 24 per cent, figures which certainly agree much better with our own experience.

In discussing the gallic fermentation, the author recommends the addition of anti-zytomic agents to prevent this undesirable change in tan-liquors. He remarks that exposure to the air promotes the gallic fermentation, and he accordingly suggests that the present process of "handling" is a mistake.

In the list of tanning materials we find the myrobalan described under the erroneous name of "myrabolan." Its size is stated as varying from that of a small hazel nut to that of the nutmeg, which would make it too small. It is suggested that the valonia might be successfully cultivated in Australia. The same would very probably be the case with sumac. In the extensive list of tanning materials we find the botanical name of the "marsh rosemary" given as *Statice coriaria*. We have always known "marsh-rosemary" as the English name for *Ledum palustre*.

The following chapter contains the methods for the examination of tan-drugs and the determination of tannin. The "barkometer"—sometimes called baktrometer (!)—is necessarily a fallacious instrument, as the specific gravity of a tan-liquor is raised by any constituent existing in solution. The author, indeed, gives the caution that this instrument should be used only for fresh solutions. We have next an account of the methods of Davy, Bell, Stephens, and Hammer, and the more trustworthy procedure of Löwenthal, with its modifications by Mr. F. W. Hewitt and Mr. H. R. Procter.

Preliminary matters having been thus disposed of, Mr. Watt comes to the art of tanning itself. He describes in succession the operations of cleansing and softening the dry hides as received, and the depilation or unhairing

process. Here we find a very necessary caution as regards the use of calcium disulphide. The hydrogen sulphide given off has a very injurious action upon the workmen exposed to it, and may even produce temporary blindness. In the raising process—which when applied to kips and skins is named “bating, puring, or drenching,”—there is a surviving tendency to use unsavoury agents, such as the dung of pigeons or of dogs, made into a paste with water.

After an account of the ordinary methods of tanning butts for sole-leather, we come to notices of patented improvements, some of which are “improvements” only in a “Pickwickian” sense. One ingenious inventor, in order to let the solution of tannin penetrate more readily through the hides, perforates them with fine steel points to the number of 100 to 300 to the square inch. Whether these holes can ever be closed up again so as to be equally watertight with an unpunctured hide is a very doubtful question.

Under the heading “Tanning by Pressure” there follows a description of several processes in which tannin is forced into the hides by pressure. In a section on “quick tanning” the author admits it as demonstrated “almost beyond the shadow of a doubt” that the process of tanning can never be both quick and good. It must be regretted, both with respect to leather and to many other articles, that those who know that a good product is in the long run the cheapest cannot be supplied.

In succession the author speaks of the manufacture of harness, belting, and upper leathers, the American methods of tanning, and hemlock tanning.

Tanning by electricity is next taken up, and though none of the processes devised has as yet achieved any decided success, it would be rash to declare that there is in this direction nothing to hope for.

Knapp's iron tanning and Heinzerling's chrome tanning are next described. Here, again, it is premature to pass judgment upon the results, though, as the author remarks, even if a better leather is produced without tannin the world will not readily believe it.

There are other interesting and important chapters on vegetable leathers, on bleaching leather, on the manufacture of Russia and Morocco leather and cordovans, on dyeing leather, on the manufactures of white leathers, glue making, and gut-dressing.

The work is abundantly illustrated, and contains few typographical errors. Some of the matter quoted appears to have been translated from the German by a writer not too well acquainted with English technical terms. The information which, we believe for the first time, is collected in this volume could only be found by searching through a bulky and costly pile of cyclopædias, technical journals, and patent specifications. Hence we consider that Mr. Watt has rendered an important service to the trade, and no less to the student of technology.

Alkali, &c., Works Regulation Act, 1881. Twentieth Annual Report on Alkali, &c., Works by the Chief Inspector. Proceedings during the Year, 1883. London: Eyre and Spottiswoode.

THE issue before us derives a melancholy interest, as being the last report from the pen of the late Chief Inspector, Dr. R. Angus Smith. His protracted illness, indeed, is mentioned in the introduction as a reason why his personal contributions to the “Report” are briefer than heretofore.

The first point to be noticed is that little increase has taken place in the total number of works under inspection, *i.e.*, 990. No fewer than 49 works have been registered for the first time, but several have been closed for a time or permanently, whilst a number of smaller works have ceased making such articles as brought them within the scope of the Act. Of the new works we find that 26 are for the manufacture of sulphate of ammonia, and 12 for chemical manures. These facts and figures

certainly go to prove that the chemical arts in the United Kingdom are not making that progress which we might wish to see—a conclusion for which there is unfortunately too much evidence from other sources.

Another general reflection which strikes us is the somewhat one-sided and arbitrary character of the law concerning noxious fumes and gases. Any chemical works emitting æriform nuisances is placed under strict surveillance; the proprietor is advised and urged—and this may not always be done with the courtesy and tact which distinguished the late Chief Inspector—to make the required improvements, and should he prove unwilling or unable to effect what is considered needful, prosecutions and fines follow. But the sulphurous acid gas evolved in the consumption of coal, whatever may be its quantity, and whatever the injury occasioned to vegetation, passes free. Not only so: the inspector walks past glass- and copper-works well knowing to what an extent they pollute the atmosphere, but without power to interfere.

Thus we find it recorded that land-owners and farmers near Castleford, in the teeth of all evidence, lay the blame of damage done to vegetation on the alkali-works there, although the inspectors show that the glass works evolve 30 tons SO₂ weekly, as against 3 tons SO₂ and 2 tons HCl evolved by the alkali works. Even the damage done by Aphides and other insect-pests is ascribed to chemical manufactures. We remember, indeed, that on one occasion, when a number of ornamental shrubs had been destroyed by a severe frost, a neighbouring manufacturer of dyers' chemicals was threatened with legal proceedings.

Considerable annoyance has in some districts been occasioned by potteries, where during the process of salt-glazing a certain quantity of hydrochloric acid is liberated. It is satisfactory to find that after a course of experiments carried on at the works of Messrs. Doulton at St. Helens and at Lambeth, this evil has been very much abated without interfering with the quality of the glaze produced. On one occasion the quantity of free acid escaping into the air has been reduced as low as 0.11 grain per cubic foot.

We next notice an interesting report on the extraction of ammonia from blast-furnace gases in Scotland—a question which derives increased importance from the substitution of coal for coke in iron-smelting. This does away with one of the main necessities for the production of coke, and lessens the importance of improved coke-ovens, which permit of the collection of the by-products. Of the matter obtained from the waste gases of blast-furnaces the tar is the least important, as it is found to be poor in those principles from which artificial colours are prepared. The ammonia is of greater value, but, as we are here reminded, its total possibilities are limited. According to calculations made not more than 27,000 tons sulphate of ammonia may be yearly obtained from the waste gases of iron works in Scotland. In England not more than 3000 tons may be expected, as coke is principally employed in the English blast-furnaces.

Two methods of obtaining ammonia, &c., from the furnace gases are here mentioned: The washing of the gases with water in presence of acid, and the washing with water alone after the gases have been sufficiently cooled.

Another important question raised in the same report is the extraction of ammonia from shale in the oil works of Scotland. The shales are exposed to destructive distillation, and after the volatile products have been given off steam, or a mixture of steam and air, is passed over the highly heated residue, with the result that an increased proportion of the nitrogen originally present appears in the form of ammonia.

A similar process has been applied to “coal-dross,” with the result of obtaining a lighting gas rich in ammonia and also tar. What “coal-dross” is does not distinctly appear,—probably the term signifies carbonaceous matter too rich in shale to be marketable as coal. From 1 ton of this dross are obtained 172,000 cubic feet

of gas, used as fuel in heating shale retorts, and from 90 to 100 lbs. of sulphate of ammonia. Nothing is said concerning the quality of the tar, which is but scanty.

Concerning the Portland cement works of North Kent and the opposite shore of the Thames there seems a variety of opinion. The fumes given off are exceedingly unsightly, as will have been noticed by every one who has happened to travel from London to Maidstone. The smell seems to us less offensive than that of the "ballast-heaps" which are constantly burning in the northern suburbs of London, no man interfering. The report before us states that "during the later stages (of cement burning) the amount of carbonic oxide is large, and, to those close by and inhaling it, poisonous." There seems to be no evidence that the fumes are harmful to vegetation. "A garden, often exposed to the white smoke from a number of kilns, did not seem to suffer in the least; both flowers and fruits grew plentifully in it." The cement manufacturers assert that since this business has been established in North Kent the ague has disappeared. The inspector, indeed, points out that ague is disappearing from all parts of the east of England, but he quotes the evidence of Dr. T. Evelyn-Crook, who has practised in Northfleet since 1848, and has been Medical Officer of Health since 1878. This gentleman states that the neighbourhood is now much more healthy than it was in 1848. The present death-rate is only 17·2 per thousand, a fact scarcely compatible with any injurious action of the fumes from the cement works.

From Castleford comes an exceedingly interesting report touching the effects of glass works. It appears that in 1840 the alkali used in the glass manufacture was soda-ash. But about twenty-five years ago salt-cake (sodium sulphate) came into use: it gradually superseded soda-ash, and is now used more extensively—if not alone. Some of the salt-cake used is the acid variety obtained from the manufacture of nitric acid and of "cylinder salts," i.e., the stronger and purer grades of hydrochloric acid. Such cake necessarily gives off much more sulphuric acid than the refined cake obtained from the alkali works. It certainly seems hard that the alkali makers should, as at Castleford, be blamed for the sins of the glass works, and be kept constantly in fear of prosecution. In the report on the south-west Lancashire district it is remarked:—"As, however, at Widnes, and still more at St. Helens, large quantities of acid vapour are thrown off continually from glass and copper works, and very much is produced during the combustion of the enormous amount of coal burnt there, people are not fully aware of the extent to which they have been relieved by the care and skill of the alkali manufacturers."

Attempts have been made to abate the dense black smoke given off from the chimneys of salt works, but so far not with any decided success. The case is peculiar and difficult. We are told, "The coals under the salt-pans are burnt not in a thin bright fire as in a steam-boiler, nor in fire of intense heat as in a metallurgical operation, but in a thick, slow fire, immediately under the salt pan. . . . If a thin, bright fire is kept, the pan suffers quickly, as the bottom is always covered more or less with salt, and also with a hard deposit of lime and magnesia known as pan-scale."

In the manufacture of bleaching-powder a difficulty is experienced. When the operation is finished a quantity—more or less—of free chlorine remains in the chamber, which must be let escape before the workmen can enter. This escape may be fairly viewed as a nuisance, seeing that even at the distance of 200 yards the smell of chlorine is occasionally distressing to the lungs. It seems, therefore, judicious to draw off the residual chlorine from a finished chamber into another chamber freshly charged with lime.

In manure works the fumes given off during the treatment of mineral phosphates with sulphuric acid have now to be absorbed in condensing towers. This regulation is no light burden for the smaller works, especially at a time

when, on account of the depression of agriculture, the manure trade is far less remunerative than was once the case.

Concerning sulphuric acid it is remarked that Mr. Menzies, of the Greenbank Alkali Works, has succeeded in boiling down sulphuric acid to full strength in iron stills, obtaining an acid of sp. gr. 1·850, colourless, and nearly free from iron.

The percentage of iron found ranges from 0·006 to 0·022.

The most unsatisfactory feature in the "Alkali Works Regulation Act" is that its provisions are equally stringent in all places. A person who should start some offensive manufacture in the midst of the hop gardens of Kent, in the Isle of Wight, at Bournemouth, or Ilfracombe, would encounter no more severe regulations than if he went to work where all vegetation has been extirpated, or where there are no inhabitants to complain. Surely a law graduated according to the locality would be greatly preferable.

On the Healthy Manufacture of Bread. A Memoir on the System of Dr. Daughlish. By B. W. RICHARDSON, M.D., F.R.S. London: Baillière, Tindall, and Cox.

THE distinction between the Daughlish process of bread-making and the ordinary or fermentation method is very simple. In both, carbonic acid is the agent for rendering the bread "light." In the common, traditional method this carbonic acid is generated by the decomposition of part of the flour, whilst Dr. Daughlish generates the gas by the action of sulphuric acid upon chalk, and incorporates it with the dough. It must be confessed that the art of making bread by fermentation as here described, and as practised in London, is decidedly nasty. Many of its offensive features, however, are merely incidental. There is nothing in the fermentation-process *per se* which compels the bakehouse to be an underground locality. "Making the dough" might, in large establishments, be performed by machinery instead of by the hands and arms of workmen not too cleanly. There is also no necessity that the men should sleep upon the boards on which the dough is afterwards weighed and moulded into loaves.

Among the evils complained of in the old system of bread manufacture we find mentioned "the necessity for using alum." Elsewhere, too, we read:—"The agent chiefly used in the bakeries has been alum. People think that alum is employed to produce whiteness of bread. That result, if obtained by it, is indirect. The great advantage of alum is to check too rapid fermentation, and it is added practically, in proportion as it is required for that intent." But if alum is necessary in making bread by the fermentation process, how comes it that it is never used in the thousands of North-English households, where the bread used is always made at home? Why should men whose whole time is devoted to this art fail to effect what every Yorkshire housewife can accomplish?

The Daughlish process has, however, many advantages, and its use would probably become universal were it not on account of prejudice.

Tablets of Chemical Analysis. (For the Detection of One Metal and One Acid.) By ARMAND SEMPLE, B.A., M.B. London: Baillière, Tindall, and Cox.

THIS little book is certainly not one we should like to see in the hands of a youthful student whose ambition is to be "a chemist." It belongs to the same class as many of the elementary manuals now published in this country, the growth of which we have had frequently to lament in these pages. "Candidates for Examinations" have here placed before them in a series of short tables the methods for detecting a single base and acid, which as far as the

object of the book goes, leaves little to be desired. The simplicity of the arrangement adopted in these tablets is such that it is difficult to conceive how any young student could go wrong in performing the operations. Under mercurous salts we read—"Liquor calcis and all the alkalies throw down a black precipitate ('black wash');" and somewhat similar language is used in other places. Is the work intended for "medical candidates"? A new reaction and compound also we find recorded thus—" $\text{HgCl}_2 + \text{SnCl}_2 = \text{HgCl} + \text{SnCl}_3 = \text{Hg} + \text{SnCl}_4$." Citrates, we are told, "are alkaline, colourless, and soluble."

In such an elementary book as the present it seems to be preposterous to give reactions for chromous and chromic salts, and for cobaltous and cobaltic salts.

Annual Report of the Director of the Mint to the Secretary of the Treasury for the Fiscal Year ending June 30, 1884. Washington: Government Printing Office, 1884.

THIS Report, which, in the main, relates to the operations of the Mints and Assay Offices of the United States, contains, also, a mass of important information collected during the year concerning the monetary statistics of foreign countries, and forms a valuable survey of the state of the coinage of the world. As regards the United States we read that "the coinage of gold was about eight millions less than in the previous year. This was caused in part by the diminished receipt of gold bullion at the San Francisco Mint, where the deposits of gold of domestic production fell off three and a half, and the total deposits of gold about three millions of dollars; and in part by a lessened coinage of gold at Philadelphia, which Mint was principally occupied in manufacturing silver and minor coins." The total coinage executed during the year consisted of ninety-two and a half million pieces, of a value of about fifty-eight million dollars. The parting and refining operations show an increase over last year's, the total values being, approximately, of gold twenty-five million dollars, and of silver fourteen million dollars.

The production of the precious metals in 1883 is estimated at thirty million dollars of gold and forty-six million dollars of silver, which represents a decline from the production of the previous year. "It resulted," the report states, "chiefly from the interruption of hydraulic gold mining in California, in many localities, by mandate of the courts, at the instance of the owners of agricultural lands damaged by the deposit of *débris*, and sediment, in the valleys, and on the bottom lands adjacent to the streams in the lower counties, and from the diminished yield of silver from some of the most productive mines of Arizona and Utah." The total production of twenty-one countries for the calendar year 1883 was 141,479 kilos. of gold and 2,747,785 kilos. of silver.

From reports received from twenty-three countries it is estimated that the value of the total coinage for the year was approximately one hundred and one million dollars in gold, and one hundred and fourteen million dollars in silver. "In the coinage of gold, the United States still stands first, although it coined a much less amount than in the preceding year. Germany follows with a coinage of over twenty-one millions; Australia sixteen millions; and Russia over twelve millions."

"Facts and Figures" concerning the Manufacture of Coke and the Collection of By-products by the Simon-Carvès Process. By J. R. BRECKON.

It is a lamentable fact that a vast amount of the real wealth of this country, estimated by millions sterling, has been and is still being dissipated in smoke. A small fraction of this loss may possibly be set down as unavoidable in connection with some of our industries. It is, however, undeniable that in some of the greatest manu-

facturing operations, especially those of a metallurgical character, a considerable fraction of this loss must be looked upon as reckless waste. The manufacturer, so long as he gains a satisfactory return for his invested capital, cares but little whether or not one-fourth of his fuel passes up his chimney, whilst with a little trouble and expense it might be recovered as a marketable article. As a rule, however, he is a "practical man," and innovations are to him enemies.

In no industry in this country more than in the metallurgy of iron has this waste been allowed to continue on a vast scale almost unchecked to within the last few years. The saving processes that have been introduced into this field have been either directly by the collection of the gases, or indirectly by a change in the manufacturing process. There remains, however, an extensive field for the inventor in connection with the coking of coals for our furnaces for the saving of valuable material. In this industry few attempts have been made towards rendering the process economical; few, at least comparatively, when we consider, as this pamphlet tells us, that 14,000,000 tons of coal are annually required to meet the demand for coke.

The great loss connected with the operation of coking as hitherto conducted has been for some years forcing itself upon the notice of our iron-masters, but the great cost of pulling down and re-erecting a new set of ovens in a large establishment, and the want of some more than ordinary enterprising manufacturer whom to imitate have acted as deterring agents in the matter; experimentation in iron manufacturing we know means thousands of pounds. As an incentive to metallurgists this little pamphlet on the Simon-Carvès coking process has been written by Mr. J. R. Breckon, in which he gives a detailed account of these ovens adapted for collecting the "waste" products evolved during the coking of coals, as well as at the same time producing coke of a first class quality, and their cost of erection and working. From this work manufacturers will be able to gain for themselves some idea of the efficiency of the process, which we learn is now being employed in several of the iron districts in this country. In an appendix, the subject is further described in two papers by Mr. Henry Simon, C.E., and Mr. Robert Dixon, reprinted from the *Journal of the Iron and Steel Institute*, the latter gentleman giving the results of his practical experience in working these coking ovens. There are added also several papers by Mr. Watson Smith, F.C.S., that have appeared at different periods bearing on the by-products obtained by condensation from the Simon-Carvès ovens compared with the products obtained from other sources of a similar character.

CORRESPONDENCE.

ESTIMATION OF IRON.

To the Editor of the Chemical News.

SIR,—In the note on the "Estimation of Iron by Potassic Permanganate in presence of Free Hydric Chloride, &c.," Dr. Hood gives no indication of acquaintance with what has been done in the same direction by C. Zimmermann. It is given in the "Reports" of the German Chemical Society (1881, vol. xiv., p. 779), and is a branch from other work.

Zimmermann avoids the injurious influence of free hydrochloric acid on permanganate in the titration of iron, by adding manganese sulphate or chloride to the liquid. It is true that the recommendation is rather that of a manganese salt than of a sulphate, but he prefers the sulphate to the chloride on account of its more powerful action, and on account of the absence of yellow colour.

Zimmermann uses a solution of 100 grms. sulphate of manganese in water, and made up to 500 c.c.

20 c.c. (= 4 grms. sulphate) of this solution, he says, is sufficient, even in presence of 50 c.c. free HCl (1·12 sp. gr.), to make the titration of a ferrous solution by potassium permanganate absolutely correct.

This statement is supported by 38 good test-experiments (in some of which $MnCl_2$ is substituted for $MnSO_4$), in which the proportions of iron, water, HCl, and manganese salt are varied.

Zimmermann adds that, in the titration of iron as above, the sulphates of nickel, cobalt, and copper do not prevent the formation of chlorine; and sulphate of zinc acts imperfectly.

Dr. Hood's results with sulphate of magnesium are very interesting, and I trust you will afford me this opportunity of placing the earlier by the side of the more recent experiments.—I am, &c.,

W. H. DEERING.

Chemical Dept., Woolwich Arsenal,
December 17, 1884.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. xcix., No. 23, December 8, 1884.

Hydro-ferrocyanic Acid and the Nitro-prussides.—A. Etard and G. Bémont.—Hydro-ferrocyanic acid, if boiled with water in a barometric apparatus to avoid contact with air is rapidly decomposed into hydrocyanic acid, and a yellowish, dense, crystalline body, the composition of which is represented by the formula—

If hydro-ferrocyanic acid is boiled with access of air there is produced not Prussian blue, as commonly stated, but a blue crystalline compound $(FeC_2N_2H_2O)_n$.

Optical Inactivity of the Cellulose of Cotton and on the Rotatory Power of Photographic Gun-Cotton.—A. Béchamp.—The author does not accept the alleged transformation of lignine into amylaceous matter. Whilst soluble starch, which is directly colourable by iodine, has a very high rotatory power, the soluble lignine of cotton, not directly colourable by iodine, has no rotatory power. Its inactivity is absolute, like that of inactive tartaric acid, although this cellulose may, by molecular modification, produce dextro-rotatory substances.

Chemical Studies on the Vegetation of the Sugar-Beet in its Second Year.—H. Leplay.—The sugar contained in the root diminishes progressively, and disappears almost entirely at the ripeness of the seed.

MISCELLANEOUS.

Royal Agricultural College, Cirencester.—Dr. Gilbert, F.R.S., Professor of Rural Economy in the University of Oxford, and the associate of Sir J. B. Lawes in the Rothamstead experimental work, has been offered and has accepted the post of Honorary Professor of Agricultural Chemistry at this college, rendered vacant by the death of the late Dr. Voelcker.

Antwerp International Exhibition, 1885.—Mr. E. A. Grattan, H.B.M.'s Consul at Antwerp, has been appointed British Commissioner for the International Exhibition, which is to be held at Antwerp next year, and Mr. P. L. Simmonds has been appointed by the Executive Council of the Exhibition at Antwerp their Agent-General for Great Britain and Ireland. The office of the Agent-General is at 35, Queen Victoria Street, and communications from intending exhibitors should be addressed to him there.

NOTES AND QUERIES.

* Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Spongy Iron.—What is the method of manufacturing spongy iron, and what are its properties and uses?—G. H. TUCKER.

MEETINGS FOR THE WEEK

SATURDAY, 27th.—Royal Institution, 3. "The Sources of Electricity," by Professor Tyndall.
MONDAY, 29th.—London Institution, 5.
TUESDAY, 30th.—Royal Institution, 3. "The Sources of Electricity," by Professor Tyndall.
THURSDAY, Jan. 1st.—London Institution, 5 and 7.
Royal Institution, 3. "The Sources of Electricity," by Professor Tyndall.
FRIDAY, 2nd.—Geologists' Association, 8.
SATURDAY, 3rd.—Royal Institution, 3. "The Sources of Electricity," by Professor Tyndall.

PATENTS, DESIGNS, & TRADE MARKS ACT, 1883.

In the matter of Letters Patent granted to Charles Rumble and Frederick Sear, Chemists, both of Belmont Works, Battersea, in the County of Surrey, for an invention of "A New or Improved Process for the Separation of Glycerine from Fatty Substances," Dated 5th September, 1883, No. 4264.

NOTICE IS HEREBY GIVEN THAT

the said Charles Rumble and Frederick Sear have applied under Sections 18 to 21 of the Patents, &c., Act, 1883, and Rules 44 to 56 of the Rules made thereunder, for leave to amend the Specification filed by them in pursuance of the said Letters Patent.

A copy of the Specification as proposed to be amended is open to public inspection at the Patent Office, and full details of the proposed amendment were advertised in the Official Journal of the Patent Office issued on the 5th day of December, 1884, No. 97, page 1264.

Any persons intending to oppose such application must leave particulars in writing of their objections to the proposed amendment at the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C., within one month from the date hereof.

Dated this 5th day of December, 1884,

H. READER LACK,
Comptroller General.
CARPMAEL and Co.,
24, Southampton Buildings,
London, W.C.,
Agents for the Applicants.

ROYAL INSTITUTION OF GREAT BRITAIN, ALBEMARLE STREET, PICCADILLY, W.

CHRISTMAS LECTURES.

LECTURE HOUR THREE O'CLOCK P.M.

PROFESSOR TYNDALL, D.C.L., F.R.S., M.R.I.—Six Lectures (adapted to a Juvenile Auditor) on THE SOURCES OF ELECTRICITY: Friction-electricity, Volta-electricity, Pyro-electricity, Thermo-electricity, Magneto-electricity; on Dec. 27 (Saturday), Dec. 30, 1884; Jan. 1, 3, 6, 8, 1885. One Guinea the Course; Children under 16, Half-a-Guinea.

AFTERNOON LECTURES BEFORE EASTER, 1885.

LECTURE HOUR THREE O'CLOCK P.M.

PROFESSOR HENRY N. MOSLEY, M.A., F.R.S.—Five Lectures on "Colonial Animals: their Structure and Life Histories;" on Tuesdays, Jan. 13, 20, 27, Feb. 3, 10. One Guinea.

PROFESSOR SIDNEY COLVIN, M.A.—Two Lectures on "Museums and National Education;" on Tuesdays, Feb. 17, 24. Half-a-Guinea.

PROFESSOR ARTHUR GAMGEE, M.D., F.R.S.—Four Lectures on "Digestion" (the subject to be continued after Easter); on Tuesdays, March 3, 10, 17, 24. One Guinea (including Course after Easter).

PROFESSOR DEWAR, M.A., F.R.S., M.R.I.—Eleven Lectures on "The New Chemistry;" on Thursdays, Jan. 15, 22, 29, Feb. 5, 12, 19, 26, March 5, 12, 19, 26. One Guinea.

CHARLES WALDSTEIN, Ph.D. Heidelberg, Hon. M.A. Cantab.—Three Lectures on "Greek Sculpture from Phidias to the Roman Era;" on Saturdays, Jan. 17, 24, 31. Half-a-Guinea.

GEORGE JOHNSTONE STONEY, Esq., M.A., F.R.S.—Three Lectures on "The Scale on which Nature Works, and the Character of some of Her Operations;" on Saturdays, Feb. 7, 14, 21. Half-a-Guinea.

CARL ARMBRUSTER, Esq.—Five Lectures on "The Life, Theory, and Work of Richard Wagner (with Illustrations, Vocal and Instrumental); on Saturdays, Feb. 28, March 7, 14, 21, 28. One Guinea.

Subscription (to Non-Members) to all the Courses during the Season Two Guineas. Tickets issued daily at the Institution, or sent by post on receipt of Cheque or Post-Office Order.

Members may purchase not less than Three Single Lecture Tickets available for any Lecture, for Half-a-Guinea.

Now ready, 8vo., pp. 520, price 10s. 6d.

A FIFTH thoroughly REVISED EDITION, embodying the Act of 1883 and all Reported Decisions to date.

THE PATENTEES' MANUAL:

BEING A TREATISE ON THE
LAW AND PRACTICE OF LETTERS PATENT.
ESPECIALLY INTENDED FOR THE USE OF
PATENTEES AND INVENTORS.

BY
JAMES JOHNSON,
OF THE MIDDLE TEMPLE, BARRISTER-AT-LAW;
and
J. HENRY JOHNSON, Assoc. Inst. C.E.,
SOLICITOR AND PATENT AGENT.

LONDON:
LONGMANS, GREEN, & CO., Paternoster Row.

BAILEY'S HYDROCHLORIC ACID PUMP.

W. H. BAILEY & CO.,

SOLE MAKERS OF

Hargreaves and Robinson's Patent Metal Plunger Pump
for raising the above Acid.

Testimony bearing upon the
efficiency of this Pump,
from Golding, Davies, and
Co., Lim., Widnes, Lanc.

Dec. 12, 1883.
DEAR SIRS.—We have used
your Hydrochloric Acid
Pump for more than twelve
months, and find it to answer
our purpose admirably. It
pumps acid at a high temper-
ature, and, so far, there has
been no wear and tear.
(Signed) THOS. CLARKSON
Secretary.

BICHROMATE OF SODA.

Potter and Higgin's Patent

A complete substitute for Bichro-
mate of Potash in Dyeing,
Calico Printing, Colour Making,
and all other manufactures
where Chromic Acid is a neces-
sary element.

*It contains as much Chromic Acid as
Bichromate of Potash.*

It is cheaper than Bichromate of Potash.

*It is more soluble than Bichromate of
Potash.*

It is of uniform strength and purity.

SOLE MAKERS—

E. P. POTTER & CO.,
LITTLE LEVER, NEAR BOLTON.

Physico-chemical notes, 285
Pickering, S. U., calorimetric determinations of magnesium sulphate, 282
heat of dissolution of the sulphates of potassium and lithium, 255
isomeric modifications of sodium sulphate, 232
Picric acid, detection and determination of, 60
Pictet, M., manufacture of wood-pulp, 189
Pinchon, M., rapid determination of fatty acids and alkali in soap, 68
Plant, annual, general progress of vegetation in an, 163, 187, 201
Plants, chemical phenomena of the respiration of, 258
cultivated, influence of different depths of sowing on, 296
formation of saltpetre in, 234
influence of heat and light on, 248
respiration of, 37
Platinised magnesium as a reducing agent, 55
Platinum chloride, preparation of, 34
Ploss, P., pigments formed on heating urine with acids, 47
Plugge, P. C., probability of a transformation of strychnine in the animal organism, 44
sodium hypobromite as reagent for gum ammoniac, 188
Polarimetric researches, 79
Pomeroy, O. T., determination of chlorine, sulphuric acid, and chrome, 175
Porcelain crucibles, numbering, 58
Portland cement, adulterations of, 33
Potash, determination of, 186
Potassic manures, use of in Bretagne, 213
permanganate, estimation of iron by, 275
Potassium and sodium in the ashes of plants, &c., determination of, 174
bromide, examination of, 176
compounds, reagents for the, 67
ferrocyanide, quinine reaction with, 68
Pratt, J. W., rapid determination of fixed ammonia, 122
Preece, W. H., relation between the "Watt" and "Horse-power," 167
- Preis, K., and B. Rayman, some reactions of iodine upon organic compounds at elevated temperatures, 104
tin bromides, 104
Prollius, F., value of isinglass, 68
Prunier, H., volumetric determination of aluminium limes and cements, 235
direct volumetric determination of lime and calcium carbonate, 153
L., tri-acetic ether of a butylic glycerine, 93
Pseudo solution and true solution, connection between, 124
Pycnometer, determination of specific gravity by means of the, 67
Pyridic bases, constitution of the, 116
hydrides, synthesis of, 21, 116
Pyrites, composition of the gaseous products of the combustion of, 284
Puyde, Cassin, 281
- QUALITATIVE** Chemical Analysis, Course of" (review), 224
Quantin, M., certain reactions of chloro-chromic acid, 235
Quartz in rocks and soils, quantitative determination of, 33
Quessand, J., determination of silver and copper in the same solution, 236
Quet, M., elementary force of a solar induction, 224
Quinine, and homo-quinine, 225
narcotine, and morphine reactions with bromine, 102
reaction with potassium ferrocyanide, 68
sulphate of commerce, assay of, 201
- RABOURDIN**, H., assay of the peppers of commerce, 153
Raby, L., new reactions of codeine and esculine, 188
Radiguet, M., and D. Tommasi, new battery with electrodes of coke, 80
Rain-waters of the City of Algiers, 272
Ramsey, W., "Experimental Profcs of Chemical Theory for Beginners" (review), 30
heats of formation of organic compounds, 15
and S. Young, vapour-pressure of acetic acid, 255
Rauoult, F. M., action of water upon double salts, 284
freezing-point of saline solutions, 127
Rasinski, P., examination of mineral oil, 69
Rayleigh, Lord, inaugural address at the British Association, 95
practical use of the silver voltmeter for the measurement of an electric current, 22
Rayman, B., and K. Preis, some reactions of iodine upon organic compounds at elevated temperatures, 104
tin bromides, 104
Refrigerator, improved, 174
Regnaud, M. J., and M. Villejean, analysis of the oily seeds of *symphonia fasciculata*, 189
purification of methyl alcohol, 80, 236
Reichert method of butter analysis, notes on, 151
Reichl, O., detection of glycerin and lignine, 175
Reinhardt, C., numbering porcelain crucibles, 58
Reinold, A. W., and A. W. Rucker, effect of an electrical current on the rate of thinning of a liquid film, 293

- Remijna purdieana, bark of 285
Remont, A., determination of silk, wool, and cotton in tissues, 123
Resin, detection of in ethereal oils, 46
Retorts, coating for, 58
Rice-meat and meal of buckwheat, distinction between, 68
Richard, E., coal-gas and carbon monoxide, 189
Richardson, B. W., "Healthy Manufacture of Bread" (review), 307
C., chemical alterations in green fodder during its conversion into ensilage, 256
determination of potassium and sodium in the ashes of plants, &c., 174
Rocks and soils, quantitative determination of quartz in, 33
Roberts's process for determining starch in urine, 177
W. C., alloys used for coinage, 158, 169
Robinson, H., re-determination of the atomic weight of cerium, 251, 284
Rommier, A., power of cultivated wine yeast, 67
Rosanilines, homologous and isomeric, probable number of, 56
Roscoe, H. E., address to the Chemical Section of the British Association, 107
diamond-bearing rocks of South Africa, 243
Rosenstichl and Gerber, MM., probable number of homologous and isomeric rosanilines, 56
Roependowski, W., contribution to the study of artificial blue colours, 84
Ross, W. A., anhydrous analysis, 247
"Blowpipe in Chemistry, Mineralogy, and Geology" (review), 290, 295
Rotheit, J., new formation of carbo tyrl, 116
Rousseau, G., and A. Saglier, production of a crystalline barium manganite, 80
Roux, L., preparation of a propyl and an amyl-naphthalin, 10
Royal Dublin Society, 23
Institution of Great Britain, 23, 223, 270, 297
School of Mines, 134
"Royal Society of New South Wales, Journal and Proceedings" (review), 224
Rubean-hydrogen, so-called, 104
Rücker, A. W., and A. W. Reinold, effect of an electrical current on the rate of thinning of a liquid film, 293
Rube, M., determination of nitrogen, 58
Russian Chemical Society, 11, 81
correspondence, 80
- SABATIER, P., composition of the saline mineral water of Salies-du-Salat, 105
Sacc, M., saltpetre near Cochabamba, in Bolivia, 80
Saffron containing alumina, 153
Saglier, A., and G. Rousseau, production of a crystalline barium manganite, 80
Sakurai, J., heats of formation of organic compounds, 283
Salicylic acid, 173, 254
in the pansy, 102
Saligenin, new synthesis of, 76
Saline mineral water of Salies-du-Salat, composition of the, 105
solutions, freezing-point of, 127
Saltpetre, formation of in plants, 234
near Cochabamba, in Bolivia, 80
- Salts, action of water upon, 254
certain, dehydrating action of, 79
halogenous, solubility of, 24
solubility of in fused nitrate of soda, 282
proportion of crystalline water of, 12
Salzer, T., proportion of crystalline water of salts, 12
Samarium, lanthanum, didymium, and decipium, equivalent weights of, 69
Sambuc, M., examination and analysis of two samples of wine from Cochinchina, 144
"Sanitary Committee of the Port of London, Report" (review), 212
Sarsin, E., and H. Fol, penetration of the light of day into the water of the Lake of Geneva, 272
Schaal, E., coating for retorts, 58
Scheibler, C., extraction of phosphoric acid from slags, 50
Scheurer-Kestner, M., production of coke, 81
Schiff, K., changes of volume during fusion, 13
Schlagdenhaufen, M., production of zinc formate in cisterns containing oil of turpentine, 188
volumetric determination of manganese, 249
Schmidt, E., caffeine in cacao, 68
saffron containing alumina, 153
Scholvin, L., certain derivatives of mercury fulminate, 164
School of Art, Crystal Palace, 142
Schulze, E., applicability of a method of determining ammonia to the extracts of plants, 57
Schutzenberger, P., certain phenomena of occlusion, 45
Schwartz, Y., and K. Kraut, on hipparasin, 12
Schweissinger, O., recognition of atropin, 273
Science and Art Teachers' National Association, 278
Normal School of, 134

Royal College of for Ireland, 141
teaching, natural, 239
"Science of Agriculture" (review), 247
Scientific and Literary Institution, Birkbeck, 141
Seidl, M., oxidation of mercury diethyl with potassium permanganate, 103
Seine, pollution of, 249
Selenio-urea, 81
Sempie, A., "Tablets of Chemical Analysis" (review), 307
Sesquioxide, chromium, determination of, 18
Sharples, S. P., action of hydrochloric acid on lead, 126
Shepherd, H. H. B., determination of nitrogen, 180
Shimidzu, T., and E. Divers, on magnesium hydrosulphide solution, 233
Silica, amor, hous, vitreous and ordinary, 25
Silicates, estimation of alkalies in, 279
Silicium phosphate, polymorphism of, 272
propyl compounds, 12
Silk, wool, and cotton, determination of, 123
Silva, R. D., synthesis of diphenylmethane derived from ethylidene chloride, 57
Silver and copper, determination of in the same solution, 236
and gold, spitting of in the vapour of phosphorus, 23
toughening in the melting crucible,
cyanide, some reactions of, 155
- Silver fulminate, decomposition of by hydrochloric acid, 256
iodide, transformation of, 80
perchlorate, fluoride, and chlorate, electrolysis of, 130
permeability of for oxygen gas, 24
quantitative determination of, 114
Simaud, F., improved refrigerator, 174
Slags, decomposition and analysis of, 195
phosphoric acid from, 50
Smith, J. K. (Mira), the late Dr. Angus Smith's Alkali Report, 200
R. A., "Life and Works of Thomas Graham" (review), 223
W., and A. Staub, certain derivatives of isodiasphyll, 232
"Smithsonian Report" (review), 248
Snow-water, examination of, 49
Soaps, rapid determination of fatty acids and alkali in, 68
Sodium and potassium in the ashes of plants, &c., determination of, 174
certain double tungstates of, 103
hypobromite as re-agent for gum-ammoniac, 188
monosulphide, preparation of, 260
sulphate, isomeric modifications of, 232
Soils, analysis of, 11
Solar induction, elementary force of a, 224
oil in petroleum, 68
spectrum, determination of the wave-lengths of the principal rays and bands of the ultra-red, 163
Solubility, researches on, 183
Sonnerat, M., preparation of a stable solution of copper for determinations of sugar, 34
Sorbajji, K. B. B., some new paraffins, 254
Specific gravity, determination of by means of the pycnometer, 67
volumes of liquid compounds, 117
Spectral rays, influence of temperature on the character of the, 128
Spectroscopic proceedings, certain, 303
